It is now well recognized that the nature of global and national affairs dictates that a wide variety of terrorism threats already exist, that others will assuredly emerge and develop, and that the United States homeland will be among the targets of such threats for the foreseeable future.¹³ Surely, the most serious concern about terrorism is that terrorists are seeking to kill and injure more and more people. And although this is undeniable, one must remember that the desired effect of terrorism is not only the physical harm to the victims but also the accompanying psychological impact on the target and the society to which it belongs. Surely, mass fatalities have an impact; images and reports of thousands dead or injured are a heinous reality of terrorism. But the concomitant fear and anxiety about one's own safety, concerns about the ability of government to protect its citizens, and the foreboding danger brought about by the potential for future acts of terror are of utmost importance to the terrorist as well. As a consequence, the terrorist's victims must be carefully selected to ensure the maximum possible psychological impact on the target.¹⁴ And while the target selection is important (e.g., urban rail hub versus rural elementary school), the timing with which the attacks are carried out—particularly if in a coordinated, simultaneous manner—is paramount to ensuring desired impacts. On Sept. 11, 2001, 2752 people lost their lives, the most fatalities of any single documented terrorist event,^{15,16} and the method of attack selected by the terrorists was one that included coordinated, layered attacks across a variety of geographic areas. Although it was a day of utter devastation, one need only think about the effects had the terrorists added follow-up attacks that included, say, a CBRN event. As such, a discussion of the two main, but certainly not exhaustive, classifications of simultaneous, layered attacks follows.

The first includes *multiple incidents in a single jurisdictional target*. Attacks of this sort may commence as a single incident (e.g., a single suicide bus bombing) but can quickly evolve into an attack against multiple targets, including first responders. For example, the March 2004 bombings in Madrid, Spain, which were the deadliest terror strikes in Europe since the bombing of Pan Am flight 103 over Lockerbie, Scotland, in 1988, killed 270, and were the worst terrorist assault in Spanish history, took

place at the height of a weekday rush hour when three separate trains were hit by 10 near-simultaneous explosions before 8 AM. The attacks occurred between 7:39 and 7:54 AM, with multiple explosions at the Santa Eugenia, El Pozo, and Atocha stations. And although three other bombs were found and detonated by police, 192 people were killed and 1800 wounded.

In attacks of this sort, multiple weapons or secondary devices are employed with the intentions not only to kill large numbers, but also to drain the resources of the affected jurisdiction by rendering an area insecure and to hamper both rescue efforts and injury control.¹⁷ In many cases, first responders become victims as well as they attempt to manage the initial incident and fall victim to the follow-up attacks.

Given the sophistication of these types of attacks, improved coordination among the perpetrators is required and will usually involve multiple persons to carry out.¹⁸ Incorporate hypothetically into this scenario the release of a chemical agent, such as the nerve gas tabun, (which is so powerful a poison that even short-term exposure to small concentrations of its vapor results in immediate symptoms and death may result¹⁹), and the effectiveness of a multimodality, layered attack becomes evident.²⁰

The second type of simultaneous attack classification involves *multiple incidents across multiple jurisdictional targets*. Here, too, tactics may begin with one or more concurrent attacks but quickly evolve into an attack against multiple targets, again including first responders, in geographically separated areas with multiple weapons or secondary devices. Attacks of this variety are the embodiment of multimodality, layered attacks. These attacks are aimed at confounding emergency response systems and depleting resources of the local jurisdiction and, in most cases, beyond to the state and federal levels. Although the events of Sept. 11, 2001, exemplify an attack of this type using conventional means, one could not begin to imagine the impacts had the perpetrators (in addition to carrying out the carefully coordinated hijackings of four commercial airliners, each filled with jet fuel, and slamming them into targets), added to their repertoire the release of a CBRN agent later in the day or in the days immediately thereafter, either somewhere in the United States or in its interests abroad. Surely the obvious ramifications, in addition to the physical and emotional trauma already requiring attention, would be further complicated by identification of the agent, an in-depth epidemiologic investigation, extended incident and resource management, and of course, resumption and recovery initiatives.

Multimodality, layered events of the future may be complicated by the use of multiple CBRN agents or the delivery of chemical and replicating agents and/or their toxins that have been carefully matched, based on their ability to generate specific symptoms, resulting in the potentiation of health effects.¹⁰ Accordingly, agent detection requires the availability of rapid diagnostic methods and procedures (e.g., syndromic surveillance) to assess illnesses that will be the result of multiple agents.¹⁰ Given the sophistication required to effectively carry out attacks of this sort, namely increased timing,

organization, and coordination of the perpetrators, and as has become increasingly popular, suicide attacks, several persons would almost certainly carry these out.

The near-simultaneous bombings of U.S. embassies in Nairobi, Kenya, and Dar es Salaam, Tanzania, which resulted in hundreds of deaths coupled with the attacks of Sept. 11, 2001, are clear examples of multiple-incident, multiple-jurisdiction, layered attacks. The demonstration of an operational capability to coordinate two nearly simultaneous attacks on United States embassies in different countries to a large extent influenced U.S. policy.²¹

Although many terrorism experts point to the change in targeting and the style of attack as evidence of a possible broadening of the strategy from mainly guerilla insurgency against U.S. forces to include a coordinated terrorist campaign that includes foreign elements, how the threat will actually evolve is difficult to predict.²² In all cases, the aim of these attacks was to maximize injury and cause complex trauma, thereby elevating the killing ratio.²³

Although the ability to conduct multiple, coordinated attacks against several targets is not new for terrorist groups such as Al-Qaeda, (which, to date, is the only organization that has successfully used suicide attacks on U.S. soil²²), the manner in which these attacks is being conducted indicates refined capabilities and sophisticated tactics,⁴ bringing into focus the reality that future terrorist attacks will likely include even greater use of multimodality, layered attack tactics.

HISTORICAL PERSPECTIVE

Until Sept. 11, 2001, a total of no more than perhaps 1000 Americans had been killed by terrorists either in this country or abroad since 1968—the year credited with marking the advent of the modern era of international terrorism because the Popular Front for the Liberation of Palestine hijacked an El Al flight on July 23 of that year.²⁴

The significance of the Sept. 11, 2001 incidents from a terrorist operational perspective is that simultaneous attacks, using far more prosaic and arguably conventional means of attack (such as car bombs), are relatively uncommon. For reasons not well understood, terrorists typically have not undertaken such coordinated operations. This was doubtless less of a choice than a reflection of the logistical and other organizational hurdles that most terrorist groups are not able to overcome.²⁴ In fact, the initial “planes operation” (as it was termed by Al-Qaeda operatives), embraced the idea of using suicide operations to blow up planes as a refinement of the original “Manila” air plot. All of the planes hijacked were to be crashed or exploded at or about the same time to maximize the psychological impact of the attacks.²⁵

During the 1990s, perhaps only one other (presumably unrelated) terrorist incident evidenced those same characteristics of coordination and high lethality: the series of attacks that occurred in Bombay in March 1993, where a dozen or so simultaneous car bombings rocked the city and killed nearly 300 persons and wounded more than 700 others.²⁶ Indeed, apart from the attacks on the same morning in October 1983 of the U.S. Marine

barracks in Beirut and a nearby French paratroop headquarters, and the IRA's near-simultaneous assassination of Lord Mountbatten and remote-control mine attack on British troops in Warrenpoint, Northern Ireland, in 1979, it is hard to recall many other significant incidents reflecting such operational expertise, coordination, and synchronization.²⁶

That is not to say, however, that similar types of operations have not been planned and foiled. Ramzi Ahmed Yousef, the convicted mastermind of the 1993 New York World Trade Center bombing, and 15 other persons reportedly intended to follow that incident in June 1993 with the simultaneous bombings of the Holland and Lincoln Tunnels and George Washington Bridge (all owned and operated by The Port Authority of New York and New Jersey, the owner of the World Trade Center) that are used daily by thousands of commuters between New Jersey and Manhattan.²⁷ What's more, the plans also included the simultaneous bombings of 11 U.S. passenger airliners while in flight over the Pacific Ocean in 1995.²⁸ The importance of simultaneity in attacks is confirmed in these events and, more recently, during the interrogation of Khalid Sheikh Mohammed on August 18, 2003.²⁵

CURRENT PRACTICE

Small arms, explosives, and incendiaries are the weapons used in most terrorist acts.¹⁵ Although the use of non-conventional weapons (i.e., WMD) must not be ignored, it is these modes of attack that have had a more significant impact, as recorded terrorist events in recent years demonstrate.^{4,15,29}

Al-Qaeda and its affiliates have demonstrated that the organization is highly determined and motivated to conduct high-profile, mass-casualty attacks and, increasingly, it is civilian, noncombatant targets that they select. The 2003 Bali nightclub bombing, Moscow theater siege, and combined Mombasa, Kenya, car bombing and surface-to-air missile attacks are indicative of this emergent and increasingly popular tactic.

It must be noted that although damage to a target—or in a multimodality, layered attack, multiple targets—may be relatively small (e.g., a single suicide bomb in a bus or a single aircraft downed), the political and psychological impacts will be rather large. To wit, the impact of bombs, and for that matter terrorist acts in general, goes beyond mortality and morbidity.³⁰ It is the creation of psychological terror, which simultaneous attacks produce so readily, that can cause chaos and panic.³¹

Response Strategies

Given the now-ubiquitous threat of terrorist acts coupled with their sudden nature, the most effective response strategy (absent preventing the attack to begin with) is for local, regional, state, and federal partners to develop flexible strategies that can be adjusted quickly and appropriately to the type of incident that occurs. This type of strategy requires management coordination, compatible communication systems, and real-time infor-

mation feedback to decision-makers that permits near immediate changes in strategy when required.¹⁵ The ability to respond across a broad technologic spectrum of potential adversarial attacks is one of the primary lessons to be learned from all terrorist attacks. Recognizing that the threat of terrorism is comparatively new to the United States and that many dimensions of the initial response to this threat are only now being implemented (e.g., the National Incident Management System and the National Response Plan) with no level of resources able to fully prevent the United States from being attacked in the future,¹³ understanding the full range of injuries and disorders, including posttraumatic stress disorder, is critical.³² Although history does not always repeat itself, it can surely serve as a gauge for what terrorists are at least capable of and how we should respond. Al-Qaeda's strength lies not in geographic possession or occupation of a defined geographic territory but in its fluidity and impermanence. The activities of Ramzi Ahmed Yousef, the reputed mastermind of the first World Trade Center Attack in 1993, involved a grand scheme to simultaneously bomb 12 American commercial aircraft in mid-flight over the Pacific Ocean (the infamous "Bojinka" plot), which did not require extensive operational bases and command nor control headquarters in an existing country to execute the planning and execution.³³

The new means of terrorist attacks we are likely to face will involve not only WMDs and weapons of mass disruption, but conventional means to attack critical infrastructural targets such as nuclear and chemical plants, agricultural nodes, and the hearts of the American and world economy, with catastrophic human and economic consequences.³²

Suicide Attacks

Suicide attacks by terrorist organizations have become more prevalent globally, and assessing the threat of these attacks has therefore gained strategic importance to the United States and its interests at home and abroad.²² Essentially a punishment strategy, suicide terror has become increasingly prevalent over the past two decades simply because terrorists have learned that attacks of this type work. The success of suicide attacks lies within two primary consequences. First, it inflicts immediate punishment against the target. Second, its success implies a threat for more punishment in the future. Implicit in the act is the powerful message that the attacker(s) could not be deterred and connects the attacker to a broader community, which one would speculate allows for the act of martyrdom. In suicide terrorism, the weaker, usually a person or small group acts as the coercer, with the stronger group (e.g., Western society) serving as the target.

In the case of Al-Qaeda, Osama bin Laden has been characterized as a terrorist CEO, organizing its "spectaculars," or high-visibility, high-casualty operations such as the Sept. 11, 2001 attacks, the bombing of the U.S.S. Cole, and the East Africa embassy bombings.³⁴ Unlike many other terrorist organizations, Al-Qaeda has no single modus operandi, making it all the more formidable.³⁴ However, simultaneous attacks using multiple bombs

coordinated to explode in several cities across the country at sites such as stores, schools, hospitals, apartment buildings, and gas stations, each vital to the U.S. economy and populace, are not beyond conception.

An innovative use of suicide bombings as a component of multimodality, layered attack methods involves the use of combining its self-destructive tactics with CBRN agents. Suicide tactics could significantly improve the potentiality of a successful CBRN weapons attack itself.³⁵ Here, the unimportance of being exposed to extremely dangerous materials permits the attacker to carry out increasingly perilous experiments, thereby expanding the chance of generating and using a potent and effective CBRN weapon.³⁵

Second, notable tactical opportunities arise for terrorists who are apathetic to making contact with a CBRN agent during delivery. In addition to greater access to the target and enhanced control over the outcome, elimination of shielding measures during the attack such as personal protective equipment decreases the risk of early detection and interdiction of the attack. Again, thinking along the lines of multimodality, layered attacks, the bodies of terrorists could also be used as crude delivery systems, if the perpetrators are infected with a contagious agent and deployed to crowded areas.

It is clear that suicide operations are responsible for a large number of fatalities. Of the 30 single most deadly terrorist incidents carried out to date since 1990, 15 involved suicide bombers, and 7 of the remaining 15 attacks were perpetrated by groups with a record of using suicide bomb delivery.³⁶ The fact that groups using this tactic are responsible for the majority of high-fatality incidents suggests that they have reached an advanced level of enemy dehumanization and are therefore psychologically closer to perpetrating mass-casualty CBRN attacks.³⁵

PITFALLS

Arguably, many people were lulled into believing that mass-casualty, simultaneous attacks in general, and those of such devastating potential as witnessed on Sept. 11, 2001, were likely beyond most capabilities of most terrorists. Yet, the tragic events of that day demonstrate how profoundly misplaced such assumptions were.²⁴ As such, the significance of past successes (e.g., largely foiling most of bin Laden's terrorist operations during the period between the August 1998 embassy bombings and the November 2000 attack on the U.S.S. Cole) and the terrorists' own incompetence and propensity for mistakes (e.g., Ahmad Ressaam's bungled attempt to enter the United States from Canada in December 1999) were likely overestimated.²⁴ Some experts believe there was significant overlap in the planning for these attacks and the one against the U.S.S. Cole in Aden. Doing so suggests a multitrack operational and organizational capability to coordinate major, multiple attacks at one time.²⁴

Preparedness

Much of the terrorism preparedness pre-9/11 focused on the comparatively low-end threat posed by car and truck

bombs against buildings or the more exotic high-end threats, involving biologic or chemical weapons or cyber-attack. In many respects, preparedness planning continues to (quite possibly erroneously) assume mass-casualty attacks involving biologic or chemical agents released at key infrastructure (e.g., air and rail terminals). As demonstrated by the attacks of 9/11 and certainly a topic of debate between politicians, homeland security personnel, and emergency management professionals, sizable gaps remain in fortifying plans for a traditional and long-proved tactic such as airline hijackings. Mitigating and preparing for tactics of this sort has been neglected in favor of other, less conventional threats (e.g., chemical, biologic, and radiologic) with the consequences of using an aircraft as a suicide weapon almost completely discounted.²⁴

Although so-called WMDs were not used in the Sept. 11 attacks, the destruction was nonetheless "massive."²² Consequently, the very real prospect of combining modern weapons technology (i.e., CBRN weapons) with an age-old willingness to die in the act of committing an attack could be unprecedentedly dangerous.²² Furthermore, with increasing numbers of casualties from multiple suicide attacks occurring globally in places such as Israel, Saudi Arabia, Morocco, Russia/Chechnya, and postconflict Iraq, a discourse on the threat of future suicide attacks is warranted.²² One need only to examine the Department of State's Patterns of Global Terrorism, 1983-2001,³⁶ to see the efficiencies gained by attacks of this sort. Pape³⁷ found that, from 1980 to 2001, suicide attacks represented only 3% of all terrorist attacks but accounted for 48% of total deaths due to terrorism.

In retrospect, it arguably was not the 1995 sarin nerve gas attack on the Tokyo subway and nine attempts to use bioweapons by the Aum Shinri Kyo cult that should have been the dominant influence on counterterrorist thinking. More accurately, a 1986 hijacking of a Pan Am flight in Karachi, where the terrorists' intentions were reported to have been to crash it into the center of Tel Aviv, and the 1994 hijacking in Algiers of an Air France passenger plane by terrorists belonging to the Armed Islamic Group, who similarly planned to crash the fuel-laden aircraft with its passengers into the heart of Paris²⁴ should have served as keen indicators of the type, scope, and overall capabilities of those responsible for events to come.

A long-standing and now proven incorrect notion is that terrorists were more interested in publicity than killing and therefore had neither the need nor interest in annihilating large numbers of people.²⁴ In 1975, Jenkins³⁸ noted that, "Terrorists want a lot of people watching and a lot of people listening and not a lot of people dead." Just 10 years later, he reiterated, "Simply killing a lot of people has seldom been one terrorist objective...Terrorists operate on the principle of the minimum force necessary. They find it unnecessary to kill many, as long as killing a few suffices for their purposes."³⁸ Clearly, the events of Sept. 11 prove such notions now to be wishful thinking, if not dangerously anachronistic.²⁴

When speaking to the notion of pitfalls, one must consider the difficult concept of "How do we assess the

threat of terrorist events that have not occurred?"³⁹ Although there is no black-and-white, one-sentence response, we know that today's terrorists are becoming demonstrably more adept in their tradecraft of death and destruction. They are more formidable in their capacity for tactical modification and innovation in their methods of attack (e.g., simultaneous and near-simultaneous deployments), and they have become increasingly competent in operating for sustained periods while avoiding detection, interception, or capture.⁴⁰

Moreover, even attacks that are not successful by conventional measures can nonetheless serve as a success for terrorists provided they are daring enough to garner media and public attention. And given the world's recent hypersensitivity to threats and suspicious incidents, which is the terrorist group's fundamental organizational imperative to act, even if their action is not completely successful but brings them publicity, their tenacious pursuit for fresh ways to overcome, circumvent, or defeat governmental security and countermeasures is fueled. Accordingly, attacks at all points along the conflict spectrum—from the crude and primitive to the most sophisticated—must be anticipated and appropriate measures employed to counter them.⁴⁰

It must be noted that a limited terrorist attack involving, not a WMD per se, but an unconventional chemical, biologic, or radiologic weapon on a small scale, either isolated or as a component of a succession of smaller incidents occurring either simultaneously or sequentially in one or more geographic locations, may yield disproportionately large consequences, generating fear and alarm and serving the terrorists' purpose just as well as a larger weapon or more ambitious attack with massive casualties.⁵

Although many may think of multimodality, layered attacks as restricted to the use of simultaneous suicide attacks, one must examine for example biologic agents, looking specifically at microorganisms, which when used in combination have the potential to create a more severe disease state.¹⁰ Similarly, infection with one agent with a shorter incubation period that may weaken overall resistance may provide easier opportunities for infection with a second organism with greater morbidity and mortality.¹⁰ The ability of multiple organisms with different levels of virulence to confuse medical officers looking for a common etiology accentuates the need for sensitive and specific diagnostic tests to be available in the field setting.¹⁰

Scenarios of the future may be complicated by the possible use of multiple agents or the delivery of chemical and replicating agents and/or their toxins that have been carefully matched based on their stability and ability to generate specific symptoms. Health effects could be potentiated. Therefore, from a medical perspective, detection requires the availability of rapid diagnostic methods and procedures to assess illnesses that will be the result of multiple agents.¹⁰

The most widespread and most open use of chemical weapons on a battlefield in recent decades was by Iraq in its conflict with Iran. Undetonated shells were sampled and several laboratories in Europe analyzed

their contents. A vesicant or blister agent (mustard) and a nerve agent (tabun) were identified. About 100 Iranian soldiers with chemical wounds were sent to European hospitals for care; their wounds were consistent with vesicant injury. A team appointed by the UN secretariat went to Iranian battlefields and hospitals and found chemical shells and patients with chemical injuries. The public outcry at the use of these weapons was less than overwhelming. Ignoring protests from the world community, Iraq continued to use these agents.⁴¹

The real issue and the most likely threat may not be the ruthless terrorist use of some weapon of mass destruction, but the calculated, deliberate, and delicately planned use of some chemical, biologic, radiologic, or nuclear weapon⁵ in conjunction with conventional means in a simultaneous or near-simultaneous time frame to achieve far-reaching psychological effects.

MEDICAL MANAGEMENT OF MASS-CASUALTY EVENTS

In the 17-minute period between 8:46 and 9:03 AM on Sept. 11, 2001, New York City and the Port Authority of New York and New Jersey had mobilized the largest rescue operation in the City's history.²⁵ In all, over 25,000 people were rescued from the World Trade Center complex on that day, and although the costs in terms of first responders' lives were great, their selfless acts will never go unnoticed. During mass-casualty events, terror victims often arrive at hospitals in clusters, whereas during more isolated assaults they arrive either as individuals or a few at a time.⁴² The medical management of events of this sort, in which the goal is to save as many lives as possible and to decrease morbidity, requires that the most senior clinician assume command of the incident and adjust the available resources optimally to the excessive needs.⁴²

Events of this kind require medical management skills, rather than clinical capabilities, to come first. Here, the aims of saving as many lives as possible and decreasing morbidity dictate skillful prioritization of decisions to restore the balance between needs and available resources. To wit, the principles of the medical management of mass-casualty events, where the medical system is overwhelmed and the balance between resources and demands is undermined⁴³ (namely, those that result from terrorist acts), have been fully described elsewhere.^{37,42} Although all terrorist attacks, conventional and unconventional, have the potential to produce significant physical and psychological trauma, simultaneous attacks by their very nature are far more efficient in overburdening medical systems at the local level, and if the nature of the simultaneous attacks is on a large scale, on the regional or national level. Consequently, the success in the management of large-scale medical events comes in extensive early preparation.⁴³

An additional contrast between isolated terrorist events and the multimodal, layered sort treated in this chapter lies in the duration of the events. Here, a short-term event such as the bombing of a single bus can be

localized in nature, requiring the response of a single jurisdiction's first responders and treatment by a local hospital, and if necessary, specialty centers. Conversely, a multimodal, layered attack may necessitate the national response system in which resources from across the nation are activated and deployed to those areas hardest hit as well as those where intelligence suggests likely near-term attacks. Here, dividing the patient load between community hospitals, large urban medical centers, and specialty-care centers (e.g., trauma, burns, hyperbaric) will help minimize the likelihood that no one facility is overwhelmed by the event.

Use of the National Incident Management System and the National Response Plan, each of which provide for the establishment of an Incident Command System/unified command should be engaged at the beginning of the event by the affected local jurisdiction. An interface between prehospital systems and receiving medical centers is paramount. The different modes of terror currently compose a new field of epidemiology that demands ongoing activities at all levels⁴³ and place increased and unique demands on first responders and in-hospital clinical, management, and support staff.

Terrorist acts produce more victims and higher mortality rates than is seen from natural disasters and, therefore, medical personnel must ensure that medical protocols exist for both the daily treatment and transportation of patients as well as situations that place unexpected demands on the system.³⁵

The current terror wave engulfs the entire world. The greatest threat to U.S. citizens comes from the possibility of further attacks orchestrated or inspired by Al-Qaeda, either in the United States or abroad.²² Contemporary terrorist behavior and tactics seek to destroy those components of our lives that celebrate the very freedom we enjoy. The reality is that we cannot deny terrorists attractive targets. Rather, through effective programs, stakeholders can make attacks more difficult to carry out and less effective.

The events of Sept. 11, 2001, are an egregious reminder of how terrorists can fulfill their aims of death, fear, and intimidation through conventional means. The terrorism of today wields conventional and nonconventional WMDs—biologic, chemical, and nuclear—that damage the body, the mind, and the soul.⁴⁴ One needs only to think of the exponential effects a multilayered, simultaneous attack scenario can have on trust in government, the economy, and national security, as compared with a single isolated attack. These events demonstrate the ability of even one significant, new terrorist incident to instantly reignite worldwide fears and concern.³³

Israel has long maintained the notion of “mega-terrorism,” a concept that embodies the notion of multimodal layered attacks. Here, not only are the obvious terrorist uses of WMDs brought to bear and specific highly symbolic locations (e.g., The White House and New York Stock Exchange) targeted, but the more prosaic types of incidents such as terrorist attacks on elementary schools or the assassination of political and business leaders (e.g., mayors, “capitalist” business executives) carried out in a short term (e.g., minutes, hours, or days) in ways that

although not necessarily causing extensive human loss to life (purely in terms of numbers), would nonetheless have profound, far-reaching psychological repercussions on the targeted society.³³

The fundamental nature and character of terrorism changed with the events of 9/11 and, moreover, has continued to change and evolve since then. Based on the simultaneous attacks carried out on that day, coupled with previous foiled attempts of that sort and the destruction of the Taliban, one can reasonably assume that the multiyear planning period of all previous Al Qaeda spectacles alone suggest that it is premature to write off Osama bin Laden or his followers.³³ Terrorism is becoming increasingly difficult to characterize as an identifiable phenomenon amenable to categorization or clear distinction. Given the success of the Sept. 11 attacks, it is difficult to make a case against a similar, more devastating attack using multiple modes of attack that may have been set in motion before Sept. 11, 2001, and is only now slowly and inexorably unfolding.³³ The masterminds behind the attack proved the impotence of the mightiest military power to protect its citizens against these kinds of devastating blows. From the terrorists' point of view, the attack on America was a perfectly choreographed production aimed at American and international audiences.²⁰

Before Sept. 11, 2001, most, if not all, acts of terrorism resulted in a great deal of publicity in the form of news reporting. But given the multimodal, layered nature of the attacks on that day, the images of commercial airliners crashing as suicide/homicide missiles into the very symbols of America's economic and military might continue to remain almost incomprehensible.²⁰ Surely the attacks could have been scheduled at night, sparing many lives, and still raked in a great deal of publicity. But the bright daylight of that once-beautiful September morning made certain that the most spectacular of sights and the loss of life would occur. In all these respects, no previous act of terrorism even came close to the events of Sept. 11.²⁰

The events of Sept. 11 demonstrated the effectiveness of multimodal, layered attacks within the United States and provide a solemn and serious reminder that this tactic remains a likely means of attack in other democracies as well. Without the capability to track down and capture surviving terrorists, as was the case in the first World Trade Center bombing and the Oklahoma City bombing, the United States (and any target society, for that matter) forfeits its capacity to bring the perpetrators to justice. Concurrently, terrorists and their supporters get the opportunity to idolize those who committed suicide in order to kill and use their examples to recruit more volunteers as human bombs.²⁰

Terrorists are well aware of the extreme difficulty, if not impossibility, in altogether preventing suicide terror, both in the example of the traditional single suicide bomber or the more advanced operations, such as those used on Sept. 11, 2001. Although the idea that terrorists may obtain and use WMDs cannot be ignored, the more immediate concern must be the prospect that Sept. 11 might well become the most attractive model for terrorism in the near future.²⁰

Operations Security, Site Security, and Incident Response

Paul M. Maniscalco, Paul D. Kim, Neil A. Commerce,
and Jeffrey A. Todd

In preparing organizations and persons for response to a high-impact/high-yield emergency incident, one of the most often overlooked requirements are operations security (OPSEC) and site security. Bound inextricably with coordination and integration strategies for response, OPSEC and site security are often compromised in the “heat of the battle” as responders with nothing but the best of intentions converge on the scene of the disaster implementing strategies that, prevent, have failed to address these most important aspects of the incident response and management strategy. The discipline to apply the principles of OPSEC and site security following a preestablished, organized, and well-practiced plan is crucial given the nature of the threat and the variety of conditions that may present themselves. Failing to address OPSEC and site security issues before an event amounts to failing to protect the protectors.

Terrorist attacks present the contemporary emergency services manager or chief officer with more complex challenges and more probable risks. Site Security and OPSEC are multifaceted concepts, bringing together elements as diverse as protecting information concerning an organization’s activities, intentions, or capabilities to scene access, traffic control, and evidence protection. Due to the fact that this involves so many different aspects of disaster response, and because it cannot be completely achieved without full integration of each of those aspects, site security is best understood broadly. Robust control of the incident and proximal areas should be the desired goal. This includes holding sway over the human and material flow into, out of, and around the site; providing for the security and safety of responding personnel; providing these responders with the ability to perform their jobs; and ensuring personnel accountability and the fulfillment of performance requirements.

For an OPSEC program to be effective, personnel must be aware of OPSEC concerns, must implement OPSEC countermeasures when appropriate, and must be observant of potential collection activities directed at their organization. This is only possible if the members of the

organization understand the range of threats affecting their organization and actively support the OPSEC program.¹

Under these definitions, the framework that makes for effective and successful deployment of OPSEC/site security strategies is the Incident Management System/unified command structure (IM/UC) as articulated in the National Response Plan (NRP) and the National Incident Management System (NIMS). Many OPSEC and site security issues can be addressed merely by properly applying these disciplined and standard structures, practices, and protocols. For example, interagency integration problems involving the establishment of a chain of command, which produced many of the issues that plagued security at the World Trade Center site in the aftermath of the Sept. 11, 2001, events, could have been significantly ameliorated by the implementation of an effective IM/UC early in the event as well as the requisite immediate establishment of a workable security perimeter. Simply restating the requirement for implementing the IM/UC system, which has already been established with the release of the NRP and the resulting NIMS, is not the purpose here. Moreover, this chapter seeks to address the issue of the role OPSEC and site security play in the response to a terrorist incident within the framework of the IM/UC process.

INCIDENT MANAGEMENT/UNIFIED COMMAND AS THE FOUNDATION

Every person who chooses to devote his or her life’s work to responding when others are fleeing must resist the urge to “run in” without fully understanding what he or she faces beyond that door, on the other side of that cloud of smoke, or around the next corner. Although this is easier said than accomplished, in a terrorist event, the survival of these people to fight another day depends on projecting or knowing what threats lay ahead. The organizational protocol that is established by IM/UC is simply the framework by which OPSEC/site security can be efficiently, effectively, and successfully established; in other words, IM/UC is required but not sufficient on its

own. Although not a panacea, IM/UC implementation is crucial for us to remediate the hard lessons learned in the recent past, fixing the problems inherent in past responses and implementing standards for OPSEC and site security.

The adoption and implementation of the NIMS-IM/UC framework addresses and corrects a large portion of site security issues by the incorporation of the talents and service provided via the law enforcement community at the command post; it is important to note, however, that not all of these issues are terrorism specific,² and the UC concept should be allied at most emergency scenes.

Many of the difficulties inherent in the massive response of multiple agencies are as prevalent in an earthquake as in a dirty bomb attack. What makes the issue of OPSEC/site security so important and unique in the context of terrorism is the particular nature of the threat. The unpredictability of terrorism creates conditions that are fluid, requiring speed and flexibility of thought and action as well as thorough planning and preparation. Furthermore, the targeting of responders and “soft targets” such as healthcare facilities and schools makes this an even more complex matter to address and manage to ensure one’s own safety and the safety of those responders that are being coordinated at the scene.

HISTORICAL PERSPECTIVE

In analyzing many major recent terrorist attacks (including and after the 1993 World Trade Center bombing), numerous areas of concern consistently emerge. By identifying each of these and focusing on the pitfalls of the response at the time, as well as stating how response could have been improved, one can hope to draw lessons and establish best practices for future incidents. As just noted, these concerns fall into two general categories. First are those that are potentially present in any sort of disaster and that can be remedied by the proper implementation of IM/UC. These include the following:

- Victim rescue in the immediate aftermath of an incident;
- Personnel needs including work shifts to ensure proper rest, adequate personal protective equipment, continuation of normal emergency medical services (EMS)/law enforcement/fire services over the course of the event;
- Organizational integration /interoperability communication issues;
- Public relations, including that with dignitaries, media, charities, families of victims/missing;
- OPSEC/site security;
- Staffing support for other elements.

Secondly, some concerns are unique to terrorism and cannot be addressed simply by the implementation of IM/UC. These therefore require further attention and creativity and are listed as follows:

- Search for secondary devices and hostile threats to the scene and responders;
- Perimeter establishment and access control;
- Traffic and crowd control;
- Evidence recovery and protection.

CURRENT MEDICINE

OPSEC/SITE Security: Challenges of a General Nature

The importance IM/UC plays in enabling successful OPSEC/site security cannot be overstated. Perhaps the key component in OPSEC/site security is communication and coordination among responders, and the primary focus of IM/UC is just that. The following section addresses each aspect of OPSEC/site security that can be helped by the implementation of IM/UC, including multiple examples from recent terrorist attacks where such implementation would have directly resulted in saved lives or property. Suggestions are then made as to how these issues can be dealt with in future events.

Victim Rescue

The first challenge to OPSEC/site security is victim rescue in the immediate aftermath of an incident. This is the initial and most dramatic problem faced by all responders during and immediately after a terrorist attack. As mentioned briefly before, a driving characteristic that defines all responders is the natural instinct to rush forward, nobly doing whatever one can to quickly save as many lives as possible. However, for both the safety of the responders and the victims, some restraint and organization must be exercised, or the overall incident outcome may become negative and people may die needlessly. Among the lasting images from the events of Sept. 11 are the hundreds of first responder personnel rushing to the scene to help all who were victimized by these horrible attacks. One striking example in a day full of actions hampering, hindering, and preventing all good intentions was the Shanksville, Pa, plane crash site, which on Sept. 11, 2001, was overwhelmed and severely congested because of response units, both on and off duty, making their way to the scene either by self-dispatch or by convincing dispatchers to send more help. The resulting chaos clogged the scene, severely complicating command and control, and confusing perimeter maintenance.³

This area of OPSEC/site security primarily deals with ensuring an effective response rather than an unorganized, potentially dangerous, and surely less effective response. Implementation of IM/UC could have diminished the reported congestion because it states that off-duty response personnel should not respond to an event unless directed to do so. Although operational doctrine dictates that you “man your post” until otherwise directed, the reality is that such a situation rarely exists. The instinct to respond is powerful and is complicated by the “*touch the plane*” phenomenon,⁴ in which people feel they have to be at the disaster scene so they can tell anyone who will listen that they were indeed there “when it happened.” Therefore, it is incumbent on the agency and organizational leaders to stress and practice operational discipline that demands coordination and adherence to strict deployment protocol. Another relevant example is the Bali bombing of October, 2002. As with all responders, the Bali responders rushed in to help

victims and save as many lives as possible, and in doing so rendered OPSEC/site security nonexistent and placed many more lives in danger in the event of another coordinated secondary attack. Although it may be difficult to find fault with the selfless actions of such responders, it is crucial that this emotional response be tempered by reason and the knowledge that restraint and discipline are not only necessary, they are required to ensure that the investigation is permitted to bring the perpetrators to justice.

Finally, there is the example of the brave responders to the World Trade Center attacks. In their zeal to charge into the scene and save as many people as possible, the “tunnel vision” they experienced allowed them to neglect properly assessing the danger to their own lives. Although this is a “unique event” in our history with no historical reference point, the fact of the matter is that the multiple planes used in the attack were an effective secondary device of significant proportion.

OPSEC/site security involves understanding the situation to the greatest degree of accuracy possible, including the possibility that attempting to rescue victims immediately may not be the wisest, safest, or most appropriate course of action. Although it may seem that delaying rescue efforts is tantamount to abandonment of our duty to act and is contrary to the oath many of us swear to, in the end lives may be saved by taking the time to fully assess the situation in a coherent fashion before executing operational response.

Personnel Needs

The security needs of response personnel are a major issue to be tackled in planning for response to a high-impact/high-yield emergency incident. These needs are varied and can be very complex, complicated, and resource demanding during and after a terrorist event.⁵ These demands are further amplified given the dual threat of the likelihood of hazardous materials being present and the active intent of the terrorist to hurt or kill as many people as possible, including responders.

One very good example of this occurred during the 1997 Tokyo sarin attacks in the subway. Japanese medical personnel lacked proper personal protective equipment; more than 20% of the staff of St. Luke's International Hospital exhibited some sort of detrimental physical effects after treating victims of the attack.⁶ Had the hospital planned properly and equipped the facility/personnel, in addition to regularly training all employees, the instances of secondary contamination would have been greatly reduced.

The most recent and well-known example of responders lacking proper personal protective equipment was the Sept. 11, 2001 attacks. Early in the response, heavy particulate asbestos was found at the site, and later Freon, cadmium, and other hazardous materials were identified, yet there were responders without proper protective equipment.⁷ This can be attributed to both poor planning and logistics acquisition problems because there was simply not enough equipment to go around. This indicated that planners failed to grasp the scope or even believe that a possible attack could occur, and poor logistics come into play because the equipment that was present was not distributed properly.⁸

Another critical aspect of protecting responders in a traditional sense involves personnel rest and rehabilitation, which are critical to the success and sustainability of an operation. Although responders are often willing to work to the point of exhaustion, this is dangerous to the responders, the victims, and the effectiveness of your operation. Fatigue creates more victims through poor decision-making, increased stress and frustration, and impaired judgment. The medical profession has been and continues to address the effects of sleep deprivation and fatigue due to errors that can be directly traced back to exhausted healthcare providers. Several well-publicized studies that chronicle the effects of long work hours in life-and-death stressful environments reveal errors have produced increased morbidity and mortality in the patients being cared for by these well-meaning professionals. Studies conducted over the last several years reveal that moderate sleep deprivation produces impairments in cognitive and motor performance equivalent to legally prescribed levels of alcohol intoxication.⁸

The last thing any coordinated response should have to deal with is victims among the responding rescue workers and responders. To help prevent and ensure the equitable and safe distribution of personnel, IM/UC has instituted a system by which the Incident Commander assigns shifts to the workers, thereby forcing rest on the weary, whether or not they realize they need it at the time.

The final personnel need addressed in this chapter is that of continuation of public services, including EMS, medical, law enforcement, and fire service, through the end of the incident and into the recovery and mitigation stages. Sustaining 911 response capacities for an entire community should be a significant goal that first responders must strive to achieve. Just because one is being confronted with a large disaster in one's community does not alleviate the obligation to ensure the best possible planning efforts to sustain “all” emergencies in the community are managed appropriately. Clearly, and especially in the case of EMS, the fiscal implications of having a sustainable and robust response system that can handle any and all 911 calls at all times is strictly prohibitive. The burden sharing that has become accepted widely is the use of mutual aid compacts between communities, regions, and now states under the Emergency Management Assistance Compact.⁹ The key to successful sustained operation is embracing this concept and employing it, as required, on a regular basis. Furthermore, reviewing response protocols for uniformity, ensuring interoperability, and having a shared vision of application of OPSEC and site security tactics are integral on “game day.”

Hospitals share the same concerns for their facilities and staff. During the planning phase for responding to disasters, hospital planners must take the time to consider a number of issues that previously did not require their attention. Such matters include increased security, physical management of patient flow, personnel protective equipment, decontamination strategies, and staff training and support. One hospital failure that resulted in much national media attention occurred in Florida during the hurricane season of 2004. In this case, Florida Hospital Ormond Memorial fired and/or

suspended about 25 nurses for not working during Hurricane Frances. The nurses were fired for not calling in, not showing up, or refusing to work, whereas others were suspended for not completing a shift.¹⁰ The hospital stated that critical care employees are required to work during a disaster under hospital policy. Some nurses responded in media accounts alleging that they were not trained to deal with these extreme scenarios and also questioned who would protect their families. In any event, the fact of the matter remains that, in a crisis, staffing rosters that were expected to be populated based on the internal disaster plan were not, leaving the facility in the lurch to cover staff vacancies and sustain operations.

Another unfortunate occurrence in the aftermath of disasters is civil unrest and criminal activity. Police presence is often distracted and concentrated at the site of the disaster, coverage is weakened in the areas where law enforcement officers would normally patrol or deploy, and if the presence is weakened enough, citizens may and have taken to looting nearby houses, commercial districts, and in some cases emergency response equipment. Examples of this can be found in the history of countless disasters, as recently as Hurricane Charley's landfall in Florida in August 2004, and there are even unsubstantiated accusations of looting by the responders themselves in the Sept. 11, 2001 to attacks on New York City.¹¹

Community planners, responders, and emergency services personnel must also consider the likelihood of a situation where events have created a large-scale area that is too dangerous for anyone to enter or respond. Responders must ask themselves two questions and must answer them honestly: (1) In such a situation, what are the primary responsibilities of responders in getting people out, keeping people from entering, and making sure that the area remains contained? (2) Are the responders prepared to evacuate, relocate, secure, and effectively close a significant portion or an entire city, as was necessary during the Chernobyl disaster?

Proper and effective deployment of law enforcement officers is a key aspect of the incident management, NIMS, and NRP. With proper law enforcement tactical implementation, the lion's share of criminal activity or any form of civil disorder can be mitigated. The implementation strategy also provides for more effective coordination of responders at the scene, affording a higher level of coherence to ensure security of all personnel, integrated operations, investigatory processes, and sustained evidentiary recovery can all be achieved.

A similar concern exists for fire services in the wake of a disaster, specifically in fire-heavy disasters. The typical response for the fire service is to rush to the scene of a major blaze, such as the World Trade Center, and engage as quickly as possible to control the threat and resolve the problem. One can only imagine the collateral dangers if coincidental fires emerge in other parts of a city, particularly in the event of a secondary terrorist attack. The successes of mutual aid are clearly evident in the various responses to a number of large-scale disasters, but especially on Sept. 11, 2001.

Emergency management professionals often speak of the "secondary" attack, but how many communities,

agencies, and/or organizations responsible for response and recovery actually have plans in place for a controlled, coordinated, organized deployment in the face of a growing disaster? Despite what most would believe and as horrible as the Sept. 11 attacks were, the United States has yet to experience a true mass-casualty, mass-fatality event that overwhelms the capabilities of the affected community and the country. We as responders must revisit the pain and shock we all felt on Sept. 11, 2001, when 3000 persons were murdered. Three thousand sounds like an unimaginable number, but to our enemies 3000 is a training exercise.

INTEGRATION

Integration issues are a crucial consideration in any response to an emergency, but they are critical for a large-scale incident. The most obvious example of this is in the immediate aftermath of the Sept. 11, 2001 attacks on the World Trade Center in New York City. Interoperability between fire and police radios was found to be a major problem during the response to the 1993 bombing of the World Trade Center, and unfortunately, the same problem reared its ugly head on Sept. 11, 2001. Because of overloaded radio equipment, firefighters in Tower 1 of the World Trade Center were unaware of reports of the imminent collapse of the tower from an New York Police Department (NYPD) helicopter and therefore did not initiate their own evacuation. This lack of communication resulted in an increased number of casualties that could have been avoided. The proper implementation of IM/UC, which stresses both horizontal and vertical information sharing, would have required interoperable radios, and the NYPD helicopter in the air above the World Trade Center would have been able to relay the information regarding the collapse to the fire department, allowing them to have a fuller understanding of the events and begin evacuating.¹²

The Moscow Theater siege of October 2002 is another tragic example of the cost of lives lost when agencies are not integrated. Chechen terrorists took over the theater, claimed the patrons as hostages, and were killed when Russian commandos pumped a toxic gas into the theater that rendered both terrorists and hostages unconscious, killing some. The refusal and delay by Russian authorities to release information regarding the type of gas used to subdue and incapacitate the Chechen terrorists rendered medical personnel unable to properly diagnose and treat the nearly 650 hostage victims of the gas, 117 of whom perished in the rescue.¹³ The unfortunate reality is authorities in the Spetsnaz (Russian Special Forces, who carried out the raid) did not involve the medical community. If the Spetsnaz had coordinated the assault and included a medical component in tactical operations, the critical medical communication and coordination would have positioned the rescue attempt for greater success, saving additional lives because the medical knowledge, treatment, and response capabilities would have been on scene and poised to effectively respond when needed.

THE PRESS AND DIGNITARIES

Public relations is an important aspect of OPSEC/site security because outside factors such as the media and the family of victims can seriously complicate a response. One good example of the lack of OPSEC/site security with respect to the media causing major problems was evident during the “Beltway Sniper” shootings of October 2002 in the Virginia, Washington, DC, and Maryland area. The sniper pair left notes for the police with specific instructions not to be relayed to the press and allegedly made numerous requests for the media not to be involved in the interaction between the snipers and police.¹⁴ The press obtained this information through the notorious “unnamed source” and went public with information that not only jeopardized the investigation, but also put many lives in danger. The resulting lack of trust between the sniper and the police interfered with communication between investigators and the perpetrators and slowed the investigation as authorities shifted focus toward damage control.

The media can be a great asset when responding to an incident, provided relations take place in a controlled, efficient manner. An example of the positive and negative roles the media can play in responding to an event was during the sarin attacks in Tokyo. The most common and frustrating problem during any response is a lack of communication, and the Tokyo incident was no exception. Personnel at local hospitals had no idea what type of hazardous material or contaminant was creating the medical problems they were encountering. The hospital and healthcare personnel dealing with the unknown became aware of the substance from watching the local television broadcasts; coincidentally, physicians who had experience with sarin and the effects on humans had also been watching. The resultant communication between the physicians viewing the news coverage and the hospitals correctly identified the culprit. Concurrently, the media was criticized for filming while people suffered and died instead of helping them to the hospital.¹⁵

Media coverage of terrorist events can be a double-edged sword, and it is up to planners to ensure that the benefits of having the media present are not outweighed by the disadvantages. This will entail having a public information officer (PIO) who is trained prior to an incident on the successful discharge of the PIO duties. This person is integrated into the command structure to assist with response information dissemination and management of the media.

In the event of a major disaster, it is common practice for officials of all levels to visit the site to offer reassurance, from Governor John Ellis Bush flying in to visit the areas devastated by Hurricane Charley in the summer of 2004 to President George W. Bush visiting New York City after Sept. 11, 2001. It is necessary to have strict OPSEC/site security to maintain the safety of these dignitaries, as well as to ensure they and their entourages do not disturb the scene and hinder the investigation. Although the visit of these dignitaries is important to reassure the public, it must not come at the cost of successfully executing the response plan at a local, state, or

national level. As has been stated, planning cannot take place in a vacuum; plans to deal with the onslaught of media and dignitaries must be a part of the ongoing community response to any event that may overwhelm a community’s ability to operate under “normal” daily conditions. Therefore, meet-and-greet sessions and planning meetings must be conducted with all involved parties to include the local media, with the primary goal that all participants have a job to do and planning before the worst case scenario occurs will allow for the completion of the mission in a safe and cooperative manner. All egos, preconceived assumptions, and negative relationships must be checked at the door.

OPSEC/SITE SECURITY DEMANDS FOR OFF-SITE OPERATIONS

Finally, there is the issue of security and staffing support for elements of the response not located directly at the event site, such as joint or regional operation centers, joint or regional information centers, multiagency coordination centers, morgues, and food distribution and donation reception sites. Although these sites may not be physically located inside the incident perimeter, they are no less likely to be targeted. These critical areas are all vulnerable to being compromised or attacked by a variety of means including, but not limited to, physical attacks with arms, explosives, criminal acts, and hazardous material dispersal.

Law enforcement officials of some type, be they federal marshals or local police or security forces, must be present to ensure protection and sustained operation of these vital services. It is absolutely vital to the success and continuation of the response that community planners; local, city, and county emergency managers; and all those who will respond (paid and volunteer) meet on a regular basis before a catastrophic emergency to promulgate prudent operational response doctrine, to ensure OPSEC and site security, and to test planning strategies through comprehensive exercising.

OPSEC/SITE SECURITY FOR A TERRORIST INCIDENT

It isn’t enough to simply adopt and fully implement the NIMS-IM/UC framework to control and overcome the majority of OPSEC/site security issues, although it is important to note that the majority of concerns, challenges, and problems faced by EMS, medical, law enforcement, security, and fire services are not unique to terrorism/WMD events. The implementation of a plan and/or a system to alleviate identified problems and to avoid new problems is only as good as the training that is provided to familiarize all those who will use the plan and/or system.

It is impossible and may border on negligence to expect that people, agencies, departments, and communities will be able to use plans designed to place everyone on “the same sheet of paper” without coherent, comprehensive, ongoing training and exercising.

In the case of a natural disaster, for example, the difficulties inherent in the massive response of multiple agencies remain. The logistics involved in mobilizing personnel, equipment, and resources coupled with emotional, hungry, tired victims and those nefarious few who are bent on taking advantage of victims in need create circumstances that will derail the best laid plans. Now, add to that a situation in which these very same people are asked to respond, faced with all the normal obstacles, but have had little or no time to be acquainted with the new plan and even less time being trained on the plan's usefulness, purpose, and operational guidance. You now have the current scenario in place; add to this already chaotic, stressful, and incredibly frustrating event the current severity and the particular nature of the threats we face in the post-Sept. 11 era.

The unpredictability of terrorism presents conditions that are highly fluid and subject not only to the whims of nature or the physics of a damaged building but to the advanced plans and suicidal determination of well-trained terrorists. Additionally, your garden-variety terrorist does not have to fear Occupational Safety and Health Administration requirements, does not have to apply for permits, does not have to worry about the adequacy of financial support, does not have labor laws and/or legal restraints preventing action, and the list goes on. The terrorist groups we have identified, and most likely those we have yet to uncover, commit, plan, train, and act in an organized, efficient, and effective manner.

An organizational structure adequate to deal with such an elusive threat, represented by NIMS-IM/UC, only provides the means by which proper measures can be successfully implemented. This, however, is a question not of whether a strategy will be properly followed but of what that particular strategy entails. The plan in no way provides implementation funding avenues, training and educational funding, staffing backfill or overtime funding that will allow comprehensive training and education, equipment acquisition and maintenance, etc. Any plan is only as good as the assumptions it is based on, and a plan certainly is useless when those who are expected to use it have yet to see the plan and have no training in implementing it.

The critical issue that must be addressed is the priority that must be given to OPSEC/site security at all incidents, not just those eventually identified as terrorism/WMD related. This will create a familiarity with OPSEC and site security for all responders and institutionalize these policies into the way we do business at all times.

The after-action reports from numerous major terrorism incidents clearly reveal shortcomings in OPSEC/site security that warrant significant emphasis and close attention by agencies developing their terrorism/WMD response plans in concurrence with NIMS-IM/UC.

There is a striking convergence of properties that characterizes this second grouping of OPSEC/site security concerns: they cannot be solved by organizational reform alone, and they are all particularly pertinent in a terrorist/WMD attack. This highly interconnected list for scene management includes perimeter establishment, access and egress control, personnel accountability, evidence

protection and chain of custody, and the search for secondary devices and threats. Solving the inadequacies in these areas requires not just that the organizational structure exist, but that it be imbedded in a prominent position within the Incident Command structure.

ESTABLISHING A PERIMETER

The effective establishment of a perimeter is often a crucial aspect of gaining control over the scene of an attack. Establishing a perimeter has ramifications in all aspects of maintaining OPSEC/site security. Force protection cannot be ensured, evidence cannot be protected, chain of custody cannot be guaranteed, and access to the scene cannot be controlled with a porous or haphazard creation of a perimeter.

The overall response to the 1995 terrorist bombing of the Alfred P. Murrah Building in Oklahoma City, Oklahoma, is an excellent model of what was right and what was wrong. There existed three layers of perimeters, quickly established by morning on the day after the bombing: the inner perimeter was designed to provide limited access to only those personnel authorized to participate in the rescue/recovery work and the criminal investigation, a staging area also served as a buffer for workers, and a cordon limited traffic access.¹⁶ Unfortunately, an effective perimeter was not established immediately, and the site quickly became overwhelmed with hundreds of well-meaning people who wanted to help in any way they could. Because no control existed over any area of the dangerous site, one convergent responder, a nurse, was killed early on due to fallen debris. The eventual establishment of an effective perimeter was accomplished by close coordination of disparate agencies and proper use of their abilities, along with the securing and construction of fencing.¹⁶

At the World Trade Center site on Sept. 11, in admittedly more trying circumstances, "Perimeter security was not adequately established, allowing large numbers of unnecessary personnel to enter," due in large part to a 5-day delay in the creation of an adequate credentialing system and the construction of a fence.¹⁶ It took an extra 4 days at the World Trade Center to establish security even approaching the perimeter set up at the Murrah building. The potential repercussions of this sort of inattention are massive.

An example of inattention is the case of 1997 bombing of a women's clinic in suburban Atlanta, in which Eric Rudolph allegedly planted a secondary explosive device timed to detonate on the arrival of personnel responding to the initial explosive event. A CNN camera crew filming an interview with a witness of the initial blast caught the nearby second explosion on film; both media and civilians were endangered because they were allowed access to an area surrounding the scene that should have been secured. The uncontrolled scene increases the potential and likelihood that persons not involved in the initial catastrophic event will become victims as a result of a secondary attack, the hazardous material (if present) will be spread to a wider area of the city, and the criminal investigation will be hampered or destroyed. Ground

zero of a terrorist attack, therefore, demands special attention to the formation of perimeters as a necessary prerequisite to full OPSEC/site security.

The cooperation and discipline required to ensure security and safety does not and will not happen overnight or because it is the right thing to do. All aspects of scene control must be carefully planned, practiced, and exercised on an ongoing basis. It is impossible to expect two completely divergent disciplines to come together and cooperate without the right training and education. One large group of people is running in to tear the scene apart to look for victims, survivors, and treat the injured. The other large group requires the meticulous preservation of evidence and maintaining the site just as it was found. There is no question that each group has vital and incredibly important roles and responsibilities, and none more important than the other. But it is naïve and irresponsible for any responding person, agency, group, or department to expect these two parallel forces to eventually meet in the middle without long-term focused efforts aimed at settling the differences and ensuring that both jobs are completed efficiently and in a timely manner. This can only be accomplished well before the need through regular meetings, educational sessions, and training. Failure to address this coordination factor before an event will result in a response that resembles a cacophony rather than the desired symphony.

EVIDENCE PROTECTION

As already stated, ensuring the preservation of evidence is another fundamental aspect of OPSEC/site security in the event of a terrorist/WMD attack. Consider the Oklahoma Department of Civil Emergency Management After Action Report, which outlines the problems that presented themselves because of the large number of volunteers who were incorporated into rescue operations without being registered or identified. “Since the site was a crime scene, all our volunteers were required to be critically screened before they could work at the bomb site,” the report stated.¹⁶ Fortunately, authorities were able to quickly implement this system to rectify the unimpeded access people had previously been afforded; about 30 unauthorized “convergent responder” volunteers were evicted from one floor alone.

This was not handled as well at the site of the 2002 Bali bombings. There, “the crime scene was seemingly ruined and unprotected” due, in addition to unavoidable circumstances involved in the response, to “the public’s curiosity,” which was apparently allowed to hinder the investigation despite the fact that a police line had been set up.¹⁸ The removal, addition, destruction, or alteration of material, whether intentional, unintentional, or simply the product of an inexperienced volunteer seeking a souvenir, could prove to be a major hindrance to the proper conduct of the criminal investigation and identification of those responsible. Even the most minute and seemingly unimportant pieces of evidence often prove to be irreplaceable in these situations and cannot afford to be compromised. To the untrained eye, the aftermath of a terrorist attack is a pile of debris or a chaotic mass of

humanity. To the trained criminal investigator, the scene is a road map that tells the complete story of the circumstances leading up to the event and the event itself. As noted above, the control of access to the site of a WMD incident through well-guarded and protected perimeters and a secure credentialing system that does not allow for forgeries is the only way to guarantee the integrity of the crime scene.

INFORMATION SECURITY AND TRAFFIC AND CROWD CONTROL

Information security and dispersal interacts with traffic and crowd control to make up an extremely important aspect of OPSEC/site security in the event of a terrorist attack. In this case, OPSEC/site security takes on a much broader scope because activity elsewhere affects the flow of people and materials in and out of the site itself, as well as the city or general area in which the attack has occurred. The frightening nature of terrorism, especially for cases in which a WMD is implicated either by fact or by speculation, could and will result in mass hysteria and chaos. In the absence of accurate, timely information from authorities, rumor-mongering can take root, leading to potentially disastrous public panic. Something in the vein of an uncontrolled large-scale attempt to flee a city in the midst of reports of a chemical or biologic outbreak would freeze attempts to contain the attack and bring more people into open exposure.

Take the following description of the evacuation of coastal Florida at the approach of Hurricane Floyd in 1999: “Even many of those not in evacuation zones fled at the sight of satellite images on the news, which depicted a monstrous Floyd larger than the entire state of Florida. . . the result was a transportation nightmare.”¹⁹ The Florida public being frightened by memories of 1992’s Hurricane Andrew is akin to today’s nationwide memory of Sept. 11, 2001; combined with sensationalizing factors such as talk of a hurricane engulfing a state or the imminent citywide release of a chemical agent, they can easily produce wholesale disorder. Full control of the site of a terrorist disaster area requires that the information being disseminated from a scene be released in multiple mediums and methods of communication to dispel rumors and with an eye to directing the public to the proper course of action. Emergency response managers and chief officers cannot lose sight of the fact that our communities are made up of cultures that interpret the same information in different ways. Keeping in mind the cultural, language, and educational barriers that make up each community requires extensive preparations to ensure a complete information-sharing plan of action. Concurrently, traffic and crowd control of the entire surrounding area must be fused with information control to ensure that on-site efforts receive proper support and aid.

Control of human traffic also has great importance in its localized form. In the rush to leave a scene to avoid injury or seek medical attention, it is very possible that citizens may unintentionally carry biologic or chemical hazards with them. Depending on the nature of the agent that has been introduced, the failure to contain contaminated

people or other material could lead to secondary infections. The 1995 sarin nerve agent attack on the Tokyo subway system is an example of the difficulties and effects associated with the uncontrolled vector of contaminated victims. In that incident, over 4000 affected, some contaminated and off-gassing victims showed up seeking medical treatment without official transport. This means that a very large number of people who either came into contact or had a good chance of coming into contact with sarin were moving freely throughout the city. It is fortunate that the toxicity of the sarin used in the attacks was not potent enough to kill many more, and the off-gassing that occurred resulted in illness and not death.

Citizens who sought medical assistance were not treated by responders prepared to bring decontamination assets to the scene, causing a high rate of secondary exposure among the medical staff at unspecialized facilities. Containment of the incident area includes, therefore, the ability to bring specialized treatment to the site: “[A]gent absorbed by cloth may be released as a vapor by the cloth for 30 minutes or more after exposure.”⁶ Again, because the sarin had been put together quickly and was only 30% pure, the agent did not lead to any serious injuries in those who were not in direct contact with the dispersal device.²⁰ However, it is startling that such an impure chemical mixture was able to affect over 20% of the hospital workers treating victims who hadn’t been in direct contact with the sarin dispersal device and had been transported from the scene over an extended period of time.²⁰ The lesson is clear: in responding to an attack in which biologic, chemical, or radiologic weapons are suspected, establishing control of the traffic of people both in and out of the area is crucial for the protection of the scene victims and those would-be victims in the surrounding communities.

SECONDARY DEVICES OR THREATS

Perhaps the most pressing and worrying element of concern is that of secondary devices and threats targeting responders and evacuating civilians. Terrorism poses a distinct, highly dangerous hazard and challenge in itself, but the potential for secondary attacks and fallout aimed at even more casualties in those responding to assist further complicates the big picture and any attempts to control the aftermath. Terrorism aims in many cases to cause as much damage or harm to as many people as possible, so the use of a “follow-up” attack should not be addressed as merely a marginal possibility but as a primary consideration.

The previously mentioned example of Eric Rudolph and his alleged involvement in abortion clinic bombings is relevant here as well. The detonation of a bomb outside of an Atlanta nightclub 1 week after the women’s clinic blast where a secondary attack was successful provided responders with enough warning to suspect such a setup in Atlanta. Fortunately, the responders remained diligent, and the secondary device that Rudolph had allegedly planted was found and disarmed before it could kill or injure any of the responders. Similar terror tactics have been used extensively by several international ter-

rorist organizations, most notably the “Real Irish Republican Army” (IRA) and the Colombian paramilitary guerilla group known as the Revolutionary Armed Forces of Colombia (FARC). IRA guerilla forces “have operated a two-bomb strategy, hoping secondary devices ‘catch’ security forces rushing to the scene of the first.”²¹ The adoption of such tactics by the enemies of the United States, given their resourcefulness and excellent access to information, should certainly not be discounted.

Preparation for such a scenario has been found lacking. In the aftermath of the collapse of the World Trade Center towers, the initial rescue phase was followed by a massive recovery effort. Within a day or so after the two towers collapsed, there were already thousands of workers on the scene. Estimates place the number of volunteers and workers at ground zero after the attacks at 30,000 to 40,000.¹⁷ At the same time, however, “risk of secondary attack was not made a priority as the rescue effort was vigorously pursued.”²¹ The buildings in the immediate vicinity were not searched for 4 days and even then took months to be cleared. There was no standard procedure for obtaining resources such as military aid. Failure to immediately secure a perimeter and control site access, as mentioned above, left avenues open through which to strike.

In addition, the majority of the nation’s federal response to the disaster was housed in one Manhattan hotel surrounded by response vehicles brightly decorated with a wide variety of responding agency’s logos, decals, and identifying placards. The worst-kept secret in the entire city of New York was where all the federal responders were resting, recuperating, and spending their down time. There is no question that a well-planned or even a last-minute secondary attack could have been carried out that would have produced a very high number of casualties due to the large number of vulnerable personnel in the area. Such an attack would have crippled the New York response, but more importantly, the secondary attack at that particular time would have crippled the nation due to the message it would have sent to those not directly affected by the events in New York and Washington, DC.

Numerous tactics could be applied in a secondary attack. The potential for snipers to receive training and apply it with startling effect was demonstrated by the killing spree undertaken by the Beltway Snipers, John Allen Muhammad and Lee Boyd Malvo. Powerful and accurate weapons such as shoulder-fired rocket-propelled grenade launchers and American-made Stinger missiles, in addition to heavily proliferated small arms, are obtainable through the international black market and have been proved to be deadly in small-scale guerilla conflicts in Africa, the Middle East, and across the globe. Suicide attacks come in many forms, including truck bombs and explosives strapped to the body, and these can also be devastating in effect. It is clear, therefore, that there is both a real threat and a worrisome example in which this threat was not prepared for sufficiently. The NYPD report makes this apparent: “NYPD lacked systematic intelligence and threat assessment function and had difficulty assessing risk of further terrorist attack in weeks after 9/11.”⁷

CONCLUSION

OPSEC and site security are the most important concepts that can be engaged through a conscientious, comprehensive effort to protect and secure vital infrastructure before, during, and after a catastrophic event. To ensure that OPSEC/site security is a concept that is embraced and promoted, dialogue with all traditional and nontraditional response agencies should occur on an ongoing basis prior to “game day.” These “meet and greet, break bread” gatherings will require the checking of egos at the door and the establishment of a real goal-oriented working session. The creation of Memoranda of Understanding that details the roles, duties, and responsibilities of all agencies and responders will assist in the development of long-term working relationships all aimed at the security, safety, and preservation of life and limb.

Integration of Law Enforcement and Military Resources with the Emergency Response to a Terrorist Incident

Eric Sergienko

In a terrorist incident, medical and rescue resources will respond to locate, extricate, treat, and transport patients. At the same time, law enforcement resources will respond to investigate, interview, and collect evidence. Medical operations can interfere with the investigation and successful prosecution of terrorist activity. Movement through the scene can disrupt or destroy evidence. At the same time, by limiting access to the scene, law enforcement can have an impact on the ability of medical responders to effectively treat patients and move them from the scene.

Integrating the law enforcement response with the medical response requires cooperation at all levels of the operation: tactically, where individual responders must work side by side; operationally, where a unified command must smoothly coordinate resources at the incident site; and strategically, where resource and response decisions must be made. Emergency medical technicians, nurses, and physicians need to be aware of evidence preservation and crime scene management. Mass fatality management will have to coincide with evidence processing.

Furthermore, in a large-scale incident, regardless of its type, military resources may respond to the scene. The military has unique assets that can respond to a terrorist incident, including weapons of mass destruction (WMD) detection, decontamination, and mitigation. They can serve to augment the medical, rescue, and law enforcement capabilities of the civilian community. However, both the military responder and their civilian requester must understand the processes that allow the use of military resources and the rules under which they function.

The potential conflicts between medical responders and law enforcement officials must be addressed prior to the actual incident. The relation between military assets and the civilian government must be established. By recognizing the distinct roles that each agency plays in responding to the terrorist incident, the responder can better address his mission and the incident commander can better utilize resources.^{1,2}

In the wake of the attacks of Sept. 11, 2001 and the anthrax mailing that followed, there is significant flux occurring in the legal and administrative framework that organizes the U.S. federal and state response to terrorist incidents. To better understand these changes, it is helpful to look at the trends in the response to terrorism as a crime and terrorism as a mass-casualty event over the last 25 years.

HISTORICAL PERSPECTIVE

Law Enforcement

Since the 1980s, in differentiating between the roles of rescuers and the roles of investigators, the terms *consequence management* and *crisis management* have been used. The Federal Emergency Management Agency (FEMA) defines *consequence management* as the actions taken to protect public health and safety, restore essential government services, and provide relief to governments, businesses, and persons affected by the consequences of terrorism. *Crisis management*, in contrast, is the measures taken to identify, acquire, and plan the use of resources to anticipate, prevent, and resolve a threat or act of terrorism.³

Consequence management is maintained at the lowest level of government possible. If the consequences of a terrorist incident can be met with resources from the local level, there should be minimal involvement of state or federal resources. If local government is not able to adequately manage the consequences of the incident, it will turn to the state government for assistance. If the state cannot meet the needs of the incident, it will turn to the federal government. At the federal level, consequence management has been the responsibility of the agency providing civil defense. Since the 1970s, this has been FEMA.⁴

In contrast, crisis management, since its conception, has been felt to be a function of the federal government. The concept of terrorism as a criminal act evolved from

the realm of sabotage and espionage where an individual, working as an agent of an enemy state, performs an action that is injurious to the government or its people. Acts of terrorism, by extension, are acts committed by transnational or nonstate organizations. As a result, these are prosecuted in the federal courts under U.S. Code. The Department of Justice was appointed the lead federal agency for crisis management in the 1980s. The Federal Bureau of Investigation (FBI) was then delegated the responsibility for crisis management.⁵

The difficulty with having two different response operations to the same incident was that each entity, rescue, and investigation had a different set of objectives. Neither felt the other had a complete view of the incident. Conflict in managing the incident was a natural outgrowth of these unshared objectives. Furthermore, there was conflict vertically as different agencies with the same function competed for control of the scene.

The Stafford Act was passed in 1974 and amended in 1988 to delineate the federal response to a disaster. The Act was not made with a specific reference to terrorism. It did, however, state that nothing within the Act was to construe an investigatory role for any federal agency other than the FBI.⁶

In 1986, in response to the Vice President's Task Force on Terrorism, President Reagan issued the first guidance on responding to terrorism. Although largely designed to address attacks outside of the United States, it named the FBI as the lead agency for dealing with acts of terrorism. The next administrative guidance on terrorism would not occur until 1996.

The first large-scale act of terrorism on U.S. territory occurred in 1993. The World Trade Center was the site of an improvised explosive device detonation that resulted in 6 deaths and more than 1000 injuries. An area 150 feet wide and 5 stories deep was destroyed. There was minimal conflict between the crisis and consequence functions of this incident. The incident was initially felt to be a transformer explosion with a resultant fire. Because of this, command and control was largely performed by Fire Department of the City of New York (FDNY). Fire ground operations were handled with resources from the FDNY only, with mutual aid being required for the emergency medical services (EMS) response. Only later did it evolve into a crime scene. The area was then processed initially by four FBI evidence technicians and four Bureau of Alcohol, Tobacco, and Firearms evidence technicians working with a local New York Police Department chemist. After-action reports indicated a minimum number of conflicts between federal and local law enforcement officials. These reports attribute this to an already established Joint Terrorism Task Force (JTTF), which had been in existence in New York City since the 1980s.^{7,9}

JTTFs have been established in 56 major metropolitan areas that have FBI field offices. Each is made up of FBI special agents and local law enforcement officers. The local officers are made Special Deputy U.S. Marshals. They share in the responsibility of gathering intelligence, investigating, and prosecuting terrorist-related crimes. Funding of the JTTF is largely through the FBI, although the local government continues to pay the salaries of its officers.¹⁰

In response to the Oklahoma City bombing in 1995, President Clinton signed Presidential Decision Directive 39 (PDD-39). The response required was greater than the resources available to the local or state government. Furthermore, the incident was recognized nearly immediately as a criminal action. Although there was immediate involvement of federal agencies, there was little coordination between the consequences and crisis functions. PDD-39 established guidelines for federal command and control in the event of a terrorist incident. Specifically, it designated the Department of Justice as the lead federal agency for operational response and crisis management. The attorney general delegated this role to the FBI. It designated FEMA as the lead federal agency for consequence management. Furthermore, it specified that crisis management would take precedence over consequence management—the FBI would remain in charge of the scene until the attorney general had turned the scene over to FEMA.¹¹

Presidential Decision Directive 62 (PDD-62) directed the federal agencies in their preresponse planning to counterterrorism and consequence management. It established a national level coordinator for security, critical infrastructure protection, and counterterrorism. It provided guidance on the role of the Department of Justice, Department of Health and Human Services, and Department of Defense in preparing the Metropolitan Medical Strike Team (now Metropolitan Medical Response System) in the first 120 cities that established them.¹²

The Concept of Operations Plan (CONPLAN) for terrorism, signed in 2000, reaffirmed the role of the Department of Justice as the lead federal agency, a responsibility that is delegated to the FBI, in the response to terrorism. As such, the FBI remained the on-scene commander until the attorney general relinquished control to FEMA. However, there was much in terms of transitioning from a focus on crisis management to creating an environment that focused on a unified command involving all agencies that had a response. The FBI would establish a Joint Operations Command (JOC) that would serve as a focus for crisis management in the unified response. It was intended to complement and work with the local agencies' Incident Command System.¹³

On Sept. 11, 2001 the World Trade Center was attacked for a second time. In a much larger and clearly more destructive attack, the response was also large and difficult to manage. Again, the JTTF was crucial in providing a guiding framework for the crisis management response. There was a coordinated response to evidence processing that seemed to minimally affect the rescue efforts. The resources of the FDNY and other rescue agencies were continued well past the rescue phase due to their expertise in urban search and rescue. The most serious concern with Sept. 11 was not a conflict between law enforcement and rescue, but the lack of coordinated communications that may have led to unnecessary morbidity and mortality. The police commander ordered the evacuation of his personnel from the building after receiving information pointing to the potential for collapse, but this was not relayed to the firefighters.¹⁴

The success of the management of the response to the Pentagon attack can largely be attributed to the ability of the first responders, the Arlington Fire Department, to assert themselves as the incident commanders. Until the initial rescue and recovery operations were completed, the command remained with one agency as the lead, while other agencies actively contributed to the management of the incident.¹⁵

The Initial National Response Plan (INRP) was enacted in September 2003 while a final National Response Plan (NRP) was being developed. The INRP uses existing documents to blend response models to increase the possibility of harmonious relations at the incident site.

When signed, the NRP will become the guiding document for federal response to terrorism, supplanting the Federal Response Plan, the INRP, and the CONPLAN. It delineates the role of the Department of Homeland Security in the response to terrorism. It proposes moving more toward a unified command with a designated Principal Federal Official (PFO) as the overall senior federal official at the scene. Using Homeland Security Presidential Directive 5 as its guidance, it will eliminate the distinction between *consequence* and *crisis* response.¹⁶

Military

The military has been involved in support to civilian disasters since the inception of the union. The use of the military for non-law enforcement response is legal and well established in both statute and case law. The military has performed *ad hoc* relief missions to natural disasters both as an immediate response to emergencies in adjacent civilian communities (as in the San Francisco earthquake of 1906) or in sustained efforts as approved by Congress. It was not until the Federal Civil Defense Act of 1950 that Congress codified the military's standing role in civilian disasters. This was later expanded in the Stafford Act in 1974 and its amendments in 1988.

However, there is often concern about the use of military in support of civilian law enforcement. Originally, the states were concerned about the federal government maintaining a standing army. In the Reconstruction Era after the Civil War, the Union Army was used to maintain order in the Southern states. The reaction to the conduct of the Army in this time was to limit the use of the Army in civilian law enforcement. Feeling that the Army's enforcement of polling laws led to the party's loss of the presidency, a Democratic Congress passed the Posse Comitatus Act in 1878. A *posse comitatus* (Latin for "power of the county") historically is a collection of able-bodied citizens working under the county sheriff to enforce the laws. Currently, under Title 18 section 1385 of the U.S. Code, the Army and Air Force are prohibited from serving as a posse or other form of law enforcement. By Department of Defense policy, this has been extended to the Navy and the Marine Corps.

Since the passing of the Posse Comitatus Act, the military has continued to respond to natural disasters to support civilian communities. Neither does the Posse Comitatus Act completely eliminate the use of the military as an aid to law enforcement. It does allow for the

suppression of riots and controlling of crowds. The last large-scale use of this provision of the U.S. Code was in 1992, when President George H.W. Bush responded to the Los Angeles riots by deploying over 4000 U.S. Army and Marine troops and "federalized" (used as part of the U.S. Army) over 4000 California National Guardsmen. Furthermore, it is important to note that the Coast Guard is excluded from the Posse Comitatus Act. The Coast Guard, part of the Department of Homeland Security, is the United States' leading maritime law enforcement agency. Its duties include drug enforcement, immigration control, and port security.¹⁷

The Stafford Act identifies the Department of Defense as a resource that may be requested by the state governor from the president. In an incident in which a disaster declaration is expected, the president can direct the secretary of defense to provide military resources to the response for a period of up to 10 days. Once a declaration has been made, the resources are available through the established Joint Field Office. Expenses that the Department of Defense incurs in either of these responses modes are reimbursable.

Additionally, under the concept of *immediate response*, a local commander can use assets available to him to provide aid to an adjacent civilian community. This immediate response is done only to prevent the loss of life or limb or to minimize property damage. Traditionally, the period of time in which an immediate response can be performed is generally considered the first 3 days of a disaster. After that period, it is expected that requests for assistance will come through the channels established for crisis or consequence management (e.g., a state governor will request assistance from the president, then the president tasks the military with providing support). Under the concept of immediate response, the local commander can provide support to law enforcement when there is the possibility of loss of life or wanton property destruction, or to restore the functions of government.¹⁸

CURRENT PRACTICE

Law Enforcement

Local law enforcement will respond to the scene of a terrorist incident as they would any major crime scene. The concept is to minimize the number of people necessary at the scene so as to keep contamination of the scene to a minimum. An internal and external perimeter will be established. There will be an attempt to track personnel entering and exiting the scene. As with the first World Trade Center bombing, there will be an attempt to process the evidence with as few people as possible.

If it is one of the 56 metropolitan areas that have a JTTF, it is likely that there will be an immediate FBI/local police response aimed at determining the cause of the incident. In the past, the JTTFs have been able to determine that incidents were not terrorist in nature more rapidly than a traditional divided approach to intelligence development.

The initial federal law enforcement response will assess the scene to determine if the event is the result of a terrorist attack. The local FBI special agent in charge (SAC) will typically do this. If the SAC determines that this is likely a terrorist event, he or she will set up a Crisis Management Group. The Crisis Management Group will begin to coordinate the crisis management aspects of a terrorist incident. Initially, they will establish an FBI command post that will coordinate their efforts with the first responders' command post that is addressing consequence management. Ideally, this will evolve into a unified command structure supported by the Department of Homeland Security's Joint Field Office and by local, state, and regional Emergency Operations Centers.¹⁹

DHS will establish a Joint Field Office within 4 to 12 hours of determining that a terrorist incident has occurred. The Joint Field Office functions in essence as an Area Command as established in ICS, or similar to a regional Emergency Operations Center (Fig. 60-1). It incorporates a coordination group, operations group, administration/finance group, logistics group, and a planning management group paralleling the ICS used at the local level.

The PFO coordinates the efforts of the command group, which incorporates the senior representative from FEMA as the federal coordinating officer and the SAC from the FBI as senior federal law enforcement officer. As well, there are liaisons from all involved federal agencies, as well as state and local representatives.

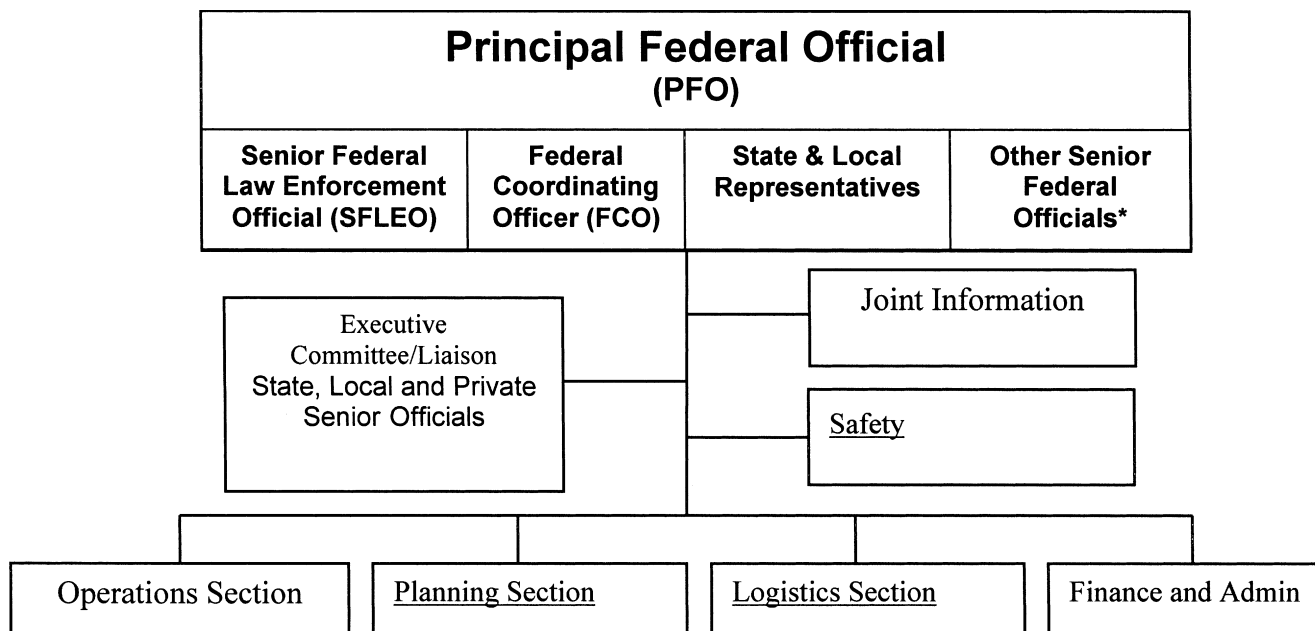

The Domestic Emergency Support Team (DEST) is a rapidly deployable interagency support team that brings to the on-scene commander the breadth of expertise available from the federal government. Typically, the

DEST will deploy immediately to an incident that may require federal support. The DEST may then become the nucleus of the Joint Field Office.^{20,21}

The FBI has had a Hazardous Materials Response Unit (HMRU) since 1996 to collect evidence in a hazardous environment. Deployed from FBI headquarters to a hazardous materials release, regardless of accidental or intentional release, the HMRU is capable of operating in a hostile environment to process it as a crime scene. In addition to the HMRU, designated FBI field offices maintain smaller, but similarly equipped Hazardous Materials Response Teams to act as an immediate response resource to local incidents. In addition, the FBI response will include an Evidence Response Team, a team of 8 to 50 members from a local field office that will process evidence from a crime scene.²²

It is expected that rescuers will need to enter the scene of a WMD release. However, to minimize the risk of contamination of the scene, multiple courses have been developed for the EMS and firefighter communities to recognize a criminal or terrorist incident, to minimize scene contamination, and to relate crime scene information to law enforcement officials.²³

At the tactical level, local special weapons and tactical teams have the need for integral EMS support. Typically, either SWAT officers are trained to the EMT or paramedic level or an experienced EMS provider is trained to operate in a tactical environment. Training for the medical provider is aimed at providing emergency care in an austere tactical environment. In addition, the EMS provider gives preventive care as well, measuring heat stress and injury potential, and enforcing work/rest cycles. Some agencies have developed a local joint task force to

*Includes the Defense Coordinating Officer (DCO)

FIGURE 60-1. Organization of Joint Field Office.

respond to a WMD release. Made up of local fire, EMS, law enforcement, and explosive ordnance disposal personnel, this task force trains personnel to provide a unified initial response within the hot zone. It has many of the capabilities of the National Guard's WMD-Civil Support Team, including agent identification, hazard mapping, and plume modeling.

Military

Civil support is the provision of Department of Defense support to U.S. civil authorities for domestic emergencies and for designated law enforcement and other activities. The Department of Defense undertakes civil support missions when its involvement is appropriate and when a clear end point for the Department of Defense role is defined. A term analogous to civil support is *military assistance to civil affairs* (MACA). This is the broad definition for the use of military resources in responding to a civilian incident.

The commander of any military force is tasked with first protecting his or her resources and personnel, being ready for his or her war-fighting mission, and keeping his or her higher authority aware of the situation. After this, excess resources can be committed to a civilian incident. Within the realm of MACA are several categories that are defined within the U.S. Code. *Military support to civil affairs* is the application of military resources to a civilian emergency or disaster. Another term that is in increasing use is *defense support to civil affairs*. Department of Defense Directive 3025.1 currently guides this.²⁴

Military aid to civil disturbance is the use of military force to quell a civil disturbance. The use of federal military assets requires an executive order from the president specifically indicating the location for assets to be deployed. The key to using military forces is retention of command and control of military resources by civilian authority.

Military support to law enforcement agencies is technical assistance rendered to civilian law enforcement agencies. This can include military resources that are not available to civilians such as aerial surveillance, technical assistance with these resources, and tactical advice. It does not include actual law enforcement powers. The Department of Defense also has authority to provide support to the U.S. Secret Service for missions related to the president of the United States. These may include airlift, communications, medical, and explosive ordnance disposal support.

Improvised nuclear device (IND) response is outlined in Department of Defense Directive 3150.5. It assumes that any IND release is an act of terrorism and establishes the FBI as the lead federal agency. It establishes the Army as the lead Department of Defense agency for response to an IND release that is not on property controlled by other Department of Defense assets.

Despite growth in the civilian response to WMD, the Department of Defense, including its Reserve and National Guard components, remains the largest repository of resources to the response to WMD release. For this reason, a response should be expected from the Department of Defense in the case of a WMD release.

However, the response is not automatic and depends on the local military commander having resources that are available to respond. Local governments with adjacent Department of Defense assets should do their best to establish Memoranda of Understanding and Mutual Aid Agreements so that resources used in the immediate response mode can freely flow across territorial boundaries. Requests for support using this mode are made from local or state government to the base commander or regional commander.²⁵

The initial pathway to request military resources, other than through immediate response, is through the state governor to the U.S. president. The president will delegate this request to the secretary of defense. The secretary of defense will turn to the director of military support (DOMS). The DOMS oversees an operational staff within the Department of Defense for the coordination of military assets in a civil emergency. Until a Joint Field Office is established with a defense coordinating officer (DCO) in place, the DOMS validates all mission requests, identifies available units, and initiates the deployment orders (Fig. 60-2).

The DCO serves as the senior Department of Defense representative within the Joint Field Office. Typically, the DCO is a senior officer (colonel, captain, or flag rank officer) who is responsible for coordinating all Department of

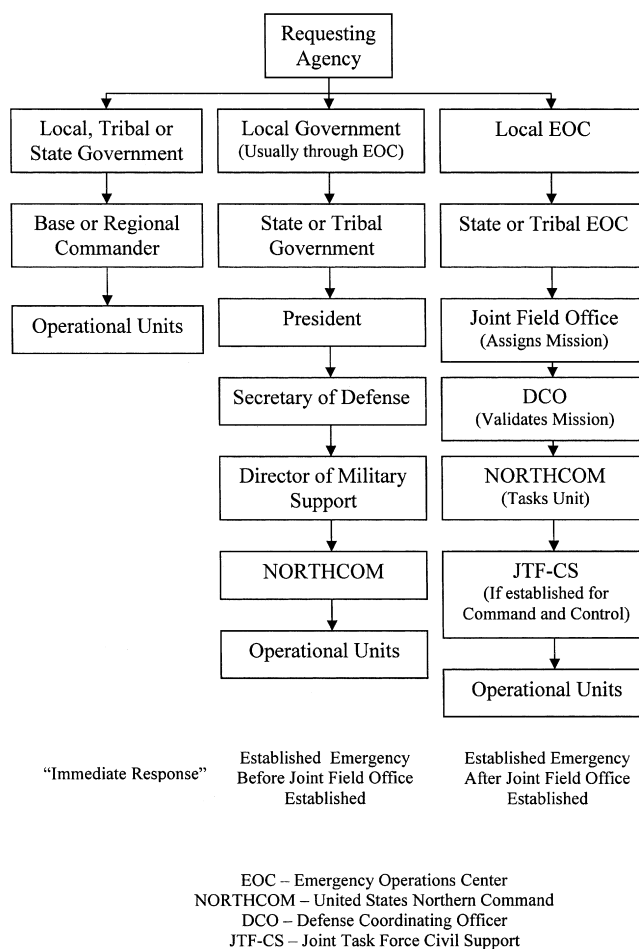

FIGURE 60-2. Pathways for requesting military assistance.

Defense elements at an incident. He or she is responsible for validating any requests made from the federal coordinating officer FCO or PFO. To assist the DCO, there is a defense coordinating element that is composed of an experienced staff of emergency planners and managers.

The emergency preparedness liaison officer (EPLO) is a senior military officer, typically a reservist, who serves to coordinate federal planning with state and local agencies. There is an EPLO associated with each state and with each FEMA region. In a typical tour, they attend planning sessions and tabletop and full-scale exercises. In the event of an actual incident, the EPLO would be activated to continue as a full-time liaison between the local and state response and the Department of Defense response. If a Joint Field Office is established with a DCO in place, the EPLO is attached to continue this role within the organized response under that office.²⁶

U.S. Northern Command (NORTHCOM) is the command and control structure for organizing Department of Defense assets into an effective homeland security response. Established in October 2002, it has minimal assets under its operational control; rather, it serves as a clearinghouse for planning and coordinating response. During an incident, NORTHCOM would receive tasking either from DOMS, prior to the establishment of a DCO, or from the DCO after he or she has been activated.

Joint Task Force Civil Support (JTF-CS) is the NORTHCOM command that would provide command and control of Department of Defense assets after a chemical, biologic, radiologic, nuclear, or explosive (CBRNE) incident. It is a standing joint task force located at Fort Monroe, Va, commanded by a "federalized" National Guard general (a guardsman usually works for a state, but when federalized becomes an asset of the regular forces). When directed by the commander of NORTHCOM, JTF-CS would deploy to the incident site and establish command and control of Department of Defense forces to provide military assistance to civil authorities. JTF-CS focuses on consequence management and would report to and work closely with the lead federal agency in this response (either FEMA or, in the case of a foreign incident, the Department of State). Typically, the DCO would be attached to the JTF-CS staff as a special assistant. The DCO would continue his or her focus of validating missions and authorizing the use of Department of Defense assets.

The Marine Corps' Chemical Biological Immediate Response Force (CBIRF) is a battalion-sized unit able to deploy to a WMD scene. It has a large integral medical unit with emergency physicians, environmental health specialists, and medical technicians. Its parent command is the 4th Marine Expeditionary Brigade (MEB), Antiterrorism (AT). The 4th MEB/AT has several other smaller units that may be tasked to a homeland security or defense mission. Currently, CBIRF is based south of Washington, DC. However, it is often staged to support national special security events.

The Army has organized its WMD response into a single organization, the Guardian Brigade. Consisting of a headquarters element, a Chemical Biological Rapid Response Team (C/B-RRT), the Technical Escort Unit (TEU), and the 52nd Ordnance Group, it is located at

Aberdeen Proving Grounds in Maryland. It is proposed that the Guardian Brigade will eventually transition to the CBRNE command.

The Army's C/B-RRT is a rapidly deployable asset from the Guardian Brigade to provide assessment of a potential chemical or biologic incident. The mission of C/B-RRT is to coordinate the activities of all Department of Defense assets responding to a CBRNE incident.

The TEU is a battalion-sized active duty Army unit. It has been in existence for over 60 years. Initially formed to provide technical support during the transport of chemical munitions, its mission has expanded to respond to the release or potential release of chemical or biologic agents. The unit's chief focus is to render safe operations of munitions that may be used to disseminate chemical or biologic agents. Typically, the TEU deploys in small teams of fewer than a dozen. Teams from the unit have been extensively deployed overseas, but the unit will also stage for national special security event.

WMD-Civil Support teams (WMD-CST) are full-time National Guard teams that have the operational role of providing an intelligence gathering and reach-back capability for the local incident commander. They are a state asset and report to the governor via the state's adjutant general (the commander of the state's National Guard). The WMD-CST consists of 22 active-duty guardsmen. Each guardsman is extensively trained in various aspects of WMD management. As a team, they can provide identification, threat modeling, mitigation, medical assessments, and recommendations and can communicate this to subject matter experts. The WMD-CST can make recommendations to the incident commander in these areas. Once in place, they can act as the initial liaison between the local incident command structure and arriving Department of Defense resources. However, they lack the depth to provide mass decontamination, treatment, or care.

The Air Force's Radiation Assessment Team is a deployable team from San Antonio, Tex, designed to respond to incidents involving radiation emergencies, from release of radioactive isotopes to WMDs. They perform analytical dosimetry, health physics, and plume modeling.

The Medical Commands of the Army, Air Force, and Navy maintain deployable medical assets. An example is the Air Force's Expeditionary Medical Support (EMEDS). EMEDS is a modular response field hospital that is built around a central resuscitation area, operating room, and intensive care unit module. The basic EMEDS can deploy in hours, is air transportable in a single C-130, can be broken down into backpack-sized loads, and has enough material to do multiple resuscitations and 10 surgeries. Additional beds and ancillary capabilities can be added as needed.

PITFALLS

Law Enforcement

"Who is in charge here?" "Who is in charge of what?" The evolution of command and control at a potential terrorism incident has evolved from divided law enforce-

ment and rescue response and a divided local and federal response to a unified command structure that treats all responding agencies as equals. Under the auspices of a principal federal officer, the command structure should fall out to meet both the crisis and consequences issues of the incident; this is the way it is designed on paper. The pitfall of the current command structure is that it includes people who have always been in charge of their own operations and are now working together.²⁷

Patient care versus evidence preservation—this is truly the yin and yang of a terrorist incident. The more we take care of patients, the more likely we are to disturb the crime scene and destroy evidence. When involved in the response to a terrorist incident, the EMS responder must stop to assess the scene not only from a mass-casualty management standpoint, but also from the forensic viewpoint. It is likely that the EMT or firefighter may be the first, and perhaps only, witness to a particular piece of evidence.

Military

The use of the military is a well-described process. For forces that are proximate to an emergency, regardless of whether it involves terrorist activity, the local commander can operate under the auspices of immediate response. These are actions that can be taken to save life or limb or to preserve property. If the event does not fall into either of these categories, the military should not be asked to deploy, nor should they agree to. The duration of response should also be taken into account. Generally, an immediate response is understood to be the first 72 hours or so of an incident.

A concept that needs further clarification is the definition of *proximate*. Can a commander who is distant from a scene, but who is the nearest available source of a scarce resource, dispatch those resources to the incident scene?

One concern of the commander using the immediate response mechanism is whether he will be reimbursed for his actions. All actions taken by the military and all requests made by their civilian cooperators should be well documented, so that later claims for costing can be justified.

Although it is clear that the Posse Comitatus Act does not apply to the use of the military resources in non-law enforcement situations, there will always be a concern expressed that the military is involved in civilian affairs. To minimize these concerns, the military should only be used for validated missions. Furthermore, military assets should not be placed in a potential situation where lethal force may be needed without clear instructions from higher authority.

Nuclear Disaster Management*

George A. Alexander

The events of Sept. 11, 2001 and the worldwide proliferation of nuclear materials, including theft and smuggling, increase the possibility that a nuclear disaster event may occur from the terrorist use of radiation as a weapon. There are two documented incidents of the threatened use of radiation as a terrorist weapon thus far,¹ both of which occurred in Russia. In 1995, Chechen insurgents buried a cesium-137 “dirty bomb” in a Moscow park and alerted the media before it was detonated. In 1998, a container of radioactive materials was found attached to an explosive mine near a railroad line in Chechnya.

Nuclear disasters can have different scenarios. An extreme situation would be the threat of a terrorist attack using a low-yield 10-kiloton nuclear weapon. The threat of a nuclear terrorist attack with a nuclear device or radioactive materials is not a question of if, but when. Many people have become aware of the threat of such an attack because of increased media attention. Successful planning for a nuclear attack or accident now becomes imperative.

This chapter presents important concepts of nuclear disaster management. The aim is to offer a basic understanding of the threat and effect of nuclear disasters, including accidents and terrorist events. This chapter provides a brief historical overview of the development of the nuclear era, the nuclear arms race, and present concerns. It highlights some basic physical and biologic principles of radiation injury that are commonly misunderstood by healthcare professionals. The chapter reviews various nuclear disaster scenarios, summarizes medical management principles, and underscores obstacles to nuclear disaster management.

HISTORICAL PERSPECTIVE

Following the discovery of radioactivity in 1896, the understanding of atomic physics increased rapidly in the early twentieth century.² Ernest Rutherford is recognized as the father of nuclear physics. In 1908 he received the

Nobel Prize for chemistry for his “investigations into the disintegration of the elements, and the chemistry of radioactive substances.”³ He was directly responsible for training many physicists at Cambridge University in England. In the latter capacity, he was also indirectly responsible for much of the nuclear physics research that was being conducted at many universities by his former students throughout the world and for the development of the nuclear era.

In 1938 Hahn and Strassman in Berlin described the phenomenon of nuclear fission.² They determined that when uranium was bombarded with neutrons, the nucleus split into two parts of comparable mass with the release of an enormous quantity of energy. This observation would lead to the Manhattan Project and eventually to the production of the atomic bomb (A-bomb).³ In 1942 Fermi achieved the first controlled self-sustaining nuclear reaction.³ In August 1945 the first atomic bombs (or fission bombs) were detonated over Hiroshima and Nagasaki, Japan.

The development of the atomic bomb would lead ultimately to the development of the even more devastating hydrogen bomb (H-bomb). In the 1950s, justification of work on the hydrogen bomb (fusion or thermonuclear bomb) was based on the fact that it produced less radioactive fallout and therefore was considered a “cleaner” nuclear weapon.⁴ Enhanced radiation weapons (neutron bombs) were later developed to minimize the effects of blast and heat on buildings and to maximize the effects of the neutrons on living organisms (e.g., to kill tank crews without causing much collateral damage).⁴

During the Cold War era, the nuclear arms race between the United States and the former Soviet Union continued for more than 30 years. By the early 1980s the number of nuclear warheads worldwide was estimated to be in excess of 40,000.⁵ The explosive power of these warheads ranged from about 100 tons up to more than 200 million tons equivalent of high explosives. During this same time period the total strength of nuclear arsenals was believed to have been equivalent to about 1 million Hiroshima bombs or 13,000 million tons of TNT (trinitrotoluene).

With the end of the Cold War in the late 1980s, the threat of Armageddon—a nuclear war between the United States and the former Soviet Union in which 200

*The views expressed in this chapter are those of the author and do not necessarily represent the official policy or position of the National Cancer Institute, the National Institutes of Health, or the Department of Health and Human Services.

million Americans might not survive the war—was eliminated.⁶ However, this apparent relief from the Armageddon syndrome has been short-lived because the twenty-first century now appears to be more dangerous and less predictable. The risk that someone might detonate a nuclear weapon in anger or retribution is probably greater than at any other time since the 1962 Cuban missile crisis.⁷ Moreover, nuclear weapons ambitions are spreading not only to states, but also to terrorist groups. Osama bin Laden has talked of acquiring nuclear weapons as a “religious duty.”⁷

Today, the most likely threat from nuclear weapons is based on a scenario of a terrorist group or rogue nation using a single, low-yield device, such as a suitcase-size tactical nuclear weapon.⁸ The second most likely threat is from an improvised nuclear device (IND) used by terrorists and composed of either weapons-grade (enriched) uranium or plutonium-239. The third most likely terrorist nuclear threat is from a radiologic dispersal device (RDD), also known as a “dirty bomb.” (See Chapter 177 for a more complete discussion of the RDD.) Although the detonation of an RDD does not produce a nuclear yield, RDDs are important because of their potential to cause a nuclear disaster using high explosives to disperse very high levels of radioactivity associated with materials from nuclear reactors, spent fuel storage depots, nuclear fuel reprocessing facilities, high-level nuclear waste sites, or transport vehicles.⁸

The development of man-made radioactive isotopes and nuclear weapons during and after World War II was an important factor in the birth of the nuclear weapons industry in the mid-twentieth century. Most of what we know today about nuclear disasters comes from the atomic bomb experience of World War II and from radiation accidents that have occurred over the past 60 years. Information on the effects of nuclear weapons has been obtained from Hiroshima and Nagasaki and from animal experimentation conducted during atmospheric tests of the 1950s.⁹ Data on the consequences of radiation accidents have been obtained from the methodical medical and scientific assessments of radiation accident victims. The existence of national and international registries on accidental radiation injuries has helped to characterize the types and patterns of radiation damage and to provide useful information for optimal medical management of victims.¹⁰ The knowledge gained from these experiences serves as the foundation of nuclear disaster management for the twenty-first century.

CURRENT PRACTICE

Nuclear weapons produce their biologic effects through the direct or indirect effects of blast, heat, and radiation.¹¹⁻¹³ The first two effects are fairly simple and the mechanisms of their injury are readily understood. Radiation, on the other hand, is a more complex noxious agent and is generally misunderstood by health professionals. Understanding how radiation interacts with matter provides insights into methods used to detect and measure radiation, reduce the biological hazards, and manage nuclear disasters and their consequences.

Basic Principles

Radiation Physics

After a nuclear weapon detonation, a tremendous amount of energy is quickly released in the form of ionizing radiation. Ionizing radiations are defined as those “types of particulate and electromagnetic radiations that interact with matter and either directly or indirectly form ion pairs.”¹⁴ Ionizing radiations can be divided into two categories: directly ionizing and indirectly ionizing. Directly ionizing radiations are charged particles (electrons, protons, beta particles, alpha particles, etc.) that have sufficient kinetic energy to produce ionizations through direct collisions with bound orbital electrons of an atom or molecule. Indirectly ionizing radiations are uncharged particles or photons (neutrons, x-rays, gamma rays, etc.) that can liberate bound orbital electrons, but only indirectly.

Both x-rays and gamma rays are photons, or small quantized packets of pure electromagnetic energy just like light. However, they have a much higher non-visible frequency. X-rays and gamma rays differ only in their origin. X-rays are produced in the outer orbital shells of atom, whereas gamma rays come from within the nucleus of the atoms. X-rays and gamma rays are low linear energy transfer radiations; that is, they deposit relatively low amounts of energy along the track of radiation as they penetrate tissue and deposit energy deep in the body. Many radioactive isotopes decay by emitting several different types of particles. The most common forms of particle radiation are alpha, beta, and neutron.

Alpha particles are massive, charged helium nuclei. Because they deposit all of their energy over a very short distance, alpha particles are classified as high linear energy transfer radiation. Because of their size, alpha particles can easily be stopped using a sheet of paper or light clothing. Beta particles are very lightly charged high-speed electron particles that can penetrate to a depth of a few centimeters. Neutron radiation is an uncharged particle that is emitted during a nuclear detonation almost exclusively from the fission and fusion processes themselves. Important factors that will prevent or minimize the effects of radiation exposure on humans include the principles of time, distance, and shielding. (See Chapter 70 for a discussion of radiation safety.)

Radiation Biology

Radiation biology is the field of study that describes the many changes that radiation produces in biological material. Charged particles (e.g., electrons, protons, beta particles, alpha particles, fission fragments) are directly ionizing because they can disrupt (ionize) chemical bonds and produce chemical and biologic changes.¹⁵ Electromagnetic radiations (e.g., x-rays, gamma rays) are indirectly ionizing because they do not themselves cause any chemical or biologic changes. Instead, they deposit kinetic energy into the material through which they pass and produce secondary charged particles (electrons) that can produce subsequent chemical and biologic alterations. Radiation can damage a cell by indirectly

interacting with water molecules in the body. This leads to the creation of unstable, toxic hyperoxide molecules (free radicals) that then damage sensitive molecules and subcellular structures. Ionizing radiations transfer energy to biologic material by two mechanisms: ionization and excitation.¹⁵

Alpha radiation is fully absorbed within the first millimeter of exposed skin. It is generally not an external radiation hazard. Alpha radiation poses serious health hazards if it is inhaled, ingested, or deposited in an open wound. If an alpha-emitting radioactive material is internally deposited, all of the radiation energy will be absorbed in a very small volume of tissue immediately surrounding each particle of material. The internal deposition of alpha particles can cause radiation injury over a long period. If a beta-emitting radioactive material is on the surface of the skin, the ensuing beta radiation causes damage to the basal stratum of the skin and produces deep "beta" burns—lesions similar to superficial thermal burns. If the beta material is incorporated internally into the body, the beta radiation can cause considerable injury. Gamma radiation is highly energetic and penetrating and therefore is both an internal and external radiation hazard. Gamma rays can cause whole-body injury. Neutron radiation is extremely penetrating and can also result in whole-body irradiation. Compared with gamma rays, neutrons can cause 20 times more damage to tissues.¹⁶

The sensitivity of cells, tissues, and organs to a dose of ionizing radiation depends primarily on two factors: the rapidity of cell division and the radiosensitivity of the cells.¹⁵ Cells are most sensitive to radiation during mitosis, when DNA is being divided. Rapidly dividing cells are more radiosensitive. Tissues and organs that depend on an active stem cell pool will be more radiosensitive than those tissues and organ systems made up of mature cellular pools with little or no stem cell activity.

Radiation Dose and Units

Quantities of radiation can be expressed in several different ways. The term *radiation exposure* applies to air only and is a measure of the amount of ionization produced by x-ray and gamma radiation in air. It is a measure of how much ionization is produced in air and is measured in coulombs per kilogram (C/kg) of dry air. The roentgen (R) is an older unit of radiation exposure and applies only to x-rays and gamma rays up to energies of about 3 MeV. (1R = 2.58×10^{-4} C/kg.)

The *radiation absorbed dose* is the amount of energy deposited in a given mass of absorbing material. The conventional unit for absorbed dose, the *rad* (radiation absorbed dose), is equal to the absorption of 100 ergs of energy in 1 gm of absorbing medium, typically tissue. (1 rad = 100 ergs/g of medium.) The SI unit of absorbed dose, the gray (Gy), is defined as the absorption of 1 Joule of energy per kilogram of medium. (1 Gy = 1 J/kg = 100 rad and 1 rad = 1 cGy.)

The term *dose equivalent* is necessary because different radiations produce different amounts of biologic damage. It is defined as the product of the absorbed dose and a factor, Q (the quality factor), that characterizes the damage associated with each type of radiation.

In the conventional system, the unit of dose equivalent is the *rem*, which is calculated from the absorbed dose as $\text{rem} = \text{rad} \times Q$. The SI unit of dose equivalent is the sievert (Sv), or sieverts = $\text{Gy} \times Q$.

Radioactivity is the activity level of a radioactive isotope expressed as the number of atoms that will disintegrate (decay) per second. One becquerel (Bq) is equal to one nuclear transformation per second. The unit in the traditional system is curie, where 1 curie (Ci) = 3.7×10^{10} Bq. The term *dose rate* is the dose of radiation per unit of time.

Nuclear Disaster Scenarios

In light of the terrorist attacks of Sept. 11, 2001, it is important to understand possible nuclear disaster scenarios. Sept. 11 was a "day of unprecedented shock and suffering in the history of the United States. The nation was unprepared."¹⁷ The greatest threat we face in the world today is from nuclear terrorism.¹⁸ The vast stockpiles of nuclear weapons and highly enriched uranium and plutonium in Russia are vulnerable to theft and illicit trafficking. Russia remains the most probable source for a terrorist to obtain a nuclear weapon or materials to construct a weapon, followed by Pakistan and North Korea. North Korea is believed to be the world's most promiscuous nuclear proliferator.¹⁸ The leaking of weapons technologies allows smaller terrorist groups to wreak havoc and cause greater destruction. Globalization has made it easier for terrorists to travel, communicate, and transport weapons. There is a burgeoning and well-organized black market for nuclear technologies and arms. Sept. 11 was a wake-up call to America. Americans do fear more terrorist attacks and more Middle East instability.¹⁹ In fact, a recent poll taken in 2003 found that four of every ten Americans say that they "often worry about the chances of a nuclear attack by terrorists."²⁰ The threats of terrorist attack will be far more serious if North Korea and Iran develop nuclear programs.

DETONATION OF NUCLEAR WEAPONS

Strategic Nuclear Weapons

Strategic nuclear weapons are devices constructed by a government or country. This category of arms made up the main strategic arsenal during the height of the Cold War. These weapons generally had a yield (or size) from 170 kilotons to 24 megatons.⁵ Interestingly, the Soviets are reported to have had some warheads with yields as high as 100 megatons. Strategic nuclear weapons could be carried to the intended target by various delivery vehicles including land-based intercontinental ballistic missiles, submarine-launched ballistic missiles, or long-range bombers. The detonation of a strategic nuclear weapon in the United States today is unlikely. However, the risk of such an event would most likely be associated with the accidental launch of a former Soviet Union nuclear weapon resulting from equipment malfunction, warning system failure, or dissidents getting hold of strategic weapons and launching them.

Tactical Nuclear Weapons

Tactical nuclear weapons are also fabricated by a government or country and have yields from less than 0.1 to more than 100 kilotons.⁵ These nuclear systems have been designed or could be used by a military organization for employment against, for example, military targets in a theater of war. Such weapons are artillery shells, ground mobile rockets and missiles, and air-launched bombs. Tactical nuclear weapons may be the size of a suitcase or backpack.

Imagine a terrorist scenario in which a 10-kiloton nuclear weapon is stolen from a Russian arsenal and detonated in New York City, San Francisco, Houston, Washington, Chicago, or Los Angeles.²⁰ If a terrorist group, such as Al Qaeda, was to rent a van and carry this nuclear weapon into the middle of Times Square in New York and detonate it next to the Morgan Stanley headquarters on Broadway, Times Square would vanish within a second.²⁰ The resulting fireball and blast wave would destroy instantly the theater district, the New York Times building, Grand Central Station, and every other building within a third of a mile from “ground zero.” The resulting firestorm would engulf Rockefeller Center, Carnegie Hall, the Empire State Building, and Madison Square Garden. On a typical workday, more than 500,000 people may crowd into an area within one-half mile radius of Times Square. A noon-time detonation could potentially kill all of these people including hundreds of thousands of others who would die from collapsing buildings, fire, and fallout. The electromagnetic pulse from the blast would destroy phones, radios, and other electronic communications. Emergency medical services and hospitals would be overwhelmed by the injured.

Improvised Nuclear Device

An IND is fabricated by a non-governmental organization or terrorist group. It is made up of either highly enriched uranium or plutonium-239. Tens of thousands of potential weapons (softball-size lumps of highly enriched uranium and plutonium) remain today in unsecured storage facilities in Russia, vulnerable to theft by criminals who could sell them to terrorists. Since the collapse of the former Soviet Union, there have been hundreds of confirmed cases of successful theft of nuclear materials. If successful, detonation of an IND could produce a nuclear yield similar to that of Hiroshima with the release of radiation, blast, and thermal pulses with considerable radioactive fallout. Fabrication of such a device would be difficult because of the sophisticated expertise and engineering required. A terrorist organization might be able to produce a partial yield, producing less effect.

Effects of Nuclear Weapons

In this section, the basic characteristics of the effects of nuclear weapons are summarized with an emphasis on the information of greatest use to nuclear disaster managers. There are numerous other references^{8,16,21,22} that treat this subject in much greater detail.

The main physical effects of nuclear weapons are blast, thermal radiation (heat), and nuclear radiation. These effects depend on the yield of the weapon, physical design of the weapon, and method of employment.²² The altitude at which a weapon is detonated will determine the relative effects of blast, heat, and nuclear radiation. Nuclear detonations are usually classified as airbursts, surface bursts, or high-altitude bursts.

The blast and thermal effects of a detonation produce the greatest number of immediate human casualties.²¹ Immediately after detonation the temperature at the center of the fireball reaches 1,000,000° C, producing a shock wave traveling at supersonic speeds, followed by hurricane-force afterwinds and an intense flash of thermal radiation. A 5-psi (pounds per square inch) blast wave and 160-mph blast winds associated with the blast wave would destroy a two-story brick house, rupture the human eardrum, or hurl a person against stationary structures.²¹ A pressure level of 15 psi could produce serious intrathoracic injuries, interstitial hemorrhage, edema, and air emboli as well as serious abdominal injuries, such as hepatic and splenic rupture.

The thermal radiation is associated with burns, including *flash burns* and *flame burns*, and certain eye injuries, including *flash blindness* and *retinal burns*. Flash burns result from the skin's exposure to a large quantity of thermal energy in a very short time, leaving the affected skin with a charred appearance. Flame burns result from the contact with a conventional fire, such as that on clothing. Flash blindness is a temporary condition; however, a retinal burn that results from looking directly at the fireball causes a permanent blind spot.

Detonation of a nuclear weapon produces a variety of nuclear radiations.²¹ Initial radiation consists of neutrons and gamma rays produced within the first minute after detonation. The main hazard from initial radiation is acute external whole-body irradiation by neutrons and gamma rays. Residual radiation is generated beyond the first minute after detonation and includes gamma rays, beta particles, and alpha particles. These radiations are produced as highly radioactive fission fragments and activated weapons material. The main hazard from residual radiation is radioactive fallout, which can remain a significant biologic hazard long after detonation.

ATTACKS ON NUCLEAR REACTORS

The potential of terrorist attack on a nuclear power plant has been mentioned by the media. However, the probability of an attack is low. The low probability is due to the high security surrounding a nuclear reactor and the safety systems incorporated into it. There is extensive shielding around the reactor core and large amounts of explosives would be needed to breach the reactor core. If an accident occurs, reactors are designed to slow down and stop the reaction. A reactor coolant system does contain some radioactivity, which could be released if the coolant system were damaged. Radioactive iodine and noble gases would probably be released. There would be immediate health effects nearby from the release. The release of large amounts of radioactive iodine could have

long-term effects such as thyroid cancer in children. It is possible that a jumbo jet could crash into a reactor or adjacent spent fuel storage facilities, but it would be difficult in the latter situation to expose a large population to radiation from “spent” fuel rods. Recent computer modeling and engineering studies suggest that the construction of most reactors could withstand a direct hit from a commercial aircraft flying into a reactor at less than 300 mph. However, some scientists question these findings and believe that penetration of the containment dome could cause the reactor to melt down. The 1986 Chernobyl nuclear power plant accident in the former Soviet Union serves as a harsh reminder of scenarios in which terrorists might possibly cause a nuclear disaster by breaching a nuclear reactor and releasing radioactive materials into the environment.

DETONATION OF A RADIOLOGIC DISPERSAL DEVICE

An RDD is a device that combines radioactive materials with conventional explosives. (See Chapter 178 for a more complete discussion of the RDD.) It may be made from traditional dynamite, TNT (trinitrotoluene), ammonium nitrate, or a variety of other explosive materials.²³ When detonated, an RDD kills or injures through the initial blast, which causes damage from the expansion of hot gases and by dispersing radioactive materials that are highly toxic over a wide geographic area without a nuclear explosion. Some common radioactive sources that have a high probability of being used in an RDD include cobalt-60, strontium-90, cesium-137, iridium-192, radium-226, plutonium-238, americium-241, and californium-252. The dispersal effects of an RDD depend on the amount of explosives, the physical form of the radioactive source, and the atmospheric conditions.²⁴ RDDs are attractive to terrorists because they are relatively easy to acquire and have the potential of causing casualties, contamination of widespread areas, adverse psychological effects on people, and economic disruption.

SIMPLE DISPERSAL DEVICE

A simple dispersal device (SDD) is a device containing a high-energy source that irradiates people or spreads radioactive material in a populated area, such as an airport, train station, sports arena, or theater. Use of such a device to cause radiation exposure in unsuspecting people is considered a terrorist act. Common radioactive sources that could be used in an SDD are the same as the sources mentioned previously for RDDs. The threat of radiation exposure from an SDD would have the same psychological effect on people as an RDD—instilling fear.

RADIATION ACCIDENTS

Information on radiation injuries has been gathered over a period of 70 to 100 years.²⁵ Important information obtained from previous worldwide radiation accidents is

useful in preparing and planning for nuclear terrorism and/or disasters. Radiation accidents can occur in situations where there are problems with nuclear reactors as well as industrial and medical sources of radiation. From 1946 to 2000, there have been more than 120 documented fatalities resulting from radiation accidents worldwide.²⁶ Serious radiation accidents in the United States have been rare.²⁷ From 1944 to June 2000, only 30 lost their lives in 13 separate radiation accidents in the United States. There were 233 other less serious accidents during the same period. In the former Soviet Union 59 deaths occurred from radiation accidents between 1950 and 2000.²⁸

There are two categories of radiation accidents.²⁹ The first category is an *external exposure* accident, that is, external irradiation from a source distant to or in close proximity to the body. Once a person has been removed from the source of radiation or the radiation-producing machine has been turned off, the irradiation stops. This exposed person does not become radioactive and there are no hazards to other people. The second category is a *contamination* accident. A person contaminated with radioactive material will continue to be irradiated until the radioactive material is removed, eliminated, or decays away. Contamination may occur in the form of radioactive gases, liquids, or particles. The contamination can be spread to other parts of the victim's body as well as to others. There is a third category of accident—a combination of the two.

The effects seen in persons who have been exposed in radiation accidents can be categorized as either deterministic or stochastic radiation effects.³⁰ Direct deterministic effects include the different types of acute and chronic radiation syndromes. The clinical manifestations of radiation injury include the latter as well as characteristic erythema, blistering, and even necrosis caused by local radiation damage. These deterministic effects occur when a specific dose-level threshold has been exceeded. The direct deterministic effects on an individual will depend on the dose of radiation received, the quality or type of radiation, the volume of tissue irradiated, and the time over which the dose is received. The stochastic effects are long-term and include, for example, the induction of cancer and potential genetic abnormalities. More in-depth information on the medical management of radiation accident patients can be found in *Medical Management of Radiation Accidents*.³¹

Principles of Medical Management

The optimal medical treatment for injury following detonation of a nuclear weapon can be found in several valuable sources.^{9,16,21,22,32-34} The interested reader is referred to these sources. Other articles^{24,33,35-37} have addressed medical treatment of individuals injured by a terrorist act involving radioactive materials.

Conventional injuries should be treated first, since radiation contamination is not a life-threatening medical emergency. Patients with traumatic blast and radiation injury should be resuscitated and stabilized. Airway, breathing, and circulation always take priority. These patients require more specialized treatment. Decontamination of patients should be carried out according to

accepted standards of radiation decontamination. (See Chapter 70 for further discussion.) Specialists in hematology, oncology, radiation, and infectious disease should be consulted. Effective treatment of internally contaminated patients requires knowledge of both the radioactive isotope and its physical form. Treatment should be instituted quickly to ensure effectiveness. However, with a terrorist incidence, initially the radioactive source or sources are not known.³³ Several general approaches may be used to treat internal radiation contamination, including reduction of absorption (Prussian blue), dilution (force fluids), blockage (potassium iodide), displacement by non-radioactive materials (oral phosphate), mobilization as a means of elimination from tissue (ammonium chloride), and chelation (Ca-DTPA and Zn-DTPA).³⁸

Patients who have received a low whole-body radiation dose may develop gastrointestinal (GI) distress within the first 2 days. Antiemetics may be effective in reducing the GI symptoms. The latter will usually subside within the first day. If not, parenteral fluids should be considered.

The prognosis for patients who have suffered traumatic blast, burn, and radiation injury is worse than for patients with radiation injury alone.³⁹ A wound that is contaminated with radioactive materials should be rinsed with saline and treated using conventional aseptic techniques.²⁴ Alpha-emitting radioactive isotopes, for example, that contaminate wounds are usually excised. In patients who receive whole-body doses of radiation greater than 100 cGy, the wound should be closed as soon as possible to prevent it from becoming an entry for lethal infection.

In spite of the wide availability of antibiotics, infections from opportunistic pathogens are a major problem among patients exposed to intermediate and high doses of radiation. In these cases the primary determinants of survival are treatment of microbial infections and aggressive resuscitation of the bone marrow.³⁹

PITFALLS

Obstacles to the provision of optimal nuclear disaster management include:

- Lack of adequate preparation of nuclear disaster management planning for possible nuclear terrorism and accidents before they occur
- Lack of coordination with local and state emergency response agencies
- Lack of understanding of the physical and biologic principles or radiation interaction by medical and public health professionals and nuclear disaster managers
- Lack of involvement of behavior and social health professionals to address the psychological consequences of nuclear terrorism and disasters
- Failure to adequately secure sources of highly enriched uranium and plutonium
- Failure to adequately secure nuclear weapons
- Failure to secure industrial and medical radiation sources and radioactive materials that would prevent any loss of control and consequent misuse

Chemical Attack

Duane C. Caneva

The rise of the asymmetric threat of terrorist activities combined with the dual-use nature of technology, its rapid advancement, and proliferation of information has made the concern of chemical attack no longer limited to the battlefield. In addition to conventional chemical warfare agents, the threat now includes use of toxic industrial chemicals and materials that, as part of an industrial-based economy, are ubiquitous in much of developed society. Preventing, preparing for, and responding to such an attack requires consideration of a myriad of issues and integration across diverse disciplines to ensure optimal use of limited resources and the development of best practices. Coordination of these efforts into a cogent emergency management program requires levels of integration across communities, jurisdictions, regions, states, agencies, and industries that will also improve our response capability to challenges of all sorts and drive us toward better business practices. This chapter focuses on the basics of preparing for and responding to a chemical attack.

HISTORICAL PERSPECTIVE

Brief History

The history of chemical warfare is rich and fascinating, an excellent summary of which is documented in the *Textbook of Military Medicine*.¹ The “modern era” began during the events leading up to and surrounding World War I. In the United States the Chemical Warfare Service was established on June 28, 1918 as part of the National Army with responsibilities for all chemical weapons research, defense, training, medical treatment, and production facilities. The offensive weapons program was officially terminated by signature to the Chemical Weapons Convention (CWC) on Jan. 13, 1993, with Senate approval on April 24, 1997, and the infrastructure converted to a strictly passive defense program.

Through this infrastructure, the U.S. military has provided valuable input toward preparations for a chemical attack. This, combined with Hazardous Materials (HazMat) Response work statutes from the Occupational Safety and Health Administration (OSHA)² and National

Fire Protection Administration (NFPA) Guidelines³ governing fire and emergency services response have served as the cornerstone for our current doctrine and policy for emergency response requirements in preparing, training for, and responding to chemical attacks in non-combat situations.

The Chemical Weapons Convention

The United Nations Chemical Weapons Convention, formally titled the “Convention on the Prohibition of the Development, Production, Stockpiling and Use of Chemical Weapons and on Their Destruction” opened up for signature on Jan. 13, 1993 after 20 years of negotiation and entered into force on April 29, 1997. Signed by 182 UN member nations to date, it describes the prohibition of use of specific chemical warfare agents, production limits for study, measures to ensure compliance, and destruction of stores of chemical stockpiles. The CWC established the Organization for the Prevention of Chemical Weapons (OPCW), located in The Hague, to serve as its operational arm, conducting verification activities, ensuring implementation of convention provisions, and providing a forum for consultation and cooperation.⁴

Chemical Agents

A chemical attack traditionally involves highly toxic chemical warfare agents that are specifically designed to cause morbidity and mortality, produced in significant amounts with appropriate dispersal technologies, and controlled under the CWC. A chemical attack can also involve toxic industrial chemicals that, while not as toxic as chemical warfare agents, are more readily available in larger quantities and are less tightly controlled. Currently, approximately 125,000 chemicals are designated as a toxic industrial chemical, generally defined as a chemical, excluding chemical warfare agents, that has an LC₅₀ (Lethal Concentration for 50% of a population exposed over a given time, t) less than 100,000 mg-min/m³ in any mammalian species, and produced in quantities exceeding 30 tons annually at any one production facility. Of these, approximately 4600 are considered “critical”⁵ and almost 400 “extremely hazardous.”⁶

Agents can be dispersed in various forms—including vapor, aerosols, smokes, liquids on surfaces, or solids—depending on the characteristics of the agent and the intended exposure route. Individual agents, their characteristics, and treatment are covered elsewhere in this section.

CURRENT PRACTICE

Current tactics, techniques, and procedures for emergency management of chemical attack have evolved from a combination of response practices from emergency services, hazardous materials (HazMat) response, and military chemical warfare defense doctrine. Various panels have developed consensus “best practices,” reports, and documents, many compiled and available at the Chemical and Biological Defense Information Analysis Center (CBIAC).⁷ The National Medical Response Teams (NMRT), part of the National Disaster Medical System (NDMS) under the Federal Emergency Management Agency (FEMA), represent civilian teams charged with responding to CBRNE mass casualties and providing decontamination and medical triage and treatment. The military developed the U.S. Marine Corps Chemical Biological Incident Response Force (CBIRF)⁸ to respond to mass casualty CBRNE attacks. Both teams represent model constructs for concepts of operations for their particular missions. The main construct of the response strategy to an incident site discussed here parallels that of CBIRF.

Doctrine and Policy

National Incident Management System (NIMS)

Homeland Security Presidential Directive 5 (HSPD-5) establishes the Department of Homeland Security (DHS) as the primary agency for Federal response to incidents of national significance and directs the DHS to develop a national strategy for management. Promulgated on March 1, 2004, the National Incident Management System (NIMS) defines the comprehensive approach in preventing, preparing for, mitigating, responding to, and recovering from domestic incidents using a standard Incident Command System (ICS) and Unified Command System (UCS) to develop a common operating picture accessible across jurisdictions and functional agencies.⁹ The approach is to be used at federal, state, local, and tribal government municipalities. As per HSPD-5, adoption of the NIMS is required at federal levels and is a condition for federal preparedness assistance for state, local, and tribal governments, essentially making it the de facto national standard at all levels of government.

For the medical community incident management, several systems are available. Hospital Emergency Incident Command System (HEICS) provides a consensus incident command system that is readily available from various Internet sources. Another comprehensive approach is the Medical and Health Incident Management (MaHIM),¹⁰ which includes a systems engineering approach in identifying all roles and responsibil-

ities required in a medical and health incident management system.

Emergency Management Programs

HSPD-5 establishes and defines five phases of emergency management as prevention, preparedness, mitigation, response, and recovery around which emergency management programs (EMPs) are built. Variably called Disaster Response Plans or various iterations, programs now encompass “all hazards” approaches to disasters and are more commonly being referred to as EMPs, which include a comprehensive plan or specific plans for various incident types. Hospitals and health system personnel have significant roles and responsibilities in each of these five phases and should coordinate via their incident management system with local and/or regional EMPs via local emergency preparedness committees (LEPCs) or other appropriate mechanisms during all phases.

For chemical attacks, critical actions in pre-incident planning phases include (1) identifying first responders/first receivers for triage as well as treatment and decontamination teams, and (2) establishing appropriate training programs, respiratory protection programs, equipment programs, exercise and evaluation programs, communication plans, evacuation procedures, shelter-in-place procedures, and warning and notification procedures. Conducting hazard and vulnerability assessments will assist in determining personal protective equipment (PPE) requirements and identifying other, specific planning requirements. This should be done in conjunction with local, municipal efforts. Community planning for hospitals should include coordinating with other regional hospitals on all aspects of emergency management programs including communications, mutual aid agreements, specialized treatments, alternate care facilities, cross credentialing, information management, supplies and logistics, and training exercises.

Finally, the critical step may be the networking and information management links that are established during the pre-incident phases; although having a plan is important, having gone through the planning process is the critical step. Such links allow for rapid reorganization or self-organization of response systems under catastrophic duress, but they must be established pre-incident to be effective.

CURRENT STANDARDS AND GUIDELINES

The current operating standards and guidelines applicable in responding to chemical attacks present challenges on several fronts. Statutes established for either the workplace or the battlefield are less than optimal for emergency, life-saving actions in mass casualty responses in an urban setting. The need for multi-disciplinary expertise in developing emergency management programs also requires that various regulatory agencies and professional societies work together in establishing more pragmatic statutes and guidelines. Challenges lie in developing standards around so many unknown entities within the

response requirements and the limited real-world experience of large-scale catastrophes. A review of some of the various agencies with statutory authority or interest, or those representing funding resources, reveals the importance of coordination and cooperation in this effort. Further detail is provided elsewhere in this text.

The *Occupational Safety and Health Agency (OSHA)*¹¹ within the *Department of Labor* serves as an advocate for worker health and safety by developing standards for workers and workplaces. This includes setting exposure levels to hazardous chemicals during work cycles as well as short-term and emergency exposure levels. It also works with the National Institute of Occupational Safety and Health (NIOSH), other federal agencies, and private industry to develop standards for general emergency planning,¹² Hazardous Waste Operations and Emergency Response Standard (HAZWOPER),¹³ and personal protective equipment (PPE)¹⁴ for emergency response personnel. More specific information is available in the OSHA Technical Manual.¹⁵ OSHA also participates in the development and evolution of the National Response Plan.

The Code of Federal Regulations serves as the basis for first responder safety in emergency response to chemical attack; however, several observations should be made. OSHA recognizes that statutory code written for emergency first responders at an incident site may be too restrictive for “first receivers,”¹⁶ or those healthcare workers who receive contaminated victims at treatment facilities. Recognizing that, OSHA has promulgated guidelines to provide hospitals with expert consensus of what are reasonably safe response practices.¹⁷ Also, incident commanders may use their expertise and experience to make a “risk assessment” that allows responders under their supervision to deviate from standards in order to save lives.¹⁸

The *National Fire Protection Association (NFPA)*¹⁹ develops guides and recommends practices, codes, and standards for the protection of firemen and emergency medical technicians. Standards are enforced through OSHA promulgation, such as those that define the PPE levels, with Level 1 being vapor-protective for hazardous chemical emergencies, Level 2 being liquid splash-protective for hazardous chemical emergencies, Level 3 being liquid splash-protective for non-emergency, non-flammable hazardous chemicals, and Level 4 being standard work clothes.²⁰ These levels correspond closely to OSHA Levels A-D respectively. NFPA also has several guidelines regarding competencies for first responders.²¹⁻²³

The *National Institute for Occupational Safety and Health (NIOSH)*,²⁴ a division of the Centers for Disease Control and Prevention (CDC), seeks to prevent work-related illness and injury by ensuring the development, certification, deployment, and use of personal protective equipment and fully integrated, intelligent ensembles. Although NIOSH establishes standards, it does not have enforcement authority. The National Personal Protective Technology Laboratory at NIOSH partners with NFPA, OSHA, the Department of Defense (DoD), the National Institute of Standards and Technology (NIST), and the National Institute of Justice (NIJ) in the development of

standards for CBRN respirators and their certification. All respirators used for response in a chemical attack must meet NIOSH certification, once those standards have been promulgated. More information is available at the CDC website.²⁵

The *Office of Law Enforcement Standards (OLES)*²⁶ at NIST, part of the NIJ, works with various agencies and partners to establish objective performance standards and equipment testing programs for critical equipment.²⁷ CBRNE standards development falls under the “Critical Incident Technologies” program area. Applying technical expertise and “gold standard” laboratory capabilities, OLES works with its partners to identify technical issues, develop standard testing protocols, identify testing labs, and develop standards for such things as communications interfaces for the first responder in protective equipment, tracking first responders, and networking sensors. The standards are then issued out through the appropriate agency with statutory authority, such as NIOSH, Environmental Protection Agency (EPA), OSHA, FEMA, NFPA, DoD, or DHS. OLES also partners with the Interagency Board (IAB, see below). PPE Guidelines are promulgated through the U.S. Department of Justice Law Enforcement and Corrections Standards and Testing Program.²⁸

The *Interagency Board for Standardization of Equipment and Interoperability*,²⁹ formed in the late 1990s through a partnership with DoD and FBI, ensures standardization and interoperability throughout the response community in preparing for and responding to weapons of mass destruction (WMDs) incidents. Although it is not a statutory setting agency, it has an expanded stakeholder list of federal and local partners that includes statutory agencies. Its four equipment subgroups—Medical, PPE and Operational Equipment, Decontamination and Detection, and Communications and Information Systems—work through a standards coordination committee, in conjunction with a science and technology committee, to develop, maintain, and update a national standardized equipment list (SEL). This SEL is maintained online at the National Memorial Institute for the Prevention of Terrorism Responder Knowledge Base site.³⁰ The site links to the current SEL and the Office of Domestic Preparedness (ODP) Authorized Equipment List (AEL), cross-references them with each other, and provides links to appropriate statutes, guidelines, and equipment vendors that have met standards.

Research, Development, and Support

In addition to many excellent academic research centers, the *Technical Support Working Group (TSWG)* conducts the U.S. interagency research and development program for combating terrorism, coordinates research and development requirements, promulgates technology information transfer, and has influence on basic and applied research, with the CBRN Countermeasure Subgroup focusing on chemical incident response issues. The TSWG has broad representation from federal agencies and has international participation. Examples of important projects funded by the TSWG include

development and certification of standard drinking tube systems for masks and development of a heat stress calculator for personnel in PPE.

Other Agencies and Departments

Specific roles of federal agencies and departments are covered elsewhere in this textbook; however, some specific agencies merit mention here.

The *Department of Health and Human Services (DHHS)* has several entities with relevance for chemical attack. The *National Library of Medicine (NLM)*, represents a ready, useful resource for information on chemicals.³¹ They have also developed a tool, WISER (Wireless Information System for Emergency Responders), to make these data portable and accessible. The mission of the *Agency for Healthcare Research and Quality (AHRQ)* is to improve the quality, safety, efficiency, and effectiveness of health care for all Americans.³² AHRQ develop models, tools, and other resources to assist hospitals in emergency preparedness that are readily available. They work closely with the Health Resources and Systems Administration (HRSA) to develop standards for providing grants to states to improve readiness.³³ AHRQ has developed several tools, including a vulnerability assessment tool specific for CBRNE for hospitals. The mission of the *Agency for Toxic Substances and Disease Registry (ATSDR)*, as an agency of DHHS, is to serve the public by using the best science, taking responsive public health actions, and providing trusted health information to prevent harmful exposures and disease related to toxic substances.

ATSDR is directed by Congressional mandate to perform specific functions concerning the effect on public health of hazardous substances in the environment. These functions include public health assessments of waste sites, health consultations concerning specific hazardous substances, health surveillance and registries, response to emergency releases of hazardous substances, applied research in support of public health assessments, information development and dissemination, and education and training concerning hazardous substances. ATSDR produces toxicologic profiles for hazardous substances found at National Priorities List (NPL) sites that are ranked based on frequency of occurrence at the sites, toxicity, and potential for human exposure. The profiles for nearly all of the 270 toxic substances on the NPL are available at the ATSDR website.³⁴

The DoD is covered in more detail in other chapters of this textbook; however, several agencies play significant roles in preparing for and responding to chemical attacks.

The *Research Development & Engineering Command (RDECOM)*, formerly known as the Soldier Biological Chemical Command (SBCCOM), represents the research and development (R&D) arm of the U.S. Army's chemical corps. RDECOM, with the *Edgewood Chemical Biological Center (ECBC)* applies this R&D effort to develop concepts of operations, training programs (they developed the 120-city Improved Response Program), partnering efforts across the chemical-biologic response paradigm, and providing publications address-

ing significant, challenging issues in chemical incident response.^{35,36} RDECOM also serves as the partnering test facility with NIOSH to perform official testing of mask/filter combinations against chemical weapons for CBRN certification. Applied technology projects include the Automated Decision Aid System for Hazardous Incidents (ADASHI), a "black box" consequence management tool for responding to chemical incidents.

The Army Forces Command *20th Support Command (CBRNE)*, formerly known as Guardian Brigade, includes the former Technical Escort Unit (TEU) and the Chemical Biological Rapid Response Team (CBRRT), and represents an expert team specializing in responding to emergency, non-lifesaving aspects of chemical incidents.

The U.S. Marine Corps' *Chemical Biological Incident Response Force (CBIRF)* is a rapid response, anti-terrorism unit located in Indian Head, MD. Specializing in life-saving aspects of emergency management in contaminated environments, the unit serves as a model for CBRNE response teams around the world. Working closely with partners at the local, state, and federal levels as well as with private industry, CBIRF contributes to development, evaluation, and validation of best practice tactics, techniques, and procedures for "all hazards" emergency management planning, improvement of response equipment, and development of advanced training techniques.

The *U.S. Army Medical Research Institute for Chemical Defense (USAMRICD)* provides the nation's primary medical laboratories charged with identifying chemical weapons threats and developing medical countermeasures, including antidotes, barrier creams, decontamination solutions, and chemoprophylaxis. The training arm of "ICD" develops and provides the chemical portion of the "gold standard" Medical Management of Chemical/Biological Casualties and the Field Management of Chemical and Biological Casualties Courses.

THE RESPONSE

While it is true that many chemicals cause their effects within seconds to minutes after exposure, the efficacy of response actions extends much longer beyond several hours, and planning assumptions should account for this. For example, during the Iran-Iraq war of the 1980s, Iran suffered several chemical warfare mass casualty attacks of nerve agents, mustard agent, or combination of the two (and sometimes in combination with conventional artillery attacks). The Iranian health system responded to these mass casualties, adjusting strategies and procedures over time by providing medical care closer to the incident site, eventually providing mobile medical teams to provide care at the scene. Lessons learned from published exploits of response include the need to treat early and far forward in order to confer maximal patient benefit, the need for an integrated system of care, and a rapid response to antidote therapy and recovery for mild, uncomplicated casualties.³⁷

Several factors make it difficult to predict response time requirements. Toxicity and lethality data of specific

agents are derived from animal models and are not easily translatable to humans. Toxicity curves are likely affected by extremes of age, confounding medical problems, and concomitant trauma, with unknown effects on the course of poisoning and greater potential for effects of sub-lethal exposures. Finally, the management of large-scale mass casualty incidents is poorly studied as well, particularly in a heterogeneous population. The additional response burden of working in PPE and having an additional decontamination step in the treatment protocol adds another dimension of complexity. The critical point is that response time requirements and treatment outcomes are not known and may be affected by a multitude of factors.

Initial Actions

Recognizing an attack

Indicators of a chemical attack generally occur rapidly. Crude explosive dissemination devices typically use a third of the explosives component as comparable conventional explosive devices in order to minimize consumption of agent and maximize spread. Consequently, improvised explosive devices (IEDs) that seem to have more smoke than blast or fire may indicate a chemical dispersal device. Vapor clouds, smokes without fires, or more sophisticated spray devices or aerosolizers in unusual places may indicate an attack. Multiple, unexplained victims with similar symptom patterns—difficulty breathing (lewisite or mustard agent if onset delayed), tearing, dimmed vision, muscle weakness, nausea (nerve agent symptoms), or burning skin and eyes—or dead animals may indicate a chemi-

cal attack. Any chemical attack is both a HazMat incident and a crime scene, and preservation of crime scene evidence should be considered when practical.

Establishing scene safety

Initial actions on scene should include maintaining a high index of suspicion for the presence of a toxic material and secondary explosive devices. Establishing a safe zone for “cold zone” operations is paramount, with approaches toward the “hot zone” from upwind and upgrade when practical. A “warm zone” or contamination reduction corridor, defines the area that is initially uncontaminated, adjacent to the hot zone where decontamination will occur. Ambulatory victims can be directed toward safe havens to await further directions as the response ensues. The incident commander—the senior, most experienced first responder on scene—determines actions.

Response Capabilities

Effective response to chemical attacks involving mass casualties is best approached by defining the response requirements at the incident site across functional capabilities. Elements will vary in size and capability depending on the requirements defined for the response, resources available, or as per the incident commander. These same elements can be used for defining requirements at remote response sites that may be needed, such as at hospitals or alternate treatment sites preparing to treat victims who were not evaluated or decontaminated at the incident site. Figure 62-1 demonstrates a typical incident site response scheme.

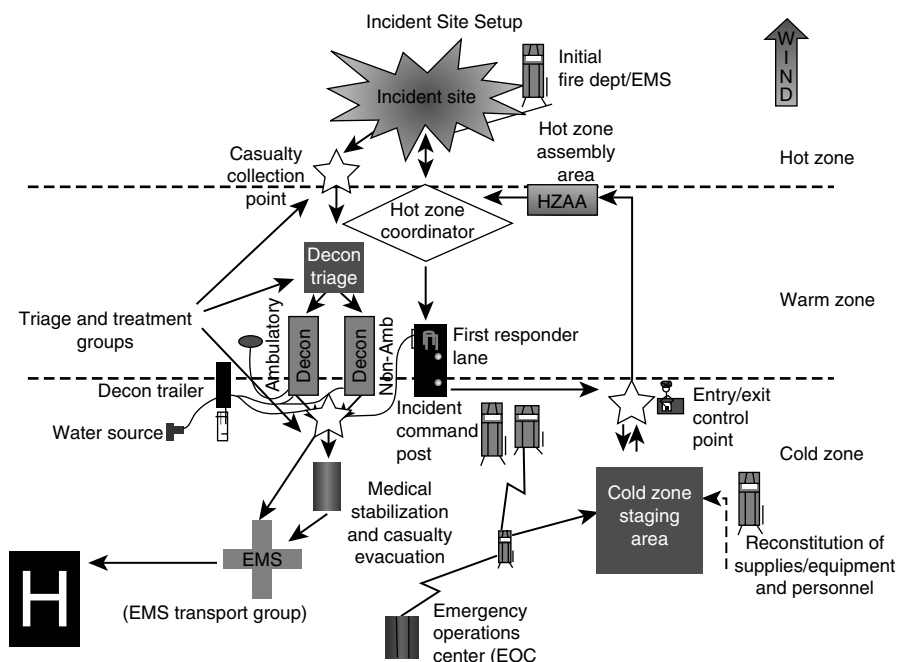

FIGURE 62-1. Typical incident site response scheme.

Command and Control

The incident commander retains not only crisis action planning responsibility, but also accountability of response personnel and liability for actions during the response. As per the NIMS, the incident command system (or unified command system) is the national standard response structure, with the “best qualified” person on scene assuming the role of incident commander, and command switching to a unified command system as soon as reasonably achievable. ICS training and Job Aids listing such things as organizational charts, roles, responsibilities, meetings, Response Action Guides, and sample forms are available from various sources.³⁸⁻⁴⁰ Handheld information technology emergency response tools (e.g., CoBRA, ADASHI, CATS, CAMEO, WebEOC) are also commercially available.

The size and impact of the incident drive the manning of the positions in the ICS, with roles and responsibilities becoming more specific as the size increases. ICS recommends that the “span of control,” or the number of personnel under a supervisor, not exceed four to six persons. The incident commander establishes a command post in a safe place near the incident site, analyzes the incident, develops the incident action plan, implements the plan, and evaluates the progress. A hazard and risk assessment allows the incident commander to determine the threats and estimate the potential course and harm in order to develop strategic goals and tactical objectives, determine required protective measures, and assign team tasking goals and missions to the various response squads, teams, or units. The risk assessment also allows the incident commander to use experience and expertise to deviate from statutory regulations, if necessary. Leaders are expected to coordinate and integrate their teams into the incident commander’s incident action plan.

Reconnaissance/Hazard Detection and Identification

Describing the environment of the “hot zone” is the role of the reconnaissance team. Merely detecting an agent is insufficient because the incident site becomes a workplace and the working parameters must be defined. Such information as oxygen levels, presence of explosive gases, presence of chemical agents, radioactivity, mechanical hazards, and structural integrity of buildings—as well as reporting on casualty numbers, locations, and conditions—must be relayed back to the incident commander for consideration in the management of the incident. Typically, this team works initially in OSHA Level A (NFPA Level 1) or Level B (NFPA Level 2) suits, since the environment is “undefined,” unknown, or levels that are an immediate danger to life and health (IDLH).

Various detection/identification technologies are available and beyond the scope of this chapter. Much research is being conducted in making handheld devices capable of detecting and identifying chemical agents. Technologies range from Dräger Tubes to ion mobility spectrometry, flame ionization, surface acoustic wave analysis, and gas chromatography/mass spectrometry (GCMS) in conjunction with solid phase micro-extraction (SPME) fibers. Information provided by the reconnaissance team

allows the incident commander to determine the appropriate level of personal protective ensemble for the various other elements of the response team. Because quantitative levels of chemicals are difficult to determine rapidly at an incident site with current technology, exposure levels based on concentration are difficult to use, often driving the decision to use higher levels of PPE.

Casualty Extraction

Casualty extraction is likely the most emotionally and physically challenging of the functional elements because it requires the ability to make life-and-death decisions in chaotic environments while undergoing demanding physical exertion and working in high levels of PPE. Victims that cannot ambulate out of a toxic environment must be carried out in order to optimize outcome. Criteria for determining prioritization of extraction are sorely lacking at this time, and current protocols are not evidence-based or optimized for survivability. Heat stress and heat exhaustion collapse are significant problems for these workers, particularly on warm, sunny days, with work cycles usually limited to 30 minutes or less.

Casualty extraction should include personnel as “victim assist teams” that also protect the response team during the critical initial set-up period when contaminated, ambulatory victims could wander outside of established control zones and decontamination corridors, interfere with set-up efforts of response personnel, or cross-contaminate clean areas. Such teams then assist with patient flow, transport, care, and crowd control.

Medical Triage, Treatment, and Transport

The medical section of the command post oversees the medical triage, treatment, and transport of patients at the incident site, interfacing with other aspects of the ICS/UCS in carrying out the incident action plan. Depending on the size of the response, there may be branches overseeing triage and treatment or transportation groups, divisions, or task forces.

Most triage systems currently in use lack evidence to support their efficacy. Further, it may be that alterations of standards of care may need to be considered.⁴¹ Recently, evidence-based triage systems employing algorithms that consider medical resources, transport times, and predicted survivability have been proposed to optimize overall survivability.⁴² Although correlated to trauma databases, it is not clear whether the same criteria used for triage prioritization would correlate to survivability for a chemical incident.

Although dependent on available resources, triage and treatment teams are best placed at naturally occurring “bottlenecks” in processing victims from the incident site “hot zone” through the contamination reduction corridor (e.g., warm zone) to a medical stabilization area in the cold zone in preparation for transfer to the EMS transportation teams. Depending on distances and specifics of the incident site, a casualty collection point might be established at the border

between the hot and warm zone where extractors can transfer victims to initial care in a relatively less-contaminated environment. This provides early access to medical attention for initial triage and treatment, such as administration of antidotes, and shortens the extraction cycle for the extraction team. Although it may be beneficial to deploy limited medical personnel into the hot zone to provide limited triage, medical direction, and antidote administration, there is, at this time, little evidence to support this as being the best use of limited medical resources.

Medical treatment teams placed on both ends of the decontamination process will facilitate better prioritization of patients processing through decontamination, provide medical oversight for patients during the formal decontamination process, and facilitate re-triage and treatment in preparation for transfer to emergency medical system transportation units. Naturally occurring bottlenecks in the decontamination process will suggest that a “decon triage” medical treatment area be established on the warm zone end of the decontamination process for non-ambulatory patients. Although little more than the ABCs (airway, breathing, circulation) can be done in the contaminated environment of the warm zone, the results of chemical attacks primarily affect the ABCs, and management of the airway in a contaminated environment should be a primary area of focus for planning and preparation for a chemical attack. Appropriate administration of antidotes is accomplished along the entire medical treatment corridor. Depending on the composition of the medical teams, special protocols requiring specialized training for antidote administration by non-licensed medical responders may be needed. These should be established during the preparation phase of an emergency management program.

PPE requirements for medical providers in the warm zone are an area of interest to OSHA, although the incident commander determines the requirement for the level. For response conducted remote from the incident site, such as at a hospital or alternate care facility, OSHA has promulgated specific guidelines mentioned previously.

Decontamination

Decontamination remains an area of intense research and development. Current best practices rely on physical removal of agents using soap and water. Use of 0.5% bleach solution has fallen out of favor. Several good consensus standards have been promulgated.⁴³⁻⁴⁶ There is evidence, however, to suggest these water-based techniques, if not performed immediately after exposure, may not be effective, and may even cause more harm.⁴⁷ Others argue for a more rational approach that considers high molecular weight solutions optimized for specific agent characteristics including solubilities.⁴⁸

For ambulatory patients, most systems essentially represent mass shower sequences through tents for set periods of time, with a range of shower times depending on various factors. Although it is commonly stated that disrobing may provide up to 90% decontamination in and of itself, some care to technique must be applied to prevent cross contamination. Decontamination of non-

ambulatory patients is time and manpower intensive. Even the most elaborate systems and experienced teams do not provide adequate throughput for true mass casualty incidents. Roller systems that allow easier, rapid movement of patients through a “car wash”-like system take more than 2 to 5 minutes per patient. Set-up times for different teams and systems vary and, if not pre-positioned, provide additional challenges because of large footprints and time to set up. In addition, mass casualty decontamination setups pose the inability to move easily if necessary and require a water source.

Several critical issues in the decontamination process are worth mentioning briefly. At least three separate lanes for processing people through should be recognized: a lane for ambulatory patients, a lane for non-ambulatory patients, and a separate lane for responders. Each group will have different decontamination requirements and priorities, and likely utilize different processes. The responder lane becomes especially critical for responders on supplied air who will usually be near the end of their air supply. Cutting clothes with “J knives” versus scissors may enhance the throughput capability and avoid hand fatigue.

Neutralizing solutions such as Reactive Skin Decontaminant Lotion (RSDL) are commercially available and offer significantly more favorable decontamination performance⁴⁹; however, further evaluation needs to be done, including FDA licensing as a medical drug if such solutions are to be used for full-body decontamination. Controlling water temperature during the decontamination process can be a challenge given portability, sourcing, and volume requirements. Decontamination lanes are typically manned with non-medical personnel, so medical oversight during the decontamination process needs to be provided with clear protocols for alerting medical providers of issues in the decontamination process. Finally, the environment in decontamination systems can become very hot and humid. The effect on personnel, as well as filter performance, must be considered.

Scene Security/Explosives Ordnance Disposal (EOD).

Scene security plays several significant roles including maintaining order, controlling and maintaining zone boundaries for contaminated areas and scene perimeters, directing traffic flow, and preventing secondary attacks that might jeopardize the initial response. EOD teams, when available, provide a sweep for secondary devices such as improvised explosive devices (IEDs) that might be targeting responders.

Supplies and Logistics

The role of logistics is to ensure the needed resources—be they supplies, equipment, personnel, or specialized services—get to the proper person or place at the proper time and in the proper amount. Actions range from maintaining and resupplying critical resources such as PPE suits and filters and decontamination supplies, to fluids and food to reconstitute the responders. It is crucial that response teams identify and carry items they will need in a given response and not represent a logisti-

cal burden when they present to an incident, and that they be able to provide accurate estimates on the duration of their resources, identify sources to replace consumed supplies, and identify any critical support requirements that the unit might have.

For logistical support of chemical attacks, there are several programs, in addition to the Strategic National Stockpile (SNS), worth mentioning that can provide critical supplies to a response in a more reasonable time frame.

The *Chempack Program*, part of the SNS Program, provides forward placement of supplies and equipment specifically needed in the event of a chemical attack to provide state and local government these critical supplies and improve the response times, spread-loading them across the nation, and placing them closer to large population centers where they might be needed.

The Emergency Management Strategic Healthcare Group, under the Veterans Health Administration (VHA) of the Department of Veterans Affairs, addresses emergency management functions for the VHA including medical support to the DoD, NDMS, and the National Response Plan as needed. VA Medical Centers maintain caches with products to respond to CBRNE incidents for treating veterans, VA staff, and other individuals seeking treatment at a VA facility.

The Department of Justice Office for Domestic Preparedness maintains the *Prepositioned Equipment Program (PEP)*.⁵⁰ The PEP sustains a community's response to CBRNE incidents by providing equipment for emergency responders and replenishing assets consumed in the response. The sets are standardized, incorporating lessons learned and experiences into the items containing PPE, detection, communications, medical, technical rescue, and decontamination equipment. Located strategically throughout the United States, they are containerized and palletized and are able to be transported on two tractor-trailers, or by air, to provide nationwide response within 12 hours. They are accompanied by a team of technicians to assist in deployment and operations of the equipment, particularly the communications and detection equipment.

As part of the NDMS, there are four specialized teams for CBRNE response located to respond regionally across the United States, the *National Medical Response Teams (NMRT)*. The teams often pre-deploy to planned events with credible threats, national special security events (NSSEs), after a CBRNE incident has occurred, or anytime the FBI determines a credible threat exists. Each team consists of 56 HazMat medical specialists with extensive training in CBRNE response. In addition to emergency life-saving response capability across the functional elements of CBRNE response, the team carries antidotes for 15,000 chemical nerve agent casualties and can deploy in conjunction with other NDMS units for extended medical treatment capabilities.

Command and Control

The Incident Command System or Unified Command System (ICS/UCS) provides a standard framework for responding to a chemical attack. The incident commander, located at the incident command post, estab-

lishes the incident action plan following general incident action guides. The NIMS provides guidance on these activities.

PITFALLS

Integration and Coordination

At the federal level, integration for emergency management response and homeland security is now the responsibility of the DHS, with the NIMS Integration Center established to oversee the process. It is incumbent on responders and managers at every level in the preparedness and response effort to ensure understanding of systems architecture, statutes, procedures, roles and responsibilities that affect them, and the integration into their emergency management program as appropriate and needed. Various tools are available that allow communities of response personnel to coordinate and communicate more efficiently.⁵¹ Use and integration of information management tools is another area undergoing rapid development and should be encouraged with development of standards. Cooperation and compromise are necessary as we identify our requirements and develop capabilities.

Learning Lessons Learned

The Memorial Institute for the Prevention of Terrorism⁵² Lessons Learned Information Sharing⁵³ is designed to capture insights from various levels of government response and share the information appropriately with emergency response personnel and homeland security officials. Active participation with a lessons learned program should be considered part of the professional responsibilities of emergency response personnel. Lessons learned come not only from actual response experiences, but also from standard training, evaluating exercises, and ensuring feedback loops in evolving and improving plans, procedures, and protocols as well as the information shared appropriately.

Standards and Guidelines

Efforts at developing standards, guidelines, and statutes that optimize the risk/benefit ratios for saving lives and property while providing safe practices for emergency response personnel are being made that include multiple disciplines and areas of expertise. The speed at which this occurs is affected by the governmental bureaucratic systems that control such processes, finite fiscal and personnel resources, and operational urgency. Response personnel must actively seek continuing education and training on current status of these as they undergo significant and rapid change.

Non-Traditional Agents

As a parting consideration, it is vital to keep in mind that many of the classical chemical warfare agents about which we learn and train are over 60 years old. With the

further progress of technology and science, it is likely that development of weapons of mass destruction will not necessarily require the resources of a state-sponsored program, and that novel agents may be developed with unfamiliar effects and presentations. As part of our preparation, we must foster and maintain our ability for critical reasoning, assessing, adapting, and improvising.

Biologic Attack

Andrew W. Artenstein

Bioterrorism can be broadly defined as the deliberate use of microbial agents or their toxins as weapons against noncombatants outside the setting of armed conflict. The broad scope and mounting boldness of worldwide terrorism, exemplified by the massive attacks on New York City and Washington, DC, on Sept. 11, 2001, coupled with the apparent willingness of terrorist organizations to acquire and deploy biologic weapons, constitute ample evidence that the specter of bioterrorism will pose a persistent global threat.

As in other aspects of daily life, and the practice of medicine in particular, the concept of “risk” is germane to considerations regarding an attack using biologic agents. *Risk*, broadly defined as the probability that exposure to a hazard will lead to a negative consequence, can be accurately calculated for a variety of conditions of public health importance (Table 63-1). However, the quantification of risk as it pertains to bioterrorism is imprecise because accurate assessment of exposure depends on the whims of terrorists, by nature an unpredictable variable. Although the probability of exposure to a biologic attack is statistically low, it is not zero; and because the negative consequences are potentially catastrophic, an understanding of biologic threat agents and a cogent biodefense strategy are important components of disaster medicine.

TABLE 63-1 U.S. MORTALITY RISK ANALYSIS*

HISTORICAL PERSPECTIVE

Biologic weapons have been used against both military and civilian targets throughout history. In the fourteenth century, Tatars attempted to use epidemic disease against the defenders of Kaffa by catapulting plague-infected corpses into the city.¹ British forces gave Native Americans blankets from a smallpox hospital in an attempt to affect the balance of power in the eighteenth century Ohio River Valley.¹ In addition to their well-described use of chemical weapons, Axis forces purportedly infected livestock with anthrax and glanders to weaken Allied supply initiatives during World War I. Perhaps the most egregious example of biologic warfare involved the Japanese program in occupied Manchuria from 1932 to 1945. Based on survivor accounts and confessions of Japanese participants, thousands of prisoners were murdered in experiments using a variety of virulent pathogens at Unit 731, the code name for the biologic weapons facility there.²

The United States maintained an active program for the development and testing of offensive biologic weapons from the early 1940s until 1969, when the program was terminated by executive order of then President Nixon, although efforts continue with regard to countermeasures against biologic weapons. The Convention on the Prohibition of the Development, Production, and Stockpiling of Biological and Toxin Weapons and on Their Destruction (BWC) was ratified in 1972, formally banning the development or use of biologic weapons and assigning responsibility for enforcement to the United Nations.¹ Unfortunately, the BWC has not been effective in its stated goals; multiple signatories, including the former Soviet Union and Iraq, have violated the terms and spirit of the agreement. The accidental release of aerosolized anthrax spores from a biologic weapons plant in the Soviet Union in 1979, with at least 68 human deaths from inhalational anthrax reported downwind, was proved years later to have occurred in the context of Soviet offensive weapons production.

Recent events have established bioterrorism as a credible and ubiquitous threat. The intentional contamination of restaurant salad bars with *Salmonella* by a

religious cult trying to influence a local election in The Dalles, Oregon in 1984³; the revelations that Aum Shinri Kyo, the Japanese cult that released sarin nerve agent in the Tokyo subway system in 1995 had unsuccessfully experimented on multiple occasions with spraying anthrax from downtown rooftops before their successful chemical attack; and the findings of the UN weapons inspectors of massive quantities of weaponized biologic weapons in Iraq during the Gulf War and its aftermath⁴ served as sentinel warnings of a shift in terrorism trends. The anthrax attacks in the United States in October and November 2001, following the catastrophic events of Sept. 11, elevated bioterrorism to the fore of the international dialogue.

CURRENT PRACTICE

Threat Assessment

Biologic agents are considered weapons of mass destruction (WMDs) because, as with certain conventional, chemical, and nuclear weapons, their use may result in large-scale morbidity and mortality. A World Health Organization (WHO) model based on the hypothetical effects of the intentional release of 50 kg of aerosolized anthrax spores upwind from a population center of 500,000 (analogous to that of Providence, RI) estimated that the agent would disseminate in excess of 20 km downwind and that nearly 200,000 people would be killed or injured by the event.⁵ Biologic weapons possess unique properties among WMDs. By definition, biologic agents are associated with a clinical latency period of days to weeks, in most cases, during which time early detection is quite difficult with currently available technology. Yet, early detection is critical because specific antimicrobial therapy and vaccines are available for the treatment and prevention of illness caused by certain biologic weapons; casualties from other forms of WMDs can generally only be treated by decontamination (with antidotes available for only some types), trauma mitigation, and supportive care. Additionally, the specter of a biologic attack provokes fear and anxiety—"terror"—disproportionate to that seen with other threats.

The aims of bioterrorism are those of terrorism in general: morbidity and mortality among civilian populations, disruption of the societal fabric, and exhaustion or diversion of resources. A successful outcome, from a terrorist standpoint, may be achieved without furthering all of these aims. The anthrax attacks in the United States in 2001 evoked fear and anxiety and diverted resources from other critical public health activities despite the limited number of casualties. In many cases, the surge capacity of our public health system was inadequate to deal with the emergency needs.

To be used in large-scale bioterrorism, biologic agents must undergo complex processes of production, cultivation, chemical modification, and weaponization. For these reasons, state sponsorship or direct support from governments or organizations with significant resources, contacts, and infrastructure would predictably be required in large-scale events. However, recent revela-

tions have suggested that some agents may be available on the worldwide black market and in other illicit settings,⁶ thus obviating the need for the production process. Although an efficient mode of delivery has traditionally been felt to be necessary, the anthrax attacks in the United States in late 2001 illustrated the devastating results that can be achieved with relatively primitive delivery methods (e.g., high-speed mail sorting equipment and mailed letters).

Numerous attributes contribute to the selection of a pathogen as a biologic weapon: availability or ease of large-scale production; ease of dissemination, usually by the aerosol route; stability of the product in storage, as a weapon, and in the environment (biologic entities differ in their physical properties); cost; and clinical virulence. The last of these refers to the reliability with which the pathogen causes high mortality, morbidity, or social disruption. The Centers for Disease Control and Prevention (CDC) have prioritized biologic agent threats based on the aforementioned characteristics,⁷ and this has influenced current preparedness strategies (Table 63-2). Category A agents, considered the highest priority, are associated with high mortality and the greatest potential for major impact on the public health. Category B agents are considered "incapacitating" because of their potential for moderate morbidity but relatively low mortality. Most of the category A and B agents have been experimentally weaponized in the past and are thus of proven feasibility. Category C agents include emerging threats and pathogens that may be available for development.

Another factor that must be addressed in assessing future bioterrorism risk is the historical track record of experimentation with specific pathogens, an area that has been informed from the corroborated claims of various high-level Soviet defectors and data released from the former offensive weapons programs of the United States and United Kingdom.^{1,6,8} It is apparent from these sources, combined with the burgeoning fields of molecular biology and genomics, that future risk scenarios may have to contend with genetically altered and "designer" pathogens. To this end, a miscellaneous grouping of potential threat agents is added to the extant CDC categories in Table 63-2. The most cautious approach to assessing risk may be to remain open to additional, novel possibilities.

Bioterrorism Recognition

By definition bioterrorism is insidious; absent advance warning or specific intelligence information, clinical illness will be manifest before the circumstances of a release event are known. For this reason, healthcare providers are likely to be the first responders to this form of terrorism. This is in contrast to the more familiar scenarios in which police, firefighters, paramedics, and other emergency services personnel are deployed to the scene of an attack with conventional weaponry or a natural disaster. Physicians and other healthcare workers must therefore maintain a high index of suspicion of bioterrorism and recognize suggestive epidemiologic clues and clinical features to enhance early recognition and guide initial management of casualties. This remains

TABLE 63-2 AGENTS OF CONCERN FOR USE IN BIOTERRORISM

HIGHEST PRIORITY (CATEGORY A)	
Microbe or toxin	Disease
<i>Bacillus anthracis</i>	Anthrax
Variola virus	Smallpox
<i>Yersinia pestis</i>	Plague
<i>Clostridium botulinum</i>	Botulism
<i>Francisella tularensis</i>	Tularemia
Filoviruses	Ebola hemorrhagic fevers, Marburg disease
Arenaviruses	Lassa fever, South American hemorrhagic fevers
Bunyaviruses	Rift Valley fever, Congo-Crimean hemorrhagic fevers
MODERATELY HIGH PRIORITY (CATEGORY B)	
<i>Coxiella burnetii</i>	Q fever
<i>Brucella</i> spp.	Brucellosis
<i>Burkholderia mallei</i>	Glanders
Alphaviruses	Viral encephalitides
Ricin	Ricin intoxication
<i>Staphylococcus aureus</i> enterotoxin B	Staphylococcal toxin illness
<i>Salmonella</i> spp., <i>Shigella</i> <i>dysenteriae</i> , <i>Escherichia coli</i> 0157:H7, <i>Vibrio cholerae</i> , <i>Cryptosporidium parvum</i>	Food- and water-borne gastroenteritis
CATEGORY C	
Hantavirus	Viral hemorrhagic fevers
Flaviviruses	Yellow fever
<i>Mycobacterium tuberculosis</i>	Multidrug resistant tuberculosis
MISCELLANEOUS	
Genetically engineered vaccine-and/or antimicrobial-resistant category A or B agents	
HIV-1	
Adenoviruses	
Influenza	
Rotaviruses	
Hybrid pathogens (e.g., smallpox-plague, smallpox-ebola)	

(Artenstein AW, Bioterrorism and Biodefense. In: Cohen J, Powderly WG, eds. Infectious Diseases, second edition. Mosby: London, 2003:99-107) Used with permission.

the most effective way to minimize the deleterious effects of bioterrorism on individual patients and on the public health.

Early recognition is hampered for multiple reasons. As discussed above, it is likely that the circumstances of any event will only be known in retrospect, therefore it may prove problematic to immediately discern the extent of exposure. Terrorists have an unlimited number of targets in most open, democratic societies; it is unrealistic to expect that without detailed intelligence data, all of these can be secured at all times. Certain sites such as government institutions, historic landmarks, or large events may be predictable targets, but there are other, less predictable possibilities. In fact, government data support businesses and other economic concerns as the

main targets of global terrorism during the period from 1996 to 2002.⁹ Metropolitan areas are considered vulnerable, but owing to the expansion of suburbs, commuters, and the clinical latency period between exposure and symptoms inherent with biologic agents, casualties of bioterrorism are likely to present for medical attention in diverse locations and at varying times after a common exposure. An event in New York City on a Wednesday morning may result in clinically ill persons presenting over the ensuing weekend to a variety of emergency departments within a 60-mile radius. Additionally, modern modes of transportation ensure that there will be affected persons thousands of miles away at both national and international locations related to a common exposure. This adds layers of complexity to an already complicated setting and illustrates the critical importance of surveillance and real-time communication in this setting.

Further hindering the early recognition of bioterrorism is that initial symptoms may be nondiagnostic. In the absence of a known exposure, many symptomatic persons may not seek medical attention early, or if they do, they may be misdiagnosed as having a flu-like illness. Once beyond the early stages, many of these illnesses progress quite rapidly and treatment may be less successful. Most of the diseases caused by agents of bioterrorism are rarely, if ever, seen in clinical practice; physicians are therefore likely to be inexperienced with their clinical presentation. Additionally, these agents by definition will have been manipulated in a laboratory and may not present with the classic clinical features of naturally occurring infection. This was dramatically illustrated by some of the inhalational anthrax cases in the United States in October 2001.¹⁰

Early recognition of bioterrorism is facilitated by the recognition of epidemiologic and clinical clues. Clustering of patients with common symptoms and signs, especially if these are unusual or characteristic of bioterrorism agents, is suggestive and should prompt expeditious notification of local public health authorities. This approach will also lead to the recognition of outbreaks of naturally occurring disease or emerging pathogens. The recognition of a single case of a rare or nonendemic infection, in the absence of a travel history or other potential natural exposure, should raise the suspicion of bioterrorism and should prompt notification of public health authorities. Finally, unusual patterns of disease such as concurrent illness in human and animal populations should raise suspicions of bioterrorism or another form of emerging infection. An effective response to bioterrorism requires coordination of the medical system at all levels, from the community physician to the tertiary care center, with public health, emergency management, and law enforcement infrastructures.

Threat Agents

This section provides a broad overview of the biologic threat agents thought to be of major current concern—largely, the CDC category A agents. Extensive coverage of specific pathogens can be found in related chapters in

this text and in other sources.¹¹ Data concerning clinical incubation periods, transmission characteristics, and infection control procedures for agents of bioterrorism are provided in Table 63-3. Syndromic differential diagnoses for select clinical presentations are detailed in Table 63-4.

Anthrax

Anthrax results from infection with *Bacillus anthracis*, a gram-positive, spore-forming, rod-shaped organism that exists in its host as a vegetative bacillus and in the environment as a spore. Details of the microbiology and pathogenesis of anthrax are found in Chapter 102. In nature, anthrax is a zoonotic disease of herbivores that is prevalent in many geographic regions; sporadic human disease results from environmental or occupational contact with endospore-contaminated animal products.¹² The cutaneous form of anthrax is the most common presentation; gastrointestinal and inhalational forms are exceedingly rare in naturally acquired disease. Cutaneous anthrax occurred regularly in the first half of the twentieth century in association with contaminated hides and wools used in the garment industry, but it is uncommonly seen in current-day industrialized countries due to importation restrictions. The last known case of naturally occurring inhalational anthrax in the United States occurred in 1976.¹³

It had been previously hypothesized that large-scale bioterrorism with anthrax would involve aerosolized endospores with resultant inhalational disease, but the recent attacks in the United States illustrate the difficulties in predicting modes and outcomes in bioterrorism: the attacks were on a relatively small scale, and nearly 40% of the confirmed cases were of the cutaneous variety.¹⁴ The serious morbidity and mortality, however, were related to inhalational disease, as was the case in the Sverdlovsk outbreak in 1979. Therefore, planning for larger-scale events with aerosolized agent seems warranted.

The clinical presentations and differential diagnoses of cutaneous and inhalational anthrax are described in Table 63-4. The lesion of cutaneous anthrax may be similar in appearance to other lesions, including cutaneous

forms of other agents of bioterrorism; however, it may be distinguished by epidemiologic as well as certain clinical features. Anthrax is traditionally a painless lesion (unless secondarily infected) and associated with significant local edema. The bite of *Loxosceles reclusa*, the brown recluse spider, shares many of the local and systemic features of anthrax but is typically painful from the onset and lacks such significant edema.¹⁵ Cutaneous anthrax is associated with systemic disease and its attendant mortality in up to 20% of untreated cases, although with appropriate antimicrobial therapy mortality is less than 1%.¹³

Once the inhaled endospores reach the terminal alveoli of the lungs, generally requiring particle sizes of 1 to 5 μm , they are phagocytosed by macrophages and transported to regional lymph nodes, where they germinate into vegetative bacteria and, subsequently, disseminate hematogenously.¹² Spores may remain latent for extended periods of time in the host, up to 100 days in experimental animal exposures.¹⁴ This has translated into prolonged clinical incubation periods after exposure to endospores; cases of inhalational anthrax occurred up to 43 days after exposure in the Sverdlovsk experience, although the average incubation period is 2 to 10 days, perhaps influenced by exposure dose.^{12,14}

Before the U.S. anthrax attacks in October 2001, most of the clinical data concerning inhalational anthrax derived from Sverdlovsk, the largest outbreak recorded. Although there is much overlap between the clinical manifestations noted previously and those observed during the recent outbreak, more detailed data are available from the recent U.S. experience. There were 11 confirmed persons with inhalational anthrax, 5 (45%) of whom died. Although this contrasts with a case-fatality rate of greater than 85% reported from Sverdlovsk, the reliability of reported data from this outbreak is questionable.¹⁴ Patients almost uniformly present an average of 3.3 days after symptom onset with fevers, chills, malaise, myalgias, nonproductive cough, chest discomfort, dyspnea, nausea or vomiting, tachycardia, peripheral neutrophilia, and liver enzyme elevations.^{10,16} Many of these findings are nondiagnostic and overlap considerably with those of influenza and other common viral respiratory tract infections. Recently compiled data suggest

TABLE 63-3 INFECTION CONTROL ISSUES FOR SELECTED AGENTS OF BIOTERRORISM

DISEASE	INCUBATION PERIOD (DAYS)	PERSON-TO-PERSON TRANSMISSION	INFECTION CONTROL PRACTICES
Inhalational anthrax	2-43*	No	Standard
Botulism	12-72 hours	No	Standard
Primary pneumonic plague	1-6	Yes	Droplet
Smallpox	7-17	Yes	Contact and airborne
Tularemia	1-14	No	Standard
Viral hemorrhagic fevers	2-21	Yes	Contact and airborne
Viral encephalitides	2-14	No	Standard
Q fever	2-14	No	Standard
Brucellosis	5-60	No	Standard
Glanders	10-14	No	Standard

*Based on limited data from human outbreaks; experimental animal data support clinical latency periods of up to 100 days (Artenstein AW Bioterrorism and Biodefense. In: Cohen J, Powderly WG, eds. Infectious Diseases, second edition. Mosby: London, 2003:99-107). Used with permission.

TABLE 63-4 PRESENTATIONS AND DIFFERENTIAL DIAGNOSES OF BIOTERRORISM AGENTS

CLINICAL PRESENTATION	DISEASE	DIFFERENTIAL DIAGNOSIS
Non-specific flu-like symptoms with nausea, emesis, cough with or without chest discomfort, without coryza or rhinorrhea, leading to abrupt onset of respiratory distress with or without shock, mental status changes, with chest radiograph abnormalities (wide mediastinum, infiltrates, pleural effusions)	Inhalational anthrax	Bacterial mediastinitis, tularemia, Q fever, psittacosis, Legionnaires' disease, influenza, <i>Pneumocystis carinii</i> pneumonia, viral pneumonia, ruptured aortic aneurysm, superior vena cava syndrome, histoplasmosis, coccidioidomycosis, sarcoidosis
Pruritic, painless papule, leading to vesicle(s), leading to ulcer, leading to edematous black eschar with or without massive local edema and regional adenopathy and fever, evolving over 3-7 days	Cutaneous anthrax	Recluse spider bite, plague, staphylococcal lesion, atypical Lyme disease, orf, glanders, tularemia, rat-bite fever, ecthyma gangrenosum, rickettsialpox, atypical mycobacteria, diphtheria
Rapidly progressive respiratory illness with cough, fever, rigors, dyspnea, chest pain, hemoptysis, possible gastrointestinal symptoms, lung consolidation with or without shock	Primary pneumonic plague	Severe community-acquired bacterial or viral pneumonia, inhalational anthrax, inhalational tularemia, pulmonary infarct, pulmonary hemorrhage
Sepsis, disseminated intravascular coagulation, purpura, acral gangrene	Septicemic plague	Meningococemia; Gram-negative, streptococcal, pneumococcal or staphylococcal bacteremia with shock; overwhelming postsplenectomy sepsis; acute leukemia; Rocky Mountain spotted fever; hemorrhagic smallpox; hemorrhagic varicella (in immunocompromised patients)
Fever, malaise, prostration, headache, myalgias followed by development of synchronous, progressive papular leading to vesicular and then pustular rash on face, mucous membranes (extremities more than the trunk); the rash may become generalized, with a hemorrhagic component and system toxicity	Smallpox	Varicella, drug eruption, Stevens-Johnson syndrome, measles, secondary syphilis, erythema multiforme, severe acne, meningococemia, monkeypox, generalized vaccinia, insect bites, Coxsackie virus infection, vaccine reaction
Non-specific flu-like illness with pleuropneumonitis; bronchiolitis with or without hilar lymphadenopathy; variable progression to respiratory failure	Inhalational tularemia	Inhalational anthrax, pneumonic plague, influenza, mycoplasma pneumonia, Legionnaire's disease, Q fever, bacterial pneumonia
Acute onset of afebrile, symmetric, descending flaccid paralysis that begins in bulbar muscles; dilated pupils; diplopia or blurred vision; dysphagia; dysarthria; ptosis; dry mucous membranes leading to airway obstruction with respiratory muscle paralysis; clear sensorium and absence of sensory changes	Botulism	Myasthenia gravis, brain stem cerebrovascular accident, polio, Guillain-Barre syndrome variant, tick paralysis, chemical intoxication
Acute-onset fevers, malaise, prostration, myalgias, headache, gastrointestinal symptoms, mucosal hemorrhage, altered vascular permeability, disseminated intravascular coagulation, hypotension leading to shock with or without hepatitis and neurologic findings	Viral hemorrhagic fever	Malaria, meningococemia, leptospirosis, rickettsial infection, typhoid fever, borrelioses, fulminant hepatitis, hemorrhagic smallpox, acute leukemia, thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, systemic lupus erythematosus

(Artenstein AW, Bioterrorism and Biodefense. In: Cohen J, Powderly WG, eds. Infectious Diseases, second edition. Mosby: London, 2003:99-107) Used with permission.

that shortness of breath, nausea, and vomiting are significantly more common in anthrax, whereas rhinorrhea is uncommonly seen in anthrax but noted in the majority of viral respiratory infections.¹⁷

Other common clinical manifestations of inhalational anthrax include abdominal pain, headache, mental status abnormalities, and hypoxemia. Abnormalities on chest radiography appear to be universally present, although these may only be identified retrospectively in some cases. Pleural effusions are the most common abnormality; infiltrates, consolidation, and/or mediastinal adenopathy/widening are noted in the majority. The latter is thought to be an early indicator of disease, but computed tomography appears to provide greater sensitivity than chest radiographs for this finding.

The clinical manifestations of inhalational anthrax generally evolve to a fulminant septic picture with progressive respiratory failure. *B. anthracis* is routinely isolated in blood cultures if obtained before the initiation of antimicrobials. Pleural fluid is typically hemorrhagic; the

bacteria can either be isolated in culture or documented by antigen-specific immunohistochemical stains of this material in the majority of patients.¹⁰ In the five fatalities in the U.S. series, the average time from hospitalization until death was 3 days (range, 1 to 5 days), which is consistent with other reports of the clinical virulence of this infection. Autopsy data typically reveal hemorrhagic mediastinal lymphadenitis and disseminated, metastatic infection. Pathology data from the Sverdlovsk outbreak confirm meningeal involvement, typically hemorrhagic meningitis, in 50% of disseminated cases.¹⁸

The diagnosis of inhalational anthrax should be entertained in the setting of a consistent clinical presentation in the context of a known exposure, a possible exposure, or epidemiologic factors suggesting bioterrorism (e.g., clustered cases of a rapidly progressive illness). The diagnosis should also be considered in a single individual with a consistent or suggestive clinical illness in the absence of another etiology. The early recognition and treatment of inhalational anthrax is likely to be associ-

ated with a survival advantage.¹⁰ Therefore, prompt empiric antimicrobial therapy should be initiated if infection is clinically suspected. Combination parenteral therapy is appropriate in the ill person for a number of reasons: to cover the possibility of antimicrobial resistance; to target specific bacterial functions (e.g., the theoretical effect of clindamycin on toxin production); to ensure adequate drug penetration into the central nervous system; and perhaps to favorably affect survival.¹⁰ In the future, it is likely that novel therapies such as toxin inhibitors or receptor antagonists will be available to treat anthrax.¹⁹ Detailed therapeutic and postexposure prophylaxis recommendations for adults, children, and special groups have been recently reviewed elsewhere.¹⁴ Anthrax vaccine adsorbed has been proved to be effective in preventing cutaneous anthrax in human clinical trials and in preventing inhalational disease after aerosol challenge in nonhuman primates.²⁰ The vaccine has generally been found to be safe but requires six doses over 18 months with the need for frequent boosting. Its availability is currently limited although it is hoped that second-generation anthrax vaccines, currently in clinical trials, will prove effective.

Smallpox

The last known naturally acquired case of smallpox occurred in Somalia in 1977; the disease was officially certified as having been eradicated in 1980, the culmination of a 12-year intensive campaign undertaken by the WHO.²¹ However, because of concerns that variola virus stocks may have either been removed from or sequestered outside of their officially designated repositories, smallpox is considered to be a potential agent of bioterrorism. Multiple features make smallpox an attractive biologic weapon and ensure that its reintroduction into human populations would be a global public health catastrophe: it is stable in aerosol form with a low infective dose; case fatality rates are historically high, approaching 30%; secondary attack rates among unvaccinated close contacts are 37% to 88% and are amplified; and much of the world's population is susceptible, as routine civilian vaccination was terminated more than two decades ago, vaccine-induced immunity wanes over time, and there is no virus circulating in the environment to provide low-level booster exposures.²² Additionally, vaccine supplies are currently limited, although this problem has begun to be addressed, and there are currently no antiviral therapies of proven effectiveness against this pathogen.

After an incubation period of 7 to 17 days (average, 10 to 12 days), the patient experiences the acute onset of a prostrating prodrome of fever, rigors, headache, and backache that may last 2 to 3 days. This is followed by a centrifugally distributed eruption that generalizes as it evolves through macular, papular, vesicular, and pustular stages in synchronous fashion over approximately 8 days, with umbilication in the latter stages. Enanthema in the oropharynx typically precedes the exanthem by a day or two. The rash typically involves the palms and soles early in the course of the disease. The pustules begin crusting during the second week of the eruption;

separation of scabs is usually complete by the end of the third week. The differential diagnosis of smallpox is delineated in Table 63-4. Historically, varicella and drug reactions have posed the most diagnostic dilemmas.²²

Smallpox is transmitted person to person by respiratory droplet nuclei and, less commonly, by contact with lesions or contaminated fomites. Airborne transmission by fine-particle aerosols has, under certain conditions, been documented.²² The virus is communicable from the onset of the enanthema until all of the scabs have separated, although patients are thought to be most contagious during the first week of the rash due to high titers of replicating virus in the oropharynx. Household members, other face-to-face contacts, and healthcare workers have traditionally been at highest risk for secondary transmission. Thus, hospitalized cases are placed in negative-pressure rooms with contact and airborne precautions to minimize this risk, and those not requiring hospital-level care should remain isolated at home to avoid infecting others.

The suspicion of a single smallpox case should prompt immediate notification of local public health authorities and the hospital epidemiologist. Containment of smallpox is predicated on the "ring vaccination" strategy, which was successfully deployed in the WHO global eradication campaign and mandates the identification and immunization of all directly exposed persons, including close contacts, healthcare workers, and laboratory personnel. Vaccination, if deployed within 4 days of infection during the early incubation period, can significantly attenuate or prevent disease and may favorably affect secondary transmission.²² Because the occurrence of even a single case of smallpox would be tantamount to bioterrorism, an epidemiologic investigation would be necessary to ascertain the perimeter of the initial release, so that tracing of initially exposed persons can be accomplished.

Botulism

Botulism, an acute neurologic disease resulting from intoxication with *Clostridium botulinum*, occurs sporadically and in focal outbreaks throughout the world related to wound contamination by the bacterium or ingestion of foodborne toxin. A detailed discussion of botulism is found in Chapter 132. Aerosol forms of the toxin, a rare mode of acquisition in nature, have been weaponized for use in bioterrorism.⁴ Botulinum toxin is considered to be the most toxic molecule known; it is lethal to humans in minute quantities. It blocks the release of the neurotransmitter acetylcholine from presynaptic vesicles, thereby inhibiting muscle contraction.²³

Botulism presents as an acute, afebrile, symmetric, descending, flaccid paralysis. The disease manifests initially in the bulbar musculature and is unassociated with mental status or sensory changes. Fatigue, dizziness, dysphagia, dysarthria, diplopia, dry mouth, dyspnea, ptosis, ophthalmoparesis, tongue weakness, and facial muscle paresis are early findings seen in more than 75% of cases. Progressive muscular involvement leading to respiratory failure ensues. The clinical presentations of foodborne and inhalational botulism are indistinguishable in experimental animals.²³

The diagnosis of botulism is largely based on epidemiologic and clinical features and the exclusion of other possibilities (see Table 63-4). Clinicians should recognize that any single case of botulism could be the result of bioterrorism or could herald a larger-scale “natural” outbreak. A large number of epidemiologically unrelated, multifocal cases should be clues to an intentional release of the agent, either in food or water supplies or as an aerosol.

The mortality from foodborne botulism has declined from 60% to 6% over the last four decades, probably as a result of improvements in supportive care and mechanical ventilation. Because the need for the latter may be prolonged, limited resources (e.g., mechanical ventilators) would likely be exceeded in the event of a large-scale bioterrorism event. Treatment with an equine antitoxin, available in limited supply from the CDC, may ameliorate disease if given early.

Plague

Plague, the disease caused by the gram-negative pathogen *Yersinia pestis*, presents in a variety of forms in naturally acquired disease and is extensively covered in Chapter 103. Plague is endemic in parts of Southeast Asia, Africa, and the western United States. Aerosolized preparations of the agent, the expected vehicle in bioterrorism, would be predicted to result in cases of primary pneumonic plague outside of endemic areas. As was the case with the anthrax attacks in the United States in 2001, however, additional forms of the disease such as bubonic and septicemic plague might also occur.

Primary pneumonic plague classically presents as an acute, febrile, pneumonic illness with prominent respiratory and systemic symptoms; gastrointestinal symptoms, purulent sputum production, or hemoptysis occur variably.²⁴ Chest roentgenogram typically shows patchy, bilateral, multilobar infiltrates or consolidations. In the absence of appropriate treatment there may be rapid progression to respiratory failure, vascular collapse, purpuric skin lesions, necrotic digits, and death. The differential diagnosis, as noted in Table 63-4, is largely that of rapidly progressive pneumonia. The diagnosis may be suggested by the characteristic small gram-negative coccobacillary forms in stained sputum specimens with bipolar uptake (“safety pin”) of Giemsa or Wright stain.²⁵ Culture confirmation is necessary to confirm the diagnosis; the microbiology laboratory should be notified in advance if plague is suspected because special techniques and precautions must be employed.

Treatment recommendations for plague have been reviewed elsewhere.²⁵ Pneumonic plague can be transmitted from person to person by respiratory droplet nuclei, thus placing close contacts, other patients, and healthcare workers at risk. Prompt recognition and treatment of this disease, appropriate deployment of postexposure prophylaxis, and early institution of droplet precautions will interrupt secondary transmission.

Tularemia

Francisella tularensis, the causative agent of tularemia, is another small gram-negative coccobacillus that would

likely cause a primary pneumonic presentation if delivered as an aerosol agent of bioterrorism. Inhalational tularemia presents with the abrupt onset of a febrile, systemic illness with prominent upper respiratory symptoms, pleuritic chest pain, and the variable development of pneumonia, hilar adenopathy, and progression to respiratory failure and death in excess of 30% of those who do not receive appropriate therapy.²⁶ The diagnosis is generally based on clinical features after other agents are ruled out. Laboratory personnel should be notified in advance if tularemia is suspected because the organism can be very infectious under culture conditions. This agent is discussed in depth in Chapter 104.

Viral Hemorrhagic Fevers

The agents of viral hemorrhagic fevers are members of four distinct families of ribonucleic acid viruses that cause clinical syndromes with overlapping features: fever, malaise, headache, myalgias, prostration, mucosal hemorrhage, and other signs of increased vascular permeability and circulatory dysregulation leading to shock and multiorgan system failure in advanced cases.²⁷ Specific agents are also associated with specific target organ effects. These pathogens, discussed in detail in Chapters 118 to 121, include the agents of Ebola, Marburg, Lassa fever, Rift Valley fever, and Congo-Crimean hemorrhagic fever.

Hemorrhagic fever viruses have been viewed as emerging infections in nature due to their sporadic occurrence in focal outbreaks throughout the world, and they are thought to be the results of human intrusion into a viral ecologic niche. They are, however, potential weapons of bioterrorism because they are highly infectious in aerosol form, are transmissible in healthcare settings, cause high morbidity and mortality, and are purported to have been successfully weaponized.⁸ Blood and other body fluids from infected patients are extremely infectious, and person-to-person airborne transmission may occur; therefore, strict contact and airborne precautions should be instituted in these cases.²⁷ Treatment is largely supportive and includes the early use of vasopressors as needed. Ribavirin is effective against some forms of viral hemorrhagic fevers but not those caused by Ebola and Marburg viruses. Nonetheless, this drug should be initiated empirically in patients presenting with a syndrome consistent with viral hemorrhagic fever until the etiology is confirmed.

Management of Special Patient Populations

The approach to the management of diseases of bioterrorism must be broadened to include children, pregnant women, and immunocompromised persons. Specific recommendations for treatment and prophylaxis of these special patient groups for selected bioterrorism agents have been recently reviewed.^{13,25,26} A general approach requires an assessment of the risk of certain drugs or products in select populations versus the potential risk of the infection in question, accounting for extent of exposure and the agent involved. The issue extends to immu-

nization because certain vaccines, such as smallpox, pose higher risk to these special groups than to others. This will affect mass vaccination strategies.

Psychosocial Morbidity

An often overlooked but vitally important issue in bioterrorism is that of psychosocial sequelae. These may take the form of acute anxiety reactions and exacerbations of chronic psychiatric illness during the stress of the event, or posttraumatic stress disorder (PTSD) in its aftermath. Nearly half of the emergency department visits during the Gulf War missile attacks in Israel in 1991 were related to acute psychological illness or exacerbations of underlying problems.²⁸ Data from recent acts of terrorism in the United States suggest that PTSD may develop in as many as 35% of those affected by the events.²⁹ In the early period after the Sept. 11, 2001, attacks in New York, PTSD and depression were nearly twice as prevalent as in historical control subjects.³⁰ Although close proximity to the events and personal loss were directly correlated with PTSD and depression, respectively, there was a substantial burden of morbidity among those indirectly involved. The psychological impact of these events and of the ongoing international concern over terrorism can be expected to be significant and sustained for society as a whole.

PITFALLS

The response to bioterrorism is unique among weapons of mass destruction because it necessitates the consequence management that is common to all disasters as well as the application of basic infectious diseases principles: disease surveillance, infection control, antimicrobial therapy and prophylaxis, and vaccine prevention. For these reasons, physicians are likely first responders to bioterrorism and are expected to be reliable sources of information for their patients, colleagues, and public health authorities.³¹

There remain a number of potential pitfalls regarding disasters involving a biologic attack that must be identified and managed to optimize the public health. As alluded to above, the clinical latency period between exposure to an agent and the manifestation of signs and symptoms is on the order of days to weeks with most of the CDC category A, B, or C agents, other than with preformed pathogen-derived toxins. For this reason, early diagnoses of the first cases are likely to prove problematic and require heightened clinical vigilance.³² Even after early victims have been diagnosed, communications among hospitals and other healthcare institutions on a local, regional, national, and international level will be essential to define the epidemiology and possibly to identify exposure sources. Given the extent and ease of rapid movement within our world, clinical presentations from a point-source biologic attack could occur in widely disparate geographic locations. Additionally, it is likely that a terrorist attack would be multifocal in any case. A similar epidemiologic approach using case definitions, case identification, surveillance, and real-time communi-

cations is necessary whether the event is a malicious attack, emergent from nature, or unknown.³³

Other potential pitfalls reside in the arena of diagnostic techniques, treatment, and prevention of disease related to biologic agents. Although an active area of research, the development of field-ready, highly predictive, rapid screening tests for agents of bioterrorism has not, as yet, progressed to the point at which such assays are approved by the U.S. Food and Drug Administration and available for deployment. Treatment and prevention issues, such as the absence of effective treatments for many forms of viral hemorrhagic fevers; shortages in the availability of multivalent anti-toxin for botulism; projected shortages in the availability of mechanical ventilators to manage a large-scale attack using botulism; lack of human data regarding the use of antiviral agents in smallpox; and the unfavorable toxicity profiles of currently available smallpox vaccines remain unresolved but active areas of research. The fact that modern molecular biologic techniques have been used to produce genetically altered pathogens with "designer" phenotypes, such as antimicrobial or vaccine resistance, adds additional layers of complexity to an already complex problem. Finally, as has been vividly illustrated during the recent epidemic of severe acute respiratory syndrome³⁴ and had been well recognized when epidemic smallpox occurred with regularity,²² transmission of infection within hospitals is common. Healthcare workers, our first line of defense against an attack using biologic agents, remain at significant occupational risk.

Future Biologic and Chemical Weapons*

James M. Madsen and Robert G. Darling

HISTORICAL PERSPECTIVE

Biologic and chemical weapons have been used throughout history.¹ For millennia, indigenous South American peoples deliberately used plant-derived arrow poisons such as curare and toxins from poison dart frogs, although these preparations were used mainly for hunting. Similar toxins were used in Africa. The ancient Greeks, for whom *toxikon* meant “arrow poison,” tipped arrows with winter aconite, and this practice continued into medieval Europe and persisted into the seventeenth century in Spain and Portugal.² Soldiers in India used smoke screens, incendiary weapons, and toxic fumes as early as 2000 BCE, and the Sung Dynasty in China employed a wide variety of arsenical smokes and other poisons in battle. The military use of toxins dates from at least the sixth century BCE, when Assyrian soldiers poisoned enemy wells with ergot-contaminated rye. In 423 BCE, during the Peloponnesian War, Thracian allies of Sparta captured the Athenian fort at Delium by using a long tube and bellows to blow a poisonous smoke from coals, sulfur, and pitch into the fort. Greek fire (likely composed of rosin, sulfur, pitch, naphtha, lime, and saltpeter) was invented in the seventh century CE and proved to be a very effective naval weapon. Various poisons saw battlefield use during medieval times, and the use of poisons for murder (including assassinations) became widespread. Other examples before the twentieth century include the contamination of water by dumping the corpses of dead humans or animals into wells, the use of snakes and other creatures as poisonous vectors, and occasionally, fomites to transmit infections such as smallpox to unsuspecting victims. This latter technique was used with remarkable success during the French and Indian War (1754-1767), when Sir Jeffrey Amherst was alleged to have given “gifts” (blankets) harboring the pus and scabs from smallpox victims to unsuspecting Native American Indians. The Indians possessed no immunity against smallpox and thus experi-

enced very high rates of infection and mortality as smallpox swept through the local tribes.³

During the late nineteenth and early twentieth centuries, the science and technology necessary for the development of sophisticated biologic and chemical weapons proceeded apace. World War I saw the first large-scale use of “poison gas,” including lacrimators, chlorine, phosgene, arsenicals, cyanide, and sulfur mustard. By the end of the war, nearly one in every three rounds was a chemical munition. Dr. Shiro Ishii and other Japanese scientists in the infamous Unit 731 worked on the weaponization of anthrax, plague, smallpox, and tetrodotoxin as well as a variety of chemical agents during World War II. There are even suspicions that the bomb used in the assassination of Reinhard Heydrich in Czechoslovakia in 1942 contained botulinum toxin.⁴ After World War II, ricin was used as an injectable assassination weapon, and in the 1970s and 1980s T-2 toxin, a trichothecene mycotoxin, was alleged to have been the toxic component of the “yellow rain” employed against H’Mong refugees from Laos. More recently, Iraq and Iran both used chemical weapons against each other in the Iran-Iraq War of the 1980s, and Iraq had a weapons program that included the development of sulfur mustard, nerve agents, “Agent 15” (an anticholinergic incapacitating agent), botulinum toxin, epsilon toxin from *Clostridium perfringens*, and aflatoxin.⁵ Militia groups in the United States and terrorist groups throughout the world have used ricin for political purposes.

American scientists started developing chemical weapons as a response to the use of chemical warfare in Europe during World War I and conducted both offensive and defensive research on biologic and chemical weapons. However, in 1969, the United States unilaterally renounced the first use of chemical agents, halted chemical-agent production, and terminated its offensive biologic weapons program.

In 1972, the Biological Weapons and Toxins Convention was created; it was signed by representatives from 104 nations, including the United States (which ratified the Convention in 1975), the Soviet Union, and Iraq, although many signatories did not consider toxins to be biologic weapons and did not consider the treaty binding on toxin use. Since that time, at least 140 nations have either signed or ratified this treaty.⁶ However, the

*The views expressed in this article are those of the author and do not necessarily reflect the official policy or position of the U.S. Army, U.S. Navy, any other U.S. military organization, or any of the places where Dr. Darling works, or any governmental organization.

Soviet Union and Iraq began violating the treaty in short order. In the Soviet Union, weapons scientists stepped up research and development of numerous biologic and chemical weapons as part of one of the largest and most comprehensive biologic-weapons programs in history. Soviet scientists created large stockpiles of weaponized anthrax, plague, smallpox, tularemia, nerve agent, mustard, and other biologic and chemical agents.⁵

In 1979, the world was put on notice of the devastating potential that biologic weapons pose to humanity. In that year, a small quantity of weapons-grade anthrax was accidentally released from a manufacturing plant located in the former city of Sverdlovsk (now Yekaterinburg) in Russia. Seventy-seven cases and 66 deaths were reported. Dr. Matthew Meselson, a Harvard scientist, was permitted to study the event many years later and reported the results of his work in a 1979 *Science* article. Meselson determined that the majority of the deaths had occurred among victims living in a narrow 4-km-wide band downwind from the plant. Animal deaths were confirmed as far as 30 km downwind. Meselson further concluded that less than 1 g of weapons-grade anthrax had been released from the plant.⁷ If his calculations are accurate, weaponized anthrax possesses staggering potential as a biologic weapon given its stability, its relative ease of production, and its ability to be dispersed in a clandestine manner over great distances.

In March 1995, after having unsuccessfully attempted to deploy biologic agents, members of the Aum Shinri Kyo cult executed a coordinated attack with the nerve agent sarin (GB) on the Tokyo subway system. Over 5500 people sought medical treatment, and a dozen died. The Aum Shinri Kyo had used sarin in Matsumoto 9 months earlier in an attack that had exposed more than 300 people and had killed 7 in an attempt to assassinate judges unfavorable to their cause.^{8,9}

The anthrax attacks in the fall of 2001 involved the use of letters containing weapons-grade anthrax mailed through the U.S. postal system. Five people died and 17 became ill with either cutaneous or inhalational anthrax. Buildings contaminated with spores included the Hart Senate Office building and the Brentwood postal facilities in Washington, DC. It cost millions of dollars to rehabilitate these buildings. The anthrax used in the attacks was determined to be extremely potent and could have caused far greater numbers of casualties had it been dispersed more widely.^{10,11}

According to Dr. Ken Alibek, former Deputy Director of Biopreparat, the Soviet Union's nominally civilian medical research institute, Soviet scientists and physicians spent large sums of money and manpower during the 1980s and 1990s developing the most lethal and potent biologic weapons known to man. In addition to weaponizing the etiologic agents of anthrax, smallpox, Marburg fever, and others, they created antibiotic-resistant strains of *Yersinia pestis* (plague), *Francisella tularensis*, and other pathogens. Furthermore, by applying genetic engineering techniques, the Soviets are also alleged to have created pathogens with novel characteristics and strains of several organisms capable of defeating certain vaccines.¹²

As we enter the biotechnologic revolution of the twenty-first century, our understanding of molecular biology, genetics, and biochemistry is exploding. The human genome has been sequenced, and it is now possible to manipulate genes from disparate organisms to create new and novel pathogens. Scientists are also able to synthesize and weaponize a number of different endogenous biologic-response modifiers including cytokines, hormones, neurotransmitters, and plasma proteases. But even nature continues to surprise us. New, naturally occurring infections with the potential to cause large-scale human diseases and death continue to emerge at an ever-increasing rate throughout the world, and it is conceivable that these pathogens could also be weaponized by enterprising scientists.

This chapter briefly reviews the future of chemical and biologic weapons as we enter this new era of explosive growth in our understanding of the life sciences. We are presented with an extraordinary opportunity to solve a host of human afflictions or to create new classes of biologic and chemical weapons that have the capacity to destroy our civilization as we know it today.

FUTURE BIOLOGIC WEAPONS

The appearance of a new or reemerging infectious disease has global implications. During the past 20 years, over 30 new lethal pathogens have been identified.¹³ A classic example of this emerging threat is pandemic influenza. In 1918, as World War I was coming to an end, the Spanish flu struck with devastating consequences. In less than 1 year, this virus was able to circumnavigate the globe and kill an estimated 40 million people.¹⁴ More recently, the emergence of severe acute respiratory syndrome (SARS) in Southeast Asia resulted from a coronavirus that jumped species from animals to humans and rapidly spread to 29 countries in less than 90 days. Novel and dormant infectious agents such as SARS or influenza appear to be emerging or reemerging with increasing frequency and with greater potential for serious consequences. Many factors contribute to the emergence of new diseases: environmental changes, global travel and trade, social upheaval, and genetic changes in infectious agent, host, or vector populations. Once a new disease is introduced into a suitable human population, it often spreads rapidly and with devastating impact on the medical and public health infrastructure. If the disease is severe, it may lead to social disruption and have a profound economic impact. Outbreaks of emerging or reemerging diseases may be difficult to distinguish from outbreaks as a result of intentional introduction of infectious diseases for nefarious purposes.

As scientists develop more sophisticated laboratory procedures and increase their understanding of molecular biology and the genetic code, the possibility of bioengineering more virulent, antibiotic, and vaccine-resistant pathogens for military or terrorist uses becomes increasingly likely. It is already theoretically possible to synthesize and weaponize certain biologic response modifiers (BRMs) as well as to engineer genomic weapons capable of inserting novel DNA into host cells.

The potential to cause widespread disease and death with any of these weapons is incalculable and concerning. Scientists and policy makers have begun to address the issue with a robust research agenda to develop medical countermeasures.

Selected Emerging and Reemerging Infections with Weaponization Potential

Because emerging diseases are so diverse and endemic to different geographic locations, their complete description is beyond the scope of this chapter. However, some of these infections may become future threats as agents of biologic warfare or terrorism. The most worrisome emerging infectious disease may well be the one we don't know about. Recent experience with HIV, Ebola fever, SARS, monkeypox, West Nile fever, and hundreds of other "new" diseases reveal that we will continue to be surprised.

Avian Influenza

Avian influenza, or highly pathogenic avian influenza, has periodically caused human infections primarily through close contact with avian species, most often through occupational contact at chicken or duck farms in Southeast Asia. As of May 2004, a large outbreak of avian influenza involving the H5N1 strain and human cases has been reported in two countries from this region.¹⁵ Thus far, no human-to-human transmission has been reported, but the potential exists for genetic reassortment between avian and human or animal strains of influenza. A recent report in the journal *Science* linked the influenza virus responsible for the 1918 epidemic to a possible avian origin.¹⁶ If true, avian influenza may pose a much greater danger to human populations than previously reported. The disease presents in humans in a fashion similar to other types of influenza viruses. It usually begins with fever, chills, headaches, and myalgias and often involves the upper and lower respiratory tract with development of cough, dyspnea, and in severe cases, acute respiratory distress syndrome. Laboratory findings may include pancytopenia, lymphopenia, elevated liver enzymes, hypoxia, a positive reverse transcriptase-polymerase chain reaction test for H5N1, and a positive neutralization assay for H5N1 influenza strain. In vitro studies suggest that the neuraminidase (NA)-inhibitor class of drugs may have clinical efficacy in the treatment and prevention of avian influenza infection.¹⁷

Human Influenza

The threat for pandemic spread of human influenza viruses is substantial. The pathogenicity of human influenza viruses is directly related to their ability to alter their eight viral RNA segments rapidly; the new antigenic variation results in the formation of new hemagglutinin (HA) and NA surface glycoproteins, which may go unrecognized by an immune system primed against heterologous strains.

Two distinct phenomena contribute to a renewed susceptibility to influenza infection among persons who

have had influenza illness in the past. Clinically significant variants of influenza A viruses may result from mutations occurring in the HA and NA genes and expressed as minor structural changes in viral surface proteins. As few as four amino acid substitutions in any two antigenic sites can cause such a clinically significant variation. These minor changes result in an altered virus able to circumvent host immunity. Additionally, genetic reassortment between avian and human or avian and porcine influenza viruses may lead to the major changes in HA or NA surface proteins known as *antigenic shift*. In contrast to the gradual evolution of strains subject to antigenic *drift*, antigenic shift occurs when an influenza virus with a completely novel HA or NA formation moves into humans from other host species. Global pandemics result from such antigenic shifts.

Influenza causes in excess of 30,000 deaths and over 100,000 hospitalizations annually in the United States. Pandemic influenza viruses have emerged regularly in 10- to 50-year cycles for the last several centuries. During the last century, influenza pandemics occurred three times: in 1918 ("Spanish influenza," a H1N1 virus), in 1957 (Asian influenza, a H2N2 subtype strain), and in 1968 (Hong Kong influenza, a H3N2 variant). The 1957-1958 pandemic caused 66,000 excess deaths, and the 1968 pandemic caused 34,000 excess deaths in the United States. The 1918 influenza pandemic illustrates a worst-case public health scenario; it caused 675,000 deaths in the United States and 20 to 40 million deaths worldwide.¹⁶ Morbidity in most communities was between 25% and 40%, and the case-mortality rate averaged 2.5%. A reemergent 1918-like influenza virus would have tremendous societal effects, even in the event that antiviral medications were effective against this more lethal influenza virus.

SARS and SARS-associated Coronavirus

SARS-associated coronavirus (SARS-CoV) emerged as the cause of SARS during 2003. That year, SARS was responsible for approximately 900 deaths and over 8000 infections in people from at least 29 countries worldwide. Before a case definition had been clearly established, Chinese authorities reported to the World Health Organization (WHO) over 300 cases of an atypical pneumonia with five related deaths, all originated from Guangdong province in China during February 2003. The infection quickly spread as infected patients traveled to Hong Kong and from there to Vietnam, Canada, and other locations. Only eight laboratory-confirmed cases occurred in the United States, but there is concern that the U.S. population is vulnerable to a widespread outbreak of SARS such as the one that occurred in China, Hong Kong, Singapore, Toronto, and Taiwan in 2003.¹⁸

A SARS case definition evolved from this initial report to the WHO by Chinese health authorities in February 2003. A case was initially defined by clinical criteria; a suspected or probable case was defined as an illness that included potential exposure to an existing case and fever with pneumonia or respiratory distress syndrome. In April 2003, a confirmed case was defined as a case from which SARS-CoV was isolated from culture.¹⁹ SARS-CoV

infections have an incubation period of 2 to 10 days. Systemic symptoms such as fever and chills followed by a dry cough and shortness of breath begin within 2 to 7 days. Patients may develop pneumonia and lymphopenia by days 7 to 10 of the illness. Most patients with SARS-CoV have a clear history of exposure either to a patient with SARS or to a setting in which SARS-CoV is known to exist. Laboratory tests may be helpful but do not reliably detect infection early during the illness. SARS-CoV should be suspected in patients requiring hospitalization for radiographically confirmed pneumonia or acute respiratory distress syndrome of unknown etiology and one of the following risk factors during the 10 days prior to the onset of illness: (1) travel to China, Hong Kong, or Taiwan, or close contact with an ill person having a history of such travel; (2) employment in an occupation associated with a risk for SARS-CoV exposure; or (3) inclusion in a cluster of cases of atypical pneumonia without an alternative diagnosis.

A “respiratory hygiene/cough etiquette” strategy should be adopted in all SARS-affected healthcare facilities. All patients admitted to the hospital with suspected pneumonia should receive the following measures: (1) They should be placed in droplet isolation until it is determined that isolation is no longer indicated (standard precautions are appropriate for most community-acquired pneumonias; droplet precautions for non-avian influenza); (2) they should be screened for risk factors of possible exposure to SARS-CoV; and (3) they should be evaluated with a chest radiograph, pulse oximetry, complete blood count, and additional workup as indicated. If the patient has a risk factor for SARS, droplet precautions should be implemented pending an etiologic diagnosis. When there is a high index of suspicion for SARS-CoV disease, the patient should be treated in terms of SARS isolation precautions immediately (including airborne precautions), and all contacts of the ill patient should be identified, evaluated, and monitored.¹⁹ Although ribavirin, high-dose corticosteroids, and interferons have been used in treatment, it is unclear what effect they have had on clinical outcome. No definitive therapy has been established. Empiric antibiotic treatment for community-acquired pneumonia by the current American Thoracic Society/Infectious Diseases Society of America guidelines is recommended pending etiologic diagnosis. Diagnostic tests for SARS-CoV include antibody testing using an enzyme immunoassay and reverse transcriptase-polymerase chain reaction tests for respiratory, blood, and stool specimens.²⁰ In the absence of known SARS-CoV transmission, testing is recommended only in consultation with public health authorities. Testing for influenza, respiratory syncytial virus, pneumococcus, chlamydia, mycoplasma, and legionella should be conducted, since the identification of one of these agents excludes SARS by case definition. Clinical samples can be obtained during the first week of illness with a nasopharyngeal swab plus an oropharyngeal swab and a serum or a plasma specimen. After the first week of illness, a nasopharyngeal swab plus an oropharyngeal swab and a stool specimen should be obtained. Serum specimens for SARS-CoV antibody testing should be collected when the diagnosis is first suspected and at later times as

indicated. An antibody response can occasionally be detected during the first week of illness, is likely to be detected by the end of the second week of illness, and at times may not be detected until more than 28 days after the onset of symptoms. Respiratory specimens from any of several different sources may be collected for viral and bacterial diagnostics, but the preferred specimens of choice are nasopharyngeal washes or aspirates.²⁰

Nipah and Hendra Viruses

The Nipah and Hendra viruses are closely related but distinct paramyxoviruses that compose a new genus within the family Paramyxoviridae. The Nipah virus was discovered in Malaysia in 1999 during an outbreak of a zoonotic infection, now called *Nipah virus encephalitis*, involving mostly pigs and some human cases.²¹ Hendra, the causative agent of Hendra virus disease, was identified in a similar outbreak involving a single infected horse and three human cases in Southern Australia in 1994.²² It is believed certain species of fruit bats are the natural hosts for these viruses and remain asymptomatic. Horses and pigs act as amplifying hosts for the Hendra and Nipah viruses, respectively. The mode of transmission from animal to humans appears to require direct contact with tissues or body fluids or with aerosols generated during butchering or culling. Personal protective equipment including gowns, gloves, and respiratory and eye protection is advised for agricultural workers culling infected animal herds. Thus far, human-to-human transmission of these viruses has not been reported.

In symptomatic cases, the onset of disease begins with flu-like symptoms and rapidly progresses to encephalitis with disorientation, delirium, and coma. Fifty percent of those with clinically apparent infections have died from their disease. There is currently no approved treatment for these infections, and therefore, therapy relies heavily on supportive care. The antiviral drug ribavirin has been used in past infections, but its effectiveness remains unproven in clinically controlled studies.²³ Although no person-to-person transmission is known to have occurred, barrier nursing and droplet precautions are recommended because respiratory secretions and other bodily fluids are known to harbor the virus. The clinical laboratory should be notified before specimens are sent because these may pose a laboratory hazard. Specimens for viral isolation and identification should be forwarded to a reference laboratory. Requests for testing should come through public health departments, which should contact the Centers for Disease Control and Prevention (CDC) Emergency Operations Center at 770-488-7100 before sending specimens.

Biologic Response Modifiers

BRMs direct the myriad complex interactions of the immune system. BRMs include erythropoietins, interferons, interleukins, colony-stimulating factors, granulocyte and macrophage colony-stimulating factors, stem-cell growth factors, monoclonal antibodies, tumor-necrosis-factor inhibitors, and vaccines.²⁴

A growing understanding of the structure and function of BRMs is driving the discovery and creation of many novel compounds including synthetic analgesics, antioxidants, and antiviral and antibacterial substances. For example, BRMs are being used to treat debilitating rheumatoid arthritis by targeting cytokines that contribute to the disease process.²⁵ By neutralizing or eliminating these targeted cytokines, BRMs may reduce symptoms and decrease inflammation. BRMs may also be used as anticarcinogens, with the following goals: (1) to stop, control, or suppress processes that permit cancer growth, (2) to make cancer cells more recognizable, and therefore more susceptible, to destruction by the immune system, (3) to boost the killing power of immune system cells, such as T cells, natural killer cells, and macrophages, (4) to alter growth patterns in cancer cells to promote behavior like that of healthy cells, (5) to block or reverse the processes that change a normal cell or a precancerous cell into a cancerous cell, (6) to enhance the ability of the body to repair or replace normal cells damaged or destroyed by other forms of cancer treatment, such as chemotherapy or radiation, and (7) to prevent cancer cells from spreading to other parts of the body.^{26,27}

More of these promising new drugs are currently in development. It can be readily theorized that research to develop various BRMs can be subverted to a malicious end. That is, instead of using BRMs to suppress cancer growth or to decrease disease susceptibility, researchers could develop compounds to cause illness and death. Other drugs could be designed to alter certain metabolic processes or to alter brain chemistry to affect cognition or mood. The opportunity for mischief is limited only by the imagination of the person with ill intent.

Bioengineered Pathogens

The rapid advance of biotechnology has the potential to alter the present and future threat of biologic weapons. Already, complete or partial genomic sequence data for many of the most lethal human pathogens (such as anthrax, plague, and the smallpox virus) have been published and are widely available via the Internet.²⁸ In addition to the enormous explosion in our knowledge of human pathogens, there is a parallel increased understanding of the complexities of the human immune response to foreign agents and toxins. Such knowledge has led to a deeper understanding of the development of basic immunity to a variety of different human infectious diseases. With this increase in scientific knowledge has come the power to manipulate the immune system at its most fundamental level. As we prepare for future threats, we must not ignore the potential quantum leap that biotechnology offers our enemies in developing new biologic-warfare threats. In fact, there is mounting evidence that new biologic agents have already been produced by former adversaries. Examples of such new threat agents and the potential effects they might have on human subjects have been detailed in the scientific and popular literature. Examples of biologic threats that could be produced through the use of genetic engineering technology include the following: (1) microorgan-

isms resistant to antibiotics, standard vaccines, and therapeutics, (2) innocuous microorganisms genetically altered to produce a toxin, a poisonous substance, or an endogenous bioregulator, (3) microorganisms possessing enhanced aerosol and environmental stability characteristics, (4) immunologically altered microorganisms able to defeat standard threat identification and diagnostic methods, (5) genetic vectors capable of transferring human and foreign genes into human cells for therapeutic purposes,²⁸ and (6) combinations of these with improved delivery systems.

POTENTIAL FUTURE CHEMICAL WEAPONS

Nature of the Problem

The threats associated with the use of chemical weapons as battlefield or terrorist weapons are not easy to assess.^{29,30} Risk assessment of use must take into account national laws, international treaties and conventions, and the likelihood of adherence to these legal obligations. Loopholes in existing agreements can be exploited to develop weapons that are technically not proscribed by international law. Goals and objectives may vary depending on whether military use is planned at the strategic, tactical, or operational level and whether the developer is a national government, a breakaway republic, a kidnapped or recruited scientist, or a terrorist cell. Risk of use may also differ depending on whether the targets are military versus civilian, human versus nonhuman (animals or plants, including livestock and crops), or individual (as in assassinations) versus large groups, and depending on whether the aim is death versus incapacitation. Risk also depends on agent availability and on the technology available for production, storage, and dissemination; current advances in technology are associated with a higher risk of weaponization. The fallibility of intelligence can be illustrated by two examples from the twentieth century and one from the twenty-first:

1. During most of World War II, the Allied perception of risk from possible chemical-agent use by Axis powers focused on those agents, primarily pulmonary agents and vesicants, known from World War I. In fact, Germany had developed a new kind of chemical-warfare agent, the compounds later to be called G-series nerve agents. Their existence came as a complete surprise to Western governments when, in the waning days of the European campaign, Allied soldiers advancing into Germany discovered buried nerve-agent munitions and entire nerve-agent factories. Why these agents were never used on the battlefield is a topic of much speculation, but in retrospect they clearly posed the most lethal, yet unrecognized, threat from Germany.³¹
2. Assessment of the chemical threat posed by Saddam Hussein at the time of the Gulf War of 1991 centered on the known Iraqi use of sulfur mustard and nerve agents during the Iran-Iraq War in the 1980s. It was not until 1998 that Reuters News Agency reported the

discovery by British intelligence that Iraq had stockpiled large quantities of a “mental incapacitant” (incapacitating agent) known as Agent 15.³²

3. The risk of use of chemical agents by Iraq after 2001 was assessed to be high partly because of the known stockpiles of sulfur mustard and nerve agents (as well as the suspected stockpiles of cyanide and the new revelations about Agent 15) from the time of the 1991 Gulf War. Although a full accounting has yet to be made, allegations have been made that most of the Iraqi chemical stockpile was actually destroyed in 1991 or soon afterward and that the risk of their use was actually very low. Whether those reports are true does not invalidate the argument that the risk from these agents was still very much debatable.

Chemical agents originally used during World War I are sometimes considered obsolete, especially in comparison to the more potent nerve agents and incapacitating agents. However, agent potency is only one part of the story. To deliver the 10 µg that represents a lethal dose for half of an exposed group (LD₅₀) of the nerve agent VX would seem to be easier than delivering the 3 to 7 g that constitute the LD₅₀ of sulfur mustard and more difficult than delivering the much smaller lethal doses of toxins such as botulinum toxin. In fact, sulfur mustard is easier to synthesize than is nerve agent and is easy to disseminate in a clandestine manner to create delayed effects. Thus, mustard still lays claim to being the “King of Gases,” and it has allegedly been used in a variety of venues since the end of World War II. Most known chemicals with toxicities equal to or greater than that of ammonia could theoretically be used as chemical-warfare or terrorism agents.

Existing Agents and Their Potential for Future Use

Existing chemicals capable of weaponization for military or terrorist use include the following:

1. Battlefield and riot-control agents
 - a. Pulmonary agents (see Chapter 93)
 - b. Vesicants (see Chapter 92)
 - c. Cyanide (see Chapter 94)
 - d. Nerve agents (see Chapter 91)
 - e. Antimuscarinic agents such as BZ and Agent 15 (see Chapter 95)
 - f. Riot-control agents (see Chapter 98)
 - g. Defoliants and other herbicides
 - h. Novichok
 - i. New chemicals employed for physicochemical effects
2. Related compounds
 - a. Battlefield incendiary agents, smokes (including standard military white obscurant smoke, or HC smoke), and other combustion products such as oxides of nitrogen and perfluoroisobutylene (PFIB)
 - b. Opioids (see Chapter 97) and other anesthetic agents (see Chapter 100)
 - c. Cholinergic agents (see Chapter 99)
 - d. Psychedelic indoles and other hallucinogens (see Chapter 96)

3. Toxic industrial chemicals or materials (see Chapter 90)
4. Poisons
5. Toxins (see Chapters 131-137)
6. Combination of chemicals

Existing chemicals remain candidate agents for future use. Some compounds not developed to cause injury or incapacitation nevertheless can be very dangerous; HC smoke, for example, can cause the same type of pulmonary damage induced by phosgene. The CDC lists nearly 70 separate chemicals, including a variety of toxic industrial chemicals and poisons, as potential agents for terrorism. These include osmium tetroxide, long-acting anticoagulants, heavy metals, toxic alcohols, and white phosphorus.³³ A recent issue of the *Morbidity and Mortality Report* includes an even longer list.³⁴ Pyrolysis products from explosions and conflagrations may release large quantities of cyanide and other toxicants that, although different from the original chemicals present, may still cause death. Industrial chemicals are readily available in large quantities as preformed compounds and should be considered high on the list of potential terrorist agents.^{35,36} Toxins, which are chemicals produced within biologic organisms, also represent high-threat agents.³⁷ New chemicals are currently being synthesized on rigid three-dimensional molecular skeletons, the most promising of which are the norbornanes. Building on norbornane geometry allows for a modular enhancement of the number of functional sites on a given molecule. Since many norbornane derivatives, such as the mixture of chlorobornanes known as the toxaphenes, are persistent and have significant acute and chronic toxicity, these derivatives have been considered potential candidates for new agents.³⁸

*Novichok*³⁹⁻⁴² (Russian for “newcomer”) refers to the alleged Russian development of a highly toxic binary nerve agent or generation of nerve agents (sometimes called “fourth-generation” agents). Only sketchy and unverifiable information is available in the unclassified literature, but the existence of these agents would demonstrate the possibility of creating new chemical compounds toxic enough to be used as chemical-warfare or terrorist agents. So-called GV analogs combining some of the properties of G-series and V-series nerve agents have also been suggested as potential new agents.³⁸ The use in 2002 of an incapacitating gas (thought to be an opioid compound derived from fentanyl and possibly mixed with another anesthetic agent) in the siege of a Moscow theater taken over by Chechen rebels was evidence either of the deployment of a preexisting anesthetic agent or of a new anesthetic compound.^{43,44} Organofluorines have been investigated because of their reported ability to defeat protective-mask or chemical-filtrations systems.³⁸ Other incapacitating agents under development exert primarily physical rather than chemical effects and include immobilizing agents (“stickums”), antitraction gels (“slickums”), and malodorants.⁴⁵

Technologic Modifications of Battlefield Chemical Agents and Delivery Systems

Ways in which existing or future battlefield chemical agents and delivery systems could be modified to

improve performance must be considered. These modifications include the following:

1. Agent thickening
2. Binarization
3. Micronization: “dusty agents”
4. Developments in delivery systems
 - a. Dual-use cyberinsects and biorobots
 - b. Nanotechnology

Small quantities of thickening agents, such as acrylates, can be added to chemical agents to increase their viscosity. Thickened agents are more persistent in the environment and in wounds than are nonthickened agents, and they are less easily decontaminated.⁴⁶ Although no nation is currently known to stockpile thickened agents, the technology for their production is relatively simple and requires only standard chemical-warfare agents and the right proportion of a thickener.^{38a,38b,47} Many industrial chemicals and other poisons could theoretically be rendered more effective as battlefield or terrorist agents by thickening.

In the 1950s, the U.S. Army began to investigate the then-new technology of binarization, although production did not accelerate until the 1960s and deployment was not widespread until the 1980s.³⁹ A binary chemical weapon did not employ a new kind of agent but rather represented a novel way of producing and storing an already existing type of agent. The idea was to make storage of chemical rounds safer by stopping the production process at the penultimate synthetic step, resulting in two precursor compounds that when mixed would create the desired agent. These two precursors could then be stored separately. Just prior to use, one component could be inserted into a round, where it would be separated from the other precursor by a thin membrane. The impact and momentum of the launch of the projectile would burst the membrane to allow for mixing of the components and in-flight production of the chemical agent. In practice, this process was often not complete, but the 20% or so of ancillary reaction product was often extremely toxic by itself. Binarization or some similar production-arrest method could theoretically be used by a clandestine terrorist cell to help evade detection and to decrease the risks associated with the production, transportation, and use of chemical agents.

Micronization is a type of particularization involving the production of extremely fine particles onto which a chemical agent can be adsorbed. During World War II, Germany explored particularization of sulfur mustard onto small carrier particles of silica (silicon dioxide), although other powdered silicates (talc, diatomite, and pumice) and clays (kaolinite and Fuller’s earth) can also be used.⁴⁸ The advantages of such “dusty agents” are increased volatility (used to facilitate the movement of relatively nonvolatile agents such as sulfur mustard and the persistent nerve agent VX into the alveoli) and increased penetration of clothing and chemical protective equipment.⁴⁹ Iraq used a “dusty mustard” composed of 65% sulfur mustard adsorbed onto silica particles ranging in diameter from 0.1 to 10 microns during its war with Iran. Micronization of a variety of chemical, biological, and toxin agents requires a certain degree of tech-

nologic sophistication that is becoming increasingly easy to acquire.

Agent delivery can potentially be modified in a variety of ways in addition to thickening and micronization. The Jordanian government released a report in 2004 of the discovery of an elaborate plot by Al Qaeda terrorists for a two-stage attack using a massive vehicle-borne improvised explosive device followed by the release of toxic chemicals to include acetones, nitric acid, and sulfuric acid.⁵⁰ Similarly, enhanced-fragmentation munitions could be used in combination with chemical agents to drive the agents more effectively into the body.

Innovative new delivery systems taking advantage of advances in robotics include the proposed use of cyberinsects and biorobots to deliver biologic agents, chemical agents, or toxins.⁵¹ Engineering on an even smaller scale is the purview of nanotechnology, also called “micromechanical engineering” and “microelectromechanical systems.”⁵² Nanotechnology takes advantage of the unique properties of materials on the scale of about a nanometer (10^{-9} meter)⁵³ and deals with the molecule-by-molecule or even atom-by-atom assembly of materials. Nanoparticles behave in unusual and unpredictable ways, are small enough to enter cells easily, and in fact are being developed to provide not only better storage and dispersal of pharmaceutical products but also more efficient transport of both biologic organisms (such as viruses) and chemical compounds into the body.⁵² In some cases they may be surprisingly toxic, partly because of the ease with which they can cross membranes (including the blood-brain barrier) and enter cells.⁵⁴ This toxicity could be exploited by governments or terrorist organizations interested not only in small-particle delivery of chemical agents but also in the ancillary and perhaps synergistic effects of the carrier materials themselves.

Nanomaterials can be encapsulation compounds such as *fullerenes*, or buckyballs, which are hollow 60-carbon geodesic shells; *nanosbells* (for example, a gold shell surrounding an inert silica core); a “self-assembled, polyamino acid nanoparticles system” under development in France; or *dendrimers*, which are onion-like layers of shells surrounding a biologically active core.⁵³ Any of these materials could be used to deliver existing or new chemical agents. Other nanomaterials include self-assembling liquids composed of cylindrical nanofibers (each 6 to 8 nm in diameter) that solidify upon injection to form structured scaffolds capable of presenting ordered peptide signals to cells. A *ferrofluid* such as a colloidal suspension of nanoscale ferrous oxide can be coupled with antibodies in a laboratory to detect and concentrate rare human cells in a diagnostic setting, but this technology could easily be adapted to target those cells in vivo. *Quantum dots* are nanoscale semiconductor crystals that show promise in the in vitro and in vivo diagnosis of a variety of conditions; although their main use is projected to be in the laboratory, animal experimentation involving injected quantum dots has demonstrated successful targeting of lymph nodes and of prostate-cancer xenografts in mice.

Adverse health effects from any of these kinds of nanoparticles could represent a primary goal for military

or terrorist operatives in addition to the toxicity of any other chemicals delivered by the nanoparticles. Water-soluble fullerenes have caused brain damage in largemouth bass,⁵⁵ dendrimers can cause osmotic and membrane damage and can activate the clotting and complement systems, and quantum dots composed of selenium, lead, and cadmium can release those metals into cells, depending on the composition of the surface coating of the dots.⁵⁵

“Designer” Chemicals from Biotechnologic Processes

Biotechnology refers to “any technological application that uses biological systems, living organisms, or derivatives thereof, to make or modify products or processes for specific use.”⁵⁶ Biotechnology includes such time-honored practices as the baking of bread and the brewing of beer, but in the twenty-first century refers in particular to genetic engineering, that is, the artificial transfer of genes from one organism to another and the consequent alteration of the genetic structure of a cell.⁵⁷ It is founded on the basic sciences of genomics (the study of the genetic composition of an organism) and proteomics (the study of the expression of the genome by means of protein synthesis). “Designer” chemicals could be produced from biotechnologic processes. These processes include the following: (1) combinatorial chemistry and ligand modification, (2) genomics and target identification, (3) microarrays, proteomics, and rational agent design, and (4) toxicogenomics, database mining, and the prediction of toxicity.⁵⁸

Combinatorial chemistry is the production of complex sets, or so-called libraries, of related compounds, as in the case of the norbornane derivatives previously described. Automated screening techniques to select for library elements with desired toxic effects on specified target organs can process several hundred thousand compounds a day against several dozen different proteins. This obviously accelerates tremendously the development of new chemical agents.

Genomics has benefited enormously from three modern scientific efforts: the Human Genome Project, the Human Genome Diversity Project, and gene therapy.⁵⁹ Identification and cataloging of hundreds of single-nucleotide polymorphisms (individual sequence variations) allows for the selection of genomic sequences to be mass-produced for insertion into cells for the creation of a specific effect. Targeting unusual sequences of high prevalence in certain populations raises the specter of genomic, or ethnic, weapons, as previously described. Less appreciated is the potential for genomics to be used to develop drugs, chemical or toxin agents that can also be targeted to specific variants within a population of humans, animals, or crops. The widespread availability of genome libraries on the Internet makes it nearly impossible to control or restrict access to the already published genomic libraries on over a hundred microbial pathogens.⁶⁰

Proteomics complements genomics by characterizing the protein expression of segments of the genome and

by making it easier to develop compounds that target or produce a specific protein. Direct gene insertion, genetic delivery via virus or bacteria, or drug tailoring to affect a given protein can all be used. A scorpion toxin has already been successfully engineered into a virus that acts as a pesticide against caterpillars. Protein sequences in toxins are partly responsible for resistance to light, oxygen, moisture, and desiccation; the insertion of genes to create altered proteins or the introduction of chemical agents engineered to cause structural changes in expressed proteins could significantly alter the toxicity of a given compound.⁵⁸ Furthermore, the widespread use of DNA microarrays (glass slides or chips imprinted with thousands of specific single-stranded DNA sequences) allows for fast automated screening of candidate compounds.

Scientists involved in the selection and evaluation of specific chemical agents can now use toxicogenomics (the study of genetic variation of response to toxins) and data mining (the computerized analysis of databases of drug and chemical information via sophisticated neural nets) as tools to eliminate less likely candidates and to algorithmically predict compounds with high toxicity or with other desired characteristics relating to environmental persistence, toxicokinetics (absorption, distribution, biotransformation, and elimination), and toxicodynamics (mechanism of action). Such tools will undoubtedly lead to the development not only of new pharmaceutical agents but also of designer toxins for military or terrorist use.⁵⁸

CONCLUSIONS

If history is any guide, new biologic and chemical weapons and novel “mid-spectrum” agents (e.g., toxins, bioregulators, synthetic viruses, and genocidal weapons) will be developed in the future, and new modifications will be found to improve the production, weaponization, storage, delivery, and action of existing agents.⁶¹ Naturally occurring emerging infectious diseases provide examples of newly identified pathogens with weaponization potential, and mid-spectrum agents such as toxins and bioregulators will undoubtedly assume more prominence with the accelerating pace of nanotechnology (for improved delivery and for synergistic toxicity) and biotechnology. Agents of any category can theoretically be engineered to target specific genes or proteins with differential population prevalence to produce genomic or ethnic weapons; and advances in proteomics, toxicogenomics, and computerized database mining could be used for the rapid and efficient development of not only new drugs but also new chemical agents for terrorism.⁶² Biotechnology has now advanced to the point that no special equipment is required beyond that available to any modern molecular-biology laboratory, and the scale of operations is also well within the means of governments and terrorist groups.⁵⁹ The threats from future modification of existing agents and from the development of new agents, new agent-development technologies, and innovative delivery systems should not and must not be underestimated.

Improvised Explosive Devices

Edward B. Lucci

Improvised explosive devices (IEDs) have become the most common weapons of terrorists. Explosions and bombings remain the most common deliberate cause of disasters involving mass casualties.¹ By definition, an IED is a conventional explosive weapon with fragmentation and blast effect, deployed in an unconventional fashion. It is generally cheap, simple in design, and easy to construct with readily available materials. IEDs vary in size, destructive capacity, and degrees of sophistication. Most are conventional high-explosive charges. However, the threat exists of including chemical, biologic, or nuclear material to improve the destructive power and psychological effect of the device.

The frequency of terrorist bombings using IEDs directed at civilian populations, particularly suicide bombings, has increased worldwide and has resulted in unexpected mass-casualty incidents descending on civilian medical systems. Victims of IEDs will frequently suffer a combination of blast, penetrating, and thermal injuries. The management of these complicated injuries often falls outside the experience of most physicians. An analysis of 220 bombings between 1969 and 1983 revealed an average of 15.3 casualties per incident, 13% of whom died at the scene, and 30% of whom were hospitalized.²

Unpredictable in timing and location, a large explosive device with multiple injured could easily strain even the most prepared emergency response systems. To be able to deal effectively with casualties from IEDs, providers must be knowledgeable of the patterns of injury and barriers to care associated with these types of terrorist events. The planning for medical management of bombing victims must revolve around the basic lessons learned from prior bombing disasters. Certain injuries must be recognized as prognostic markers of severity and be selected out for immediate care to optimize survival. Fortunately, the majority of blast victims who survive transfer to the hospital can be successfully treated.³ The goal of this chapter is to outline broad principles that are generally applicable to the effective delivery of medical care in a sudden-impact disaster resulting from terrorists' use of IEDs.

HISTORICAL PERSPECTIVE

Since the emergence of gunpowder and explosives on the battlefield, victims have been exposed to the blast

effects of explosive devices. The history of IEDs is closely tied to the history of terrorists and counter-insurgents who have used them. The first recorded use of a terrorist explosive was in Antwerp, Belgium, in 1585. Seven tons of gunpowder was placed on a river barge and detonated by insurgents to destroy a bridge on the River Schelt.^{1,4} The modern era of terrorism began in the late 1960s and has been the most destructive in history.⁵ Since then, the number and destructive power of bombings has steadily increased. There was a 10-fold increase in terrorist bombings worldwide between 1968 and 1980. In the United States alone, there were 12,216 bombing incidents between 1980 and 1990, the vast majority of which resulted from pipe bomb-type IEDs.⁶

Terrorist attacks are extremely diverse, particularly with regard to type of explosive device, size of charge, and location of detonation. The medical literature describes various terrorist attacks using IEDs in Great Britain, France, Israel, Italy, Lebanon, Saudi Arabia, South America, Spain, sub-Saharan Africa, the United States, and Yemen.^{2,3,7-13}

IEDs have been used against the U.S. military in Vietnam, Lebanon, Saudi Arabia, and most recently in Iraq. In Vietnam, IEDs were more commonly referred to as "booby traps" and usually were concealed to detonate when a nearby "harmless" object was encountered. These IEDs usually consisted of a conventional explosive device such as a grenade, artillery shell, or mine. A common form was the pipe bomb, a length of pipe filled with trinitrotoluene (TNT) and fused with a detonating cord. Fragments such as nails or glass were often added. As many as 14% of U.S. Army casualties in Vietnam were generated by booby trap-type IEDs.¹⁴ Today, pipe-bomb use occurs almost daily worldwide.¹⁵

Northern Ireland became the scene of an urban terrorist campaign in August 1969. IEDs were deployed against the public and against security forces, and in some cases the bombers themselves became the victims. Multiple studies have characterized the nature of these bombings and examined the casualty profiles. During the period of August 1969 to June 1972, there were at least 1500 hospitalizations in Northern Ireland resulting from terrorist bombings and 117 deaths (most deaths occurred before reaching the hospital).¹⁶⁻¹⁸ Bombs ranged from 2 to 200 lb.¹⁸ A 1978 review of 1532 bombing victims (78 explosions, 13 of which had more than 20 victims

transported), revealed 16% were admitted, and less than 1% of those who reached the hospital died. Twenty-five percent required a surgical procedure, most of which were simple wound cleaning and suturing.^{16,18}

IED detonations associated with collapsing a structure have had devastating consequences.^{19,20} A major loss of American lives from a terrorist bombing with a vehicle-borne IED occurred in 1983 in Beirut, Lebanon. The suicide detonation of a truck packed with ammonium nitrate resulted in an explosive force equivalent to 6 to 12 tons of TNT, the largest deliberate non-nuclear man-made explosion to date. The explosion collapsed the four-story airport terminal building housing U.S. forces. There were 346 casualties with 234 (68%) immediate deaths. Most survivors had noncritical injuries.^{1,2}

In the late 1970s and early 1980s, several cities in Israel were victimized by terrorist bombings. The emergence of suicide bombings in the 1990s led to an increase in the magnitude and severity of incidents. Between 1994 and 1998 there were 18 suicide bombings in Israel alone—12 in crowded urban areas and 4 in crowded buses. An in-depth review of 4 bombings in 1996 revealed a total of 297 victims.⁸ A 7.8% fatality rate occurred in open-air bombings versus 49% in the confined space of a bus. Victims in buses had a higher incidence of primary blast injury (PBI), which was predominantly lung injury and more extensive burns, but no difference was found regarding number of burns, penetrating injuries, or traumatic amputations when compared with injuries among open-air bombing victims.⁷

In Iraq today, terrorists have integrated pipe-bombs, mortars, artillery projectiles, anti-tank mines, rockets, and other explosive-filled ordnance, into simple command-detonated devices, either hard-wired or radio controlled allowing remote detonation via battery-powered remote car alarm, doorbell, pager, or cell phone²¹ (Fig. 65-1). During Operation Iraqi Freedom (OIF), U.S. and Coalition forces experienced 708 incidents of IED attacks during one 90-day period alone.²¹

FIGURE 65-1. Garage door opener detonation device (notice wire).

Currently in Iraq, IEDs are being camouflaged to resemble roadside garbage or debris, hidden in roadside abandoned vehicles, or placed in potholes, under rocks, or in animal carcasses, and they are deployed both individually and as “daisy-chained” munitions (i.e., linked munitions exploding in series). They have been most commonly targeted against unarmored vehicles in small convoys or the rear of larger convoys.²¹ Roughly 50% of IEDs encountered during OIF failed to function properly. The average IED in Iraq during OIF has been estimated to be 1 to 2 kg; however, large vehicle-borne IEDs (VBIEDs) containing bulk explosives have been detonated with devastating effect.²¹

CURRENT PRACTICE

Clinical Effects of Blast Injury

An IED will create wounds according to several effects: the blast effect from the force of the explosion, the ballistic effect of flying fragments, and the thermal effect from the explosion's heat. These effects will generate casualties according to the victim's distance from the epicenter of the explosion (Fig. 65-2). Persons who are close to the explosion will show evidence of all types of injuries; those farther away will sustain only penetrating injury. Persons receiving combined ballistic, blast, and thermal injuries usually suffer mutilating blast injury and are unlikely to survive. Generally speaking, the closer one is to an exploding device, the less likely one is to survive or even enter the medical treatment system.²²

High-explosive detonation is a high-speed, almost simultaneous chemical decomposition of solid or liquid explosive into a gas. The result is an expanding sphere of high-pressure, high-temperature gas blast wave propagating radially from the explosion at or above the speed of sound, the magnitude and speed of which is dependent on the type and size of explosive and the surrounding medium.²³ The presence of reflecting surfaces (such as a wall) may magnify the original incident pressure many times, and severe blast injury may be seen in patients thought to be a safe distance from the blast.^{13,24} Stress and shear waves, spalling, implosion, and inertia are some of the proposed mechanisms by which the blast wave damages tissue.^{25,26}

The ability of a blast to cause damage to the body depends on the blast load, that is, the peak pressure and duration of overpressure produced by the explosion.²⁷ The three factors that govern the blast load imposed on the body include:

1. The size of the explosion;
2. The medium in which it explodes;
3. The distance from the center of the explosion.

Many factors can reduce the blast loading on the body within confined spaces, such as pillars, furniture, and other victims.^{16,17} British research suggests a charge equivalent to 20 kg of TNT that explodes more than 6 m from the body is unlikely to cause severe blast injury to the lungs in an open-space explosion.²⁸

FIGURE 65–2. The probability of sustaining trauma is related to the casualties' distance from the epicenter.

Explosions resulting from IED detonation can cause a great variety of injuries. There are three injury types propagated by an explosive blast: the blast pressure effect, the fragmentation effect, and the impact effect from the victim being thrown against an object, traditionally termed primary, secondary, and tertiary blast injuries, respectively.^{2,17,25,26} Studies have suggested that the majority of bombing injuries are from secondary or tertiary blast effect^{18,27} and are most often soft tissue, orthopedic, and head injuries.^{18-20,29} The head and neck are the areas most vulnerable to injury.³⁰ Severe head injury is the leading cause of death in blast victims.^{3,16,17,20,29,31} Penetrating neck and torso trauma is also a common cause of death.¹⁸

PBIs are caused by the direct concussive effect of the blast wave on the body, are unique to explosions, and are characterized by damage to air-filled organs. The lungs, ears, and gastrointestinal tract are most susceptible.^{25,31} Solid organs are protected from PBI. PBI of the lung is the hallmark of PBI caused by explosions but is not the most common injury.⁷ It is essentially manifested as pulmonary contusions.^{27,32} Significant blast injury to the lung causes intra-alveolar hemorrhage and edema and a rapid fall in oxygenation.³¹ PBI is uncommon in survivors of terrorist bombings; however, it is found to be common in victims who die at the scene, in victims of explosion in an enclosed space, and in patients who are “severely wounded.” Investigators report an incidence of 1% to 2% in surviving casualties. A significantly higher percentage of PBIs are reported in the Israeli literature, but the occurrence is still less than 20%.^{2,3,7,18,32}

Injury to the lung is the cause of the greatest morbidity and mortality. In lung injury, limited peak inspiratory pressure, volume-controlled ventilation, and permissive hypercapnia have benefited patients. Some advocate the prophylactic placement of chest tube thoracostomy in patients with a deteriorating condition.^{25,33}

Tympanic membrane rupture is the least severe form of PBI and another hallmark injury of the blast wave. Tympanic membrane rupture is common and is considered an indication of a patient's exposure to blast.⁹ All who were severely injured in a study by Katz et al.³ had ruptured tympanic membranes.³⁴ If this structure is clinically intact, serious blast injury is unlikely.^{16,30} Spontaneous healing occurs in 50% to 80% of patients, with some permanent hearing loss being reported in up to 100% of victims.⁷

Another hallmark of blast injury is the appearance of air emboli in the pulmonary and coronary vessels.^{9,16} For neurologic deterioration attributed to air emboli, some have advocated hyperbaric therapy.¹⁶ Sometimes no distinct injuries are identifiable. In Israel, as many as 30% of fatalities in suicide bombings had no obvious external cause of death.⁷ It is postulated that in cases where no visible external injuries exist, cardiac dysrhythmia or air emboli caused cardiac arrest.⁹

Primary blast injury of the bowel is variable in explosions and has more commonly been considered a consequence of underwater explosion only.³ The colon is the most common site of hemorrhage and perforation. Presentation of this type of injury may be acute or delayed.^{3,33}

Secondary blast injury is caused by rapid acceleration of projectiles embedded in the explosive or flying debris caused by the explosion. The resulting ballistic injury patterns will reflect the velocity and shape of the bomb fragments or flying glass, for example. This is the predominant injury among surviving casualties and the critical factor is the anatomic site penetrated.^{2,22} In many studies, virtually all injuries seen in survivors were caused by secondary missiles rather than the blast wave itself.¹⁶

Tertiary blast injuries are a result of the impact of a victim being thrown against an object. These are managed as conventional trauma, either blunt or penetrating if secondarily impaled.

Miscellaneous injuries encompass all other injuries due to the explosive device such as those resulting from fire and heat, including flash burns, smoke inhalation, and crush injury.¹⁶ External burns are usually superficial due to the short duration of the explosive flash, and clothing offers some degree of protection unless the person is caught in a building or vehicle ignited by the explosion.³³

Civilian bombings usually result in low mortality rates unless there is a structural collapse or a very large explosive charge or an explosion within a confined space occurs.^{9,34} On average, about 1% to 5% of victims will die at the scene, 25% to 50% of those transported will need admission, approximately 10% will be seriously injured, and a smaller percentage will require surgery.^{3,33,34} The majority of victims seeking medical care will be slightly injured with abrasions, lacerations, and contusions.³⁴ Fatalities tend to incur multiple injuries: head, blast lung, abdominal, and chest injuries and traumatic amputa-

tions.^{2,3,8} Injuries most commonly seen in fatalities include head/brain injury (66%), skull fracture (51%), diffuse lung contusion (47%), tympanic membrane rupture (45%), and liver laceration (34%).³⁰

Among survivors, soft tissue and musculoskeletal injuries are caused most commonly by secondary and tertiary blast effects. Critical injuries occur infrequently in bombing survivors, and abdominal injury is rare, but may be associated with either the blast wave and hollow viscous perforation or acceleration/deceleration (tertiary blast) injury.²

Traumatic amputation is a marker of severe injury not usually associated with survival and is frequently associated with other injuries, such as chest and abdominal injuries.^{12,16} Patients may suffer from mangled extremities as a result of an incident involving an IED. Predicting the ultimate viability of a mangled extremity remains a challenge for orthopedic surgeons.^{11,30,35}

Factors that correlate with ultimate outcome and optimum survival in victims of blast due to an IED include explosive force, anatomic site of injury, time interval from injury to treatment, and availability of surgeons.^{1,2}

Key Management Principles of Victims of IEDs

Triage and Management of the Victims of IEDs in the Field

The goal of field management should be to quickly identify the critically injured patients who need immediate care and to provide them with life-saving procedures, stabilization, and transport to surrounding hospitals as rapidly as possible, avoiding a “second wave” phenomenon. Four phases at the scene have been suggested⁷:

1. A *chaotic phase* lasts 15 to 25 minutes, characterized by the lack of a leader. Victims who can walk will evacuate themselves to the nearest hospital. The first to arrive at the hospital are those with minor injuries, and these victims seldom receive any treatment at the scene.⁷
2. Next comes a *reorganization phase* lasting up to 60 minutes characterized by the leader (usually emergency medical services [EMS] personnel) assuming control at the scene. This is likely the most important management phase.⁷ The leader ensures life-threatening injuries are identified and prioritized for evacuation. The goals of medical leadership at the site must include rapidly establishing communication with local EMS and ensuring safety at the scene.³⁰ The number of casualties and severity of injuries must be accurately communicated to EMS to ensure optimal distribution of patients to receiving facilities. Scene safety remains a paramount concern because both secondary explosive device detonation as an observed tactic of terrorists and hazardous debris in a collapsed structure threaten rescuers.^{2,24} At the site, the presence of a crater and building collapse are important observations regarding blast strength.³³
3. A *site-clearing phase* lasts 1 to 3 hours, depending on the need for extrication.⁷ The EMS commander

should ensure that no victims are missed. Hospital “exportable” teams, essential in rural mass-casualty scenarios, would arrive on site.

4. The *late phase* is a poorly defined period between when the site is cleared of victims and 24 to 48 hours afterward. Some victims with slight wounds may not acknowledge their injuries for many hours after the event and may seek medical care at this time.⁷

The presence of multiple wounds in the same casualty and the presence of multiple casualties require that treatment be prioritized both in the field and at the hospital. The challenge of field triage in the bombing incident is to identify the minority of casualties who are critically injured and require immediate care among the great majority of less severely injured casualties. U.S. and European data suggest that 85% of surviving victims may be triaged and treated as outpatients.³⁶ Rapid and accurate triage could significantly reduce mortality among bombing survivors, whereas routine over-triage could result in loss of potentially salvageable lives as nearby medical facilities become overwhelmed.² Urban locations are likely to enhance the value of accurate triage. In isolated locations where prolonged transport of critically injured and delayed treatment must be taken into account, over-triage may become a necessity.² Victims with no evidence of external trauma and no loss of consciousness can be cleared in the field.¹² The activity level of potential blast-exposed persons should be reduced at the scene because data suggest victims of pulmonary PBI fare poorly when significant physical activity follows blast injury.³⁷ Occasionally it may be necessary to amputate a mangled extremity to free an entrapped patient. Although this is rarely required in the disaster setting, it should still be performed at the lowest possible level.³⁰

No major difference exists between initial care to a patient with blast injury and victims of other more conventional trauma. Definitive care should not occur at the triage area in the field. Basic guidelines should include the following⁷:

1. Victims who are apneic, pulseless, and not moving should be considered dead.⁷ Cardiopulmonary resuscitation at the scene is futile and not indicated.
2. Airway management with C-spine control is effective treatment in an unconscious patient with an unsecured airway or inadequate ventilation. Victims with respiratory distress require early advanced life support. Patients who are intubated and ventilated are at high risk for tension pneumothorax. In a suspected pneumothorax in the field under positive pressure ventilation, needle decompression is prudent, particularly if the patient will require air evacuation.⁷
3. Control of hemorrhage in the field is necessary for treatment of external bleeding of the extremities. Application of a tourniquet is appropriate only if direct pressure has failed.⁷ Administration of intravenous fluid should not delay transport to the hospital.
4. Fracture alignment is critical and may restore blood flow in the mangled extremity. Because splinting material will be scarce, limb-to-limb and limb-to-body splinting will suffice temporarily.

5. Covering open wounds with dressings is desirable but should not delay transport if not readily available.

Hospital Management of IED Victims

Effective triage by the most experienced hospital provider (often a surgeon or emergency physician) at the hospital unloading point for ambulances should place patients into “urgent” versus “nonurgent” categories, depending on their need for surgery.⁷ Nonurgent patients (i.e., those for whom delayed or minimal care is required) are not in need of surgery in the next few hours. Unless a patient dies on arrival, the decision to declare a patient “expectant” (i.e., unsalvageable) should be made in the resuscitation bay only after more thorough evaluation.⁷

Patients categorized as “urgent” should receive resuscitation in accordance with advanced trauma life support protocols. Hemodynamically unstable patients should be transferred to the operating room as soon as possible, for definitive control of bleeding.⁷ There is no place for emergency department thoracotomy in traumatic arrest from a terrorist bombing.^{7,25} Deteriorating respiratory function is most likely secondary to blast effect; however, bilateral tension pneumothoraces should be ruled out with needle decompression. The minimal acceptable treatment for severe thoracic trauma is empiric chest tube thoracostomy.⁷ Due to the high velocity associated with fragments, all penetrating wounds of the chest and abdomen should be explored.³⁰ PBI should be considered in all persons exposed to blast, although serious PBIs are uncommon in survivors. The immediate management of patients with suspected PBI should include a response tempered with physiologic end points for oxygenation, ventilation, and fluid replacement.³³

Stable patients with abdominal trauma are managed with nasogastric decompression, intravenous fluids, antibiotics, and analgesia.⁷ Focused abdominal ultrasound evaluation, if available, is superior to time-consuming diagnostic peritoneal lavage (DPL). Computed tomography (CT) scans should be performed judiciously in the initial phase when casualties are still arriving. The only mandatory CT scans performed initially are for head injury in patients with altered mental status to rule out intracranial bleeding.⁷ Plain radiographs unlikely to affect the immediate management of patients should be deferred, at least until all urgent patients have been evaluated.

Initially, when the ultimate number of casualties is unknown, the hospital capacity must be protected because conservation of critical hospital resources is paramount. Therefore, in the immediate aftermath of the explosion, minimal acceptable care is permitted on a temporary basis, with concentration placed on the maximal number of salvageable patients. Initial surgical procedures may need to be in the form of damage control surgery. When casualties are no longer arriving, optimal care should be the goal.⁷

Nonurgent patients are referred to the predesignated area where they are reevaluated for admission or discharge as soon as possible. Guidelines for the use of blood should be restricted and a preselected upper limit of units to be transfused for individual victims should be determined to avoid premature depletion of resources.⁷

Fragmentation injuries predominate in patients presenting to the hospital. In bombing victims, wound contamination caused by high-velocity fragments is more extensive, and primary closure should not be attempted.

Injury to the lungs will be the greatest cause of morbidity and mortality. Clinically, blast lung presents early. The diagnosis is suspected on clinical grounds and confirmed by chest radiograph. This diagnosis must be excluded in patients who require general anesthesia or air evacuation and prophylactic chest tube thoracostomy has been advocated in PBI under these circumstances due to the risk of tension pneumothorax. When PBI is suspected and operative procedures are required, local, regional, or spinal anesthesia is preferred over general anesthesia.³⁷ Patients suffering from PBI to the lungs require intensive care unit management. Many casualties will require positive pressure ventilation for a variety of reasons. Pressure-controlled ventilation, high-frequency ventilation, and permissive hypercapnia have been successful modes of respiratory support.^{7,33}

Missed injuries after bombings are not uncommon and should be avoided by repeat examinations. For patients in whom PBI is suspected, some period of observation is prudent.^{25,33} PBI of the auditory system can be easily overlooked. Isolated tympanic membrane rupture is not a marker for life-threatening PBI, and absence of rupture makes pulmonary PBI unlikely unless the patient was wearing hearing protection.¹⁶ Prior to discharge, all patients must be evaluated for tympanic membrane injury and ocular injuries from flying debris.^{7,16}

Following immediate life-saving surgical procedures, nonexsanguinating chest and abdominal injuries that endanger life should undergo operation.⁷ After this, surgical treatment of closed-head injuries with intracranial hemorrhage is warranted. Extremity injuries including bone and vascular injury should be stabilized; however, time-consuming vascular and nerve reconstruction is inappropriate at this point. Wound cleansing and debridement are the last group of patients to undergo operation. Secondary distribution of patients in need of orthopedic fixation and debridement to neighboring hospitals for more timely surgical care is appropriate.⁷

Some of the injured as well as some of the rescuers will suffer posttraumatic stress. Staff debriefing sessions should be held immediately after acute events.³⁸

Algorithms exist for the management of respiratory distress, neurologic abnormalities, and gastrointestinal injury in a blast casualty.³⁷

PITFALLS

Planning in detail for a disaster can be an overwhelming task doomed to incompleteness. Planning instead for disasters of moderate size will yield a better chance of succeeding. Ideally, any plan should allow for modular expansion of response.³⁸ In a similar sense, planning for low-probability events such as a terrorist bombing competes with day-to-day activities.³⁸ Any opportunity to share intelligence between law enforcement and the medical community that might assist in improving response planning should be exploited.

Communications plans must ensure that communication capability continues after explosion and mass-casualty incident. Effective communication would improve casualty flow from the site to the hospital and ensure optimal distribution of patients and help prevent a second-wave phenomenon at receiving hospitals. Even in the United States, 67% of disasters had no communication existing between the disaster site and the receiving hospitals.^{38,39}

A lack of experienced medical leadership at the scene may be a significant impediment to appropriate treatment and medical regulation in evacuation at the site.^{10,30} In addition, over-triage is common in both the prehospital and hospital setting.^{2,34} In one large study, over-triage averaged 59%, but in many studies it has been considerably higher.¹⁸

Virtually all blast victims will have some degree of hearing impairment, which will complicate attempts to communicate with survivors but requires no field management.^{24,30} Hearing protection can attenuate external overpressure and protect against tympanic membrane rupture.^{37,38}

A high index of suspicion is helpful in detecting occult injuries in bombing victims. Arterial air embolism to the brain or heart may be the most common cause of death in immediate survivors and often occurs at the initiation of positive pressure ventilation.³³ Mechanical ventilation should be avoided due to the risk of air embolization and further barotraumas, when possible.^{16,37} Bowel perforation, while uncommon, frequently may have a delayed onset of symptoms.¹² In addition, severe injuries to the gastrointestinal tract from blast rarely occur in isolation, and these other injuries may mask the less obvious and subacute bowel injury.³ Although there are few survivors of blast injury sufficiently severe to cause bowel perforation, isolated abdominal PBI may be clinically silent until complications are advanced.^{3,16} Compartment syndrome may be seen wherever limb fractures, vascular injuries, and crush injuries occur in the setting of explosion and collapsed structures. The diagnosis is largely clinical and a healthy index of suspicion is required.

Primary closure of blast wounds have a high rate of secondary infection and should be avoided.^{12,16,37} The use of body armor (ballistic vest) offers protection against secondary and tertiary blast effects but may be associated with an increased incidence of PBI.^{30,37,40,41}

Lastly, movement on medical evacuation aircraft requires special patient preparation, particularly if concern for pneumothorax or need for mechanical ventilation exists.⁴²

CONCLUSIONS

It is clear that terrorism will continue to plague societies in the twenty-first century. It is less clear what form the threat will take. Acts of terrorism in the United States and internationally have grown more destructive during the past decade, and this trend can be expected to continue.⁵ As advances in weapons technology present new challenges to the disaster medicine community, success will require further commitment to develop creative ways to meet those challenges.⁴³

Terrorist bombings using IEDs, one type of sudden-impact disaster, occur without warning; however, they possess certain predictable characteristics based on historical data. An organized and coordinated response will reduce mortality and preserve resources for patients most in need of care. Medical providers must identify the pattern of primary, secondary, and tertiary injuries associated with IEDs, in addition to recognizing the hallmarks of blast injury and significance of markers of serious injury. Hospital resources must be expended in the optimal manner, to include prudent hospital triage and surgical care, in order to deliver the best possible outcome for victims of terrorist bombings associated with IEDs.

Directed-Energy Weapons

M. Kathleen Stewart and Charles Stewart

As new technology becomes available and the military uses become apparent, terrorists will adopt it and often increase its lethality. Directed-energy weapons include microwave-radiation emitters, particle beam generators, and lasers. Directed-energy weapons rely on electromagnetic waves or subatomic particles that impact at or near the speed of light. Several of these weapons have already been tested in combat and are now potentially available to terrorists.

Whatever the form of electromagnetic energy used for the directed-energy weapon, they all share certain characteristics that make them revolutionary weapons:

- They hit a target at the speed of light.
- They are line-of-sight weapons.
- The price of use is typically a small fraction of what it costs to fire a missile or a large gun. Low- and medium-power lasers can be cheaply obtained.
- They are able to engage many different targets because of their instantaneous effects and the ease of re-aiming them.

HISTORICAL PERSPECTIVE

Lasers

Immediately after the development of the first functional laser, the military (and hence terrorist) potential of the laser was apparent. Modern pulsed lasers can reach energy levels of up to millions of watts in a fraction of a second.

Lasers are the only directed-energy weapons currently fielded by both the United States and other military forces. In many cases, the laser is not intended as a weapon, per se, but rather as a targeting device for another weapon such as a missile or a “smart” bomb. The properties of the laser are particularly suited for this purpose. The military in many nations developed lasers for use as range finders and target designators.

Laser light has special qualities, including the following:

- The light released is *monochromatic*; it contains one specific wavelength of light (one specific color). The wavelength of light is determined by the amount of

energy released when the electron drops to a lower orbit. This wavelength depends on the material of the laser and the method by which it was stimulated to emit light.

- The light released is *coherent*. It is “organized”—each photon moves in step with the others (i.e., the waves of the electromagnetic radiation are in phase in both space and time). This means that all of the photons have wave fronts that launch in unison and the beam is parallel.
- The light is very *directional*. A laser light has a very tight beam and is very strong and concentrated. A light bulb, on the other hand, releases light in many directions, and the light is very weak and diffuse.
- Finally, laser light does not disperse over long distances due to this parallel nature (collimation) of the laser beam.

Military laser devices can easily cause retinal injury, even at a distance of many miles. Military planners found that this optical effect can be used as an anti-personnel system to actively disable personnel by blinding or “dazzling” them. By 1985, the British Navy had developed an unclassified weapon that was fitted aboard ships to blind oncoming enemy pilots at ranges up to 3 miles.

Many thousands of target-designation and distance-ranging lasers have been manufactured and sent out with troops of multiple countries. Because of this availability, they may find their way into the hands of terrorists and be used against U.S. civilians. Other civilian lasers can be easily adapted to similar purposes.

Muggers in England have used simple laser pointers to blind victims before robbing them.¹ There have been many anecdotal reports of eye pain and headaches lasting for several weeks after brief ocular exposures to laser-pointer beams.² The pathology of this pain is difficult to understand, since lasting pain is not a common consequence of retinal laser treatment for diabetes, when a considerable amount of laser energy is delivered to the retina.^{3,4}

Lasers have already been used by terrorists in an attempt to blind helicopter pilots.⁵ It would be no great stretch for a terrorist to mount a relatively powerful laser on a truck or within a car and attempt to blind pilots who are landing at a commercial civilian airport.⁶ Likewise, simple lasers may destroy vision in law enforcement officers responding to a terrorist attack.

Microwave-Radiation Emitters

Long-term exposure to high-intensity microwaves can produce both physical and psychological effects on humans, including sensations of warmth, headaches, generalized fatigue, weakness, and dizziness. The effect depends on the power output of the weapon and the distance between the generator and the person.

The U.S. Air Force has fielded a microwave system (area denial system, or ADS) that uses the surface heat production of very-high-power microwaves to induce people to leave an area.

Particle Beam Generators

A particle beam is a directed flow of atomic or subatomic particles. These high-energy particles, when concentrated into a beam, can melt or fracture metals and plastics. They also generate X-rays at the point of impact. These weapons are in development stages only and would be quite unlikely to be found in the hands of terrorists.

CURRENT PRACTICE

There is no foolproof countermeasure for a blinding laser. Each of the available protective efforts will hinder a person's ability to see and to carry out activities requiring sight.

Laser radiation does not travel through opaque objects. Any opaque cover will provide protection against all but very-high-power military lasers. Avoid looking directly at any laser beam or its reflection, if at all possible. Reflections off shiny surfaces may cause damage, despite forward cover. Wearing an eye patch on one eye offers partial protection from blinding lasers; unfortunately, it also deprives the wearer of depth perception and peripheral vision. Patching only prevents blinding in the patched eye.

The present method of protection from the laser threat is quite simple: a pair of "protective sunglasses" can be fashioned that reflect the laser light but let other wavelengths through, so that the wearer can see to do other tasks. These helmet visors or goggles would prevent laser radiation from damaging the wearer's eyes. This works well if the laser threat has been previously identified and is limited to one or two wavelengths. However, there are multiple frequencies available in lasers.

The management of casualties from the effects of laser light is discussed later in this chapter. The triage of these casualties can be accomplished by use of the triage algorithm as shown in Figure 66-1.

Casualties from consequent events, such as a blinded driver or pilot crashing his or her vehicle, are managed in the customary fashion covered by trauma protocols. There would be no difference in management of these casualties if they had a concomitant eye injury.

Key Management Issues

Laser Eye Injury

The eye is the part of the body most vulnerable to laser hazards. Eye damage can occur at much lower-power levels than those causing changes to the skin. This damage may be either temporary or permanent, depending on the wavelength and power of the laser. Because the eye is more sensitive and the pupil is larger during darkness, laser weapons have a greater effect at night than during the day. Generally, eye injuries are far more serious than injuries to the skin.

If the person is using a see-through optical device, such as binoculars, the beam strength is magnified and greater injury to the eye can result. Even modestly powered lasers can temporarily blind an unprotected human looking through a telescope or binoculars. Higher-power lasers can be used to destroy objects in flight or on the ground.

The light intensity of the image formed on the retina is 100,000 times greater than the light intensity at the front of the eye. It is this considerable *optical gain* that creates an eye hazard when laser beams enter the eye. When a person is exposed to laser light, they can be temporarily blinded (dazzling), be blinded for a prolonged time (photolysis), or incur permanent changes in visual function from retinal lesions or hemorrhages.

Far-infrared radiation, which ranges from 3000-nm to 1-mm wavelengths, is absorbed primarily by the cornea (Fig. 66-2). A high-energy laser pulse may severely burn or perforate the cornea. Severe burns or perforations should not be patched, and the eye should be protected to ensure that the vitreous humor does not leak out. Minor laser burns to the cornea may be treated with an eye patch and appropriate eye antibiotics.

Some infrared radiation in the IR-A range (700- to 1400-nm wavelength) and the IR-B range (1400 to 3000 nm) is absorbed directly by the lens. Radiation in the 400- to 1400-nm wavelength range (visible light and IR-A) is the most hazardous because it is transmitted by the optical components of the eye. It reaches the retina, where most of the radiation is absorbed in the retinal pigment epithelium and in the choroid, the dark brown layer with exceptionally large blood vessels and high blood flow rate. The infrared spectrum is often used for military target-designation lasers.

FIGURE 66-1. Steps in laser injury triage.

Damage to the retina or hemorrhaging from retinal damage can cause a complete loss of vision. Persons who see large dark spots at or near the center of their vision, who have a large floating object in their eye, or who have an accumulation of blood in the eye should be promptly evacuated to a hospital with ophthalmologic support. Hemorrhage into the eye should be treated by positioning the patient in a head-up position to allow the blood to settle into the lower part of the eye. Laser burns to the retina do not require an eye patch. Indeed, an eye patch may reduce the person's remaining vision.

There is no currently accepted treatment for laser-or light-induced eye injuries. A laser eye injury can worsen with time, so anyone with a suspected laser eye injury should be both evaluated promptly and again at regular intervals.

Laser Skin Burns

The risk of skin injury is greater than the risk of eye injury by a laser because humans have a lot more skin tissue than eye tissue. However, skin injuries from lasers are much less serious than eye injuries. In part, this is because skin injuries often don't have the dire consequences of eye injuries and partly because the eye concentrates the laser's beam as described above. With enough power and duration, a laser beam of any wave-

length in the optical spectrum can penetrate the skin and cause deep internal injury.

The pain from thermal injury to the skin by most targeting lasers is enough to alert a victim to move out of the beam path. Unfortunately, a number of high-power and visible lasers and infrared lasers are now used in industry. These are capable of producing significant skin burns in less than a second.

PITFALLS

Knowing the type of laser involved in an injury may be very valuable. Table 66-1 provides a breakdown of laser type bioeffects. It must be stressed that, to be effective, laser protective goggles or glasses must be donned before exposure to the laser and must have the appropriate frequency rejection characteristics for the laser used. This presents a difficult problem for law enforcement and providers of emergency medical services who may be faced with any of these lasers as a terrorist threat.

It is expected that a tunable (frequency-agile) laser threat will also develop soon. The technical approach used to protect against fixed-frequency lasers cannot be applied to protection from the agile threat or even to protection from a larger number of fixed-frequency threats. As more band-rejection filters are built into a

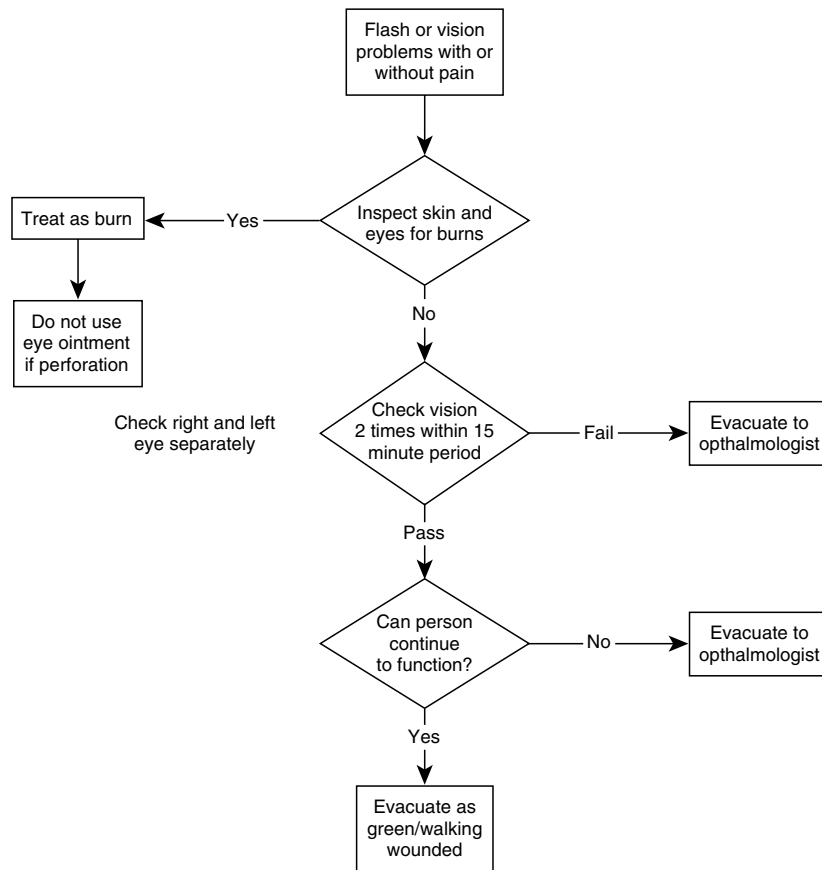

FIGURE 66-2. The patient with a laser eye injury may have sharp eye pain, sudden loss of vision, streaky or spotty vision, or disorientation. The damage to the eye tissue may vary with the wavelength of the laser.

TABLE 66-1 SUMMARY OF BIOEFFECTS OF COMMONLY USED LASERS

LASER TYPE	WAVELENGTH (μm)	BIOEFFECT Process	TISSUE AFFECTED			
			Skin	Cornea	Lens	Retina
CO ₂	10.6	Thermal	X	X		
HFl	2.7	Thermal	X	X		
Erbium-YAG	1.54	Thermal	X	X		
Nd-YAG*	1.33	Thermal	X	X	X	X
Nd-YAG	1.06	Thermal	X			X
Gas (diode)	0.78-0.84	Thermal	†			X
He-Ne	0.633	Thermal	†			X
Ar	0.488-0.514	Thermal/ Photochemical	X			X‡
XeFl	0.351	Photochemical	X	X		X
XeCl	0.308	Photochemical	X	X		

CO₂, Carbon dioxide; HFl, hydrogen fluoride; YAG, yttrium aluminum garnet; Nd, neodymium; He-Ne, helium-neon; Ar, argon; XeFl, xenon fluoride; XeCl, xenon chloride.

*Wavelength at 1.33 μm or more common in some Nd-YAG lasers has demonstrated simultaneous cornea/lens/retina effects in biologic research studies.

†Power levels not normally sufficient to be considered a significant skin hazard.

‡Photochemical effects dominate for long-term exposures to retina (exposure times more than 10 seconds).

sandwich, transmission of light through the visor at other wavelengths decreases also, making it unusable at night and limiting its utility in the daytime.

Emergency Department Design

Robert H. Woolard

In the United States, hospitals build new emergency departments (EDs) every 15 to 20 years. Renovations of existing EDs occur every 5 to 10 years. The main concerns of ED designers are providing efficient spaces for routine care, handling peak volumes, and anticipating future needs. Well-designed EDs accommodate daily, weekly, and seasonal tidal peaks and valleys in patient flow. The variety of high- and low-acuity illnesses and injuries requires EDs to prioritize care into critical, emergent, and urgent treatment. EDs meet community needs for specialized care by providing areas for unique care needs with pediatric, cardiac, trauma, geriatric, or poison centers. Often only as a last thought do EDs include some design features for disaster and mass-casualty response.^{1,2} In the wake of terror-related events, such as the New York City World Trade Center disaster on Sept. 11, 2001, many EDs are being designed or renovated to meet new disaster needs. These designs and renovations include decontamination, isolation, and other specialized treatment areas, as well as expanding capacity to treat multiple victims within or next to EDs.

HISTORICAL PERSPECTIVE

In the aftermath of recent terror events and subsequent disaster planning, hospital architects have begun to design EDs to better meet the needs anticipated from a terror attack. Some ED design lessons have been learned from terror events. From the Tokyo sarin gas event and other natural disasters, such as earthquakes, hospitals know they will need to plan for surge capacity. Methods of alerting ED staff early and protecting emergency care providers from contamination are needed, another lesson made clear by the Tokyo sarin gas event in which many emergency providers were contaminated. The New York City World Trade Center event illustrated the need to respond to a disaster scene and continue to treat a sustained increase in ED volume over prolonged periods. In New York, the clean-up phase after the event led to prolonged increased prehospital and ED volume. Most care was provided by emergency personnel working close to ground zero. From the anthrax mailings in the wake of the World Trade Center event, we can learn to anticipate the need for accurate public information.

The ED remains the most available point of access to immediate healthcare in the United States. ED designers are now anticipating increased volumes of patients that might be generated by disaster or a terror event. Although a stressed public needs information and health screenings that perhaps can be met by providers outside the ED, the ED will be accessed for counseling and screening when other services are overwhelmed or delay to access is encountered. In past disasters, shelter needs were met outside the ED. However, needs for quarantine during bioterror events may create shelter needs in EDs.

ED design and response capability after Sept. 11 has become a larger concern for public disaster planners, the federal government, and hospital architects. Two federally funded projects coordinated by emergency physicians, one at Washington Hospital Center (ER1) and another at Rhode Island Hospital (RIDI), have developed and released recommendations. ER1 suggests designs for a new ED that meets any and all anticipated needs of a disaster event.³ RIDI has developed new disaster-response paradigms, training scenarios, and response simulations that also can be used in ED design.⁴

CURRENT PRACTICE

ED design would be tremendously enhanced if a prototype “disaster-ready” ED such as ER1 could be built. ED designers may not be able to create an “all-risks-ready” ED given financial constraints. However, incorporating disaster-ready suggestions when EDs are renovated or built new will improve our readiness and may be more financially feasible. New building materials, technologies, and concepts will continue to inform the effort to prepare EDs for terror attack. Urban ED trauma centers are attempting to develop capacity to serve as regional disaster resource centers and respond out to a terror event. These EDs are designed to incorporate larger waiting and entrance areas, adjacent units, or nearby parking spaces in their plans to ramp up treatment capacity. More decontamination and isolation capacity is being built to help control the spread of toxic or infectious agents. Information systems are being made available to provide real-time point-of-service information and any

needed “just in time” training for potential terror threats. The technology needed to respond to a terrorist event, such as personal protective equipment (PPE), is becoming more widely available and is stored where easily available in EDs. Although mass decontamination can occur close to the disaster scene, EDs are gearing up to decontaminate, isolate, and treat individuals or groups contaminated with biologic or chemical materials. Four elements of ED design are being addressed to prepare EDs for terror events: scalability, security, information systems, and decontamination.

Scalability, Surge, and Treatment Capacity

EDs are generally designed with sufficient, but not excess, space. The number of treatment spaces needed in an ED is usually matched to the anticipated ED patient volume; roughly 1 treatment space per 1100 annual ED visits or 1 treatment space per 400 annual ED hospital admissions is recommended.¹ According to disaster planners, a major urban trauma center ED built for 50,000 to 100,000 visits per year should have surge capacity up to 100 patients per hour for 4 hours and 1000 patients per day for 4 days. One Sept. 11 challenge is to provide “surge capacity” to meet anticipated patient needs. Hospitals are woefully overcrowded, and EDs are routinely housing admitted patients.⁵⁻⁷

EDs are now being designed to allow “growth” into adjacent space: a ground level or upper level, a garage, or a parking lot. Garage and parking lot space has been used in many disaster drills and mass exposures. Garages and parking lots are more purposely designed with separate access to streets, allowing separation of disaster traffic and routine ED traffic. Needed terror-response supplies (e.g., antidotes, respirators, personal protective gear) are being stored near or within the ED. The cost of ventilation, heat, air conditioning, communication, and security features often prohibits renovation of garages. More often, tents are erected over parking lots or loading areas. Modular “second EDs,” tents or structures with collapsible walls (fold and stack), have been deployed by disaster responders. These can be used near the main ED, preserving the ED for critical cases. Some hospitals are considering beds in halls, patient rooms, and other spaces to increase their ability to generate surge capacity. Hallways can provide usable space if constructed wider and equipped with medical gases and adequate power and lighting. Often only minimal modifications are necessary to make existing halls and lobbies “dual-use” spaces. Some hospitals have increased space by installing retractable awnings on the exterior over ambulance bays or loading docks. Tents are often used outside EDs as decontamination and treatment areas in disaster drills. Tents with inflatable air walls have the added benefit of being insulated for all-weather use.

In the military, the need to provide treatment in limited space has resulted in the practice of stacking patients vertically to save space and to reduce the distances that personnel walk. U.S. Air Force air evacuation flights have stacked critical patients three high. These bed units could be deployed for a mass event. Portable modular units are also available to help EDs address the space

needs. Unfortunately, many EDs rely on other facilities in the regional system. In a terror event on a hospital campus, the ED function may need to be moved to a remote area within the hospital. Many disaster plans designate a preexisting structure on campus as the “backup” ED. The area is stockpiled with equipment, and plans for access and patient and staff movement are developed.

Although the capacity to handle patient surges is being addressed regionally and nationally, large events with high critical care volumes may overtax the system of the trauma centers regionally. The National Medical Disaster System can be mobilized to move excess victims and establish field hospitals during events involving hundreds or thousands of victims.

The ED plan to provide treatment during disaster must consider evacuation, since the event may produce an environmental hazard that contaminates the ED. Evacuation of ED patients has been addressed by ED designers. Some EDs have the capacity to more easily evacuate. In better planned EDs, stairwells have floor lights to assist in darkness. Stairways are sufficient in size to allow backboarded patients to be evacuated. The communication and tracking system includes sensors in corridors and stairways. Patient records are regularly backed up to portable disk and available for evacuation.

Security

Securing the function of an ED includes securing essential resources: water, gases, power, ventilation, communication, and information. ED security involves surveillance, control of access and egress, threat mitigation, and “lock-down” capacity. Surveillance exists in almost all EDs. Many ED parking and decontamination areas are monitored by cameras. The wireless tracking system can also be part of the surveillance system. A tracking system can create a virtual geospatial and temporal map of staff and patient movement. Tracking systems have been used in disaster drills to identify threat patterns. Most EDs have identification/access cards and readers. Chemical and biologic sensors for explosives, organic solvents, and biologic agents are becoming available. When selecting a sensor, designers consider sensitivity, selectivity, speed of response, and robustness.⁸⁻¹² Sensor technology is an area of active research that continues to yield new solutions that are being incorporated into EDs. In concept, all entrances could be designed to identify persons using scanning to detect unwanted chemicals, biologic agents, or explosives and to detain and decontaminate as needed.

Most EDs have multiple entry portals for ingress of patients, visitors, staff, vendors, law enforcement personnel, and others. EDs are using screening and identification technologies at all entrances in combination with closed circuit video monitoring. Personnel must be dedicated for prompt response when needed. Automation of identification can efficiently allow safe flow of patients, staff, and supplies. Vehicle access has been managed by barcoding staff and visitor vehicles. At some road access points, automated scanners could monitor and control vehicle access. Modern EDs limit the number of entrances and channel pedestrian and vehicular traffic through identification control points. For the most part,

points of entrance into the ED can be managed with locking doors, ID badge control points, and surveillance to allow desired access for staff and supplies. Thoughtful planning should facilitate rapid access between the functional areas such as the ED, operating rooms, and critical care units. Movement within and between buildings needs to be controlled and must allow a total lockdown when necessary.

Direct threats to the ED include blasts and chemical, biologic, and environmental contamination. There are several strategies to mitigate blast. Twelve-inch-thick conventional concrete walls, using commercially available aggregates (147 lb per cubic foot) affords reasonable blast protection.^{16,17} On some campuses, the space between the ED and the entrance is designed largely to prevent direct attack.¹⁸ However, atriums are terror targets. Although atriums are useful as overflow areas, their windows and glass create hazardous flying debris. Given the threat of blast attack, communication, gas, electric, water, and other critical services should be remote from vulnerable areas and shielded when they traverse roads and walkways. Protection against release of chemical and biologic agents inside or outside the ED requires a protective envelope, controlled air filtration in and out, an air distribution system providing clean pressurized air, a water purification system providing potable water, and a detection system. Better HVAC systems can pressurize the envelope and purge contaminated areas.

Information

Anticipated computing needs for ED operations during disaster events are immense. In most EDs, large amounts of complex and diverse information are routinely available electronically. Overflow patients in hallways and adjacent spaces can be managed with mobile computing, which is available in many EDs. Wireless handheld devices can facilitate preparation for disasters and allow immediate access to information by providers in hallways and decontamination spaces. Multiple desktop workstations are available throughout most EDs. During disaster, displays of information that will aid decision-making include bed status, the types of rooms available, the number of persons waiting, and ambulances coming in. Monitors now display patient vital signs, telemetry, and test results. Significant improvements in efficiency and decision-making can be achieved when more real-time information is available to decision-makers. Multiple computer screens enhance ED readiness.

Clinical decision tools, such as UpToDate,¹⁹ make information readily available to providers. These and other “just-in-time” resources will be needed when practitioners treat unusual or rare diseases not encountered in routine practice. The wide variety of potential disaster scenarios argues for the availability of just-in-time information. Information specific to a disaster event should be broadcast widely on multiple screens in many areas. Cellular links and wireless portable devices should also receive information. Access to information has been enhanced in most EDs through cell phone use, etc. This facilitates making information available to guide each staff member.

Diagnostic decision support systems have been demonstrated to help practitioners recognize symptom complexes that are uncommon or unfamiliar. Information systems should be capable of communicating potential terror event information regularly. Many EDs have log-on systems that require staff to read new information. In a disaster-ready ED, a list of potential threats could be posted daily. However, the utility of computer references or on-call experts is limited by the practitioner’s ability to recognize a situation that requires the resource.

Computer-based patient-tracking systems are available for routinely tracking patients in most EDs. Some computer-based tracking systems have a disaster mode that quickly adapts to a large influx of patients allowing for collation of symptoms, laboratory values, and other pertinent syndromic data. In many regions, EDs serve as a terror surveillance network. Routine data obtained on entry are passively collected and transferred to a central point for analysis. In the event of a significant spike in targeted patient symptom complexes, these data can trigger an appropriate disaster response. The capacity for this entry point surveillance should be anticipated and built into any disaster-ready ED information system.²¹⁻²³ For example, data terminals allowing patient input data at registration similar to electronic ticketing at airports could passively provide information. This self-service system could add to ED surge capacity. Similarly, real-time bed identification, availability, and reservation systems used to assist patient management in some EDs could aid ED function during disaster. Movement to an inpatient bed is a well-documented choke point recognized nationally during normal hospital operations and becomes an issue during disaster.

Lobby screens can facilitate family access to information during a disaster, displaying information about the event and patient status. During disasters, family members can be given access to screens to query for missing persons. Computers with Internet access that could display event information are available in patient rooms in some EDs.

During the anthrax mailings, public hysteria taxed the healthcare system. Posttraumatic stress, anxiety, and public concern over possible exposure to a biologic or chemical agent may generate a surge of minor patients at EDs. Within some EDs, lecture halls or media centers are available (generally used for teaching conferences) but could provide health information and media briefings during disaster. The media are an important source of public information and must be considered when planning disaster response. Information from a media center in the ED could be released to the Internet and closed-circuit screens. Accurate information can allay public concerns and direct the public to appropriate resources and access points.

Isolation and Decontamination

Many EDs have patient decontamination (DECON) areas. Adequate environmental protection for patients undergoing DECON is necessary and includes visual barriers from onlookers, segregation of the sexes, and attention to per-

sonal belongings.^{24,25} In many EDs, DECON areas are being added to accommodate mass exposures. EDs have added or augmented DECON facilities. DECON areas should have a separate, self-contained drainage system, controlled water temperature, and shielding from environmental hazards. Exhaust fans are used to prevent the buildup of toxic fumes in these decontamination areas. For most EDs, mass DECON has been accomplished by using an uncovered parking lot and deploying heated and vented modular tent units. Uncovered parking areas adjacent and accessible to the ED have been enabled for disaster response. Other EDs use high-volume, low-pressured showers mounted on the side of a building. Serial showers allow multiple patients to enter at the same entrance and time. However, serial showers do not provide privacy, can be difficult for an ill patient to access, and can lead to recontaminated water runoff. Also, persons requiring more time may impede flow and reduce the number of patients decontaminated. Parallel showers built in advance or set up temporarily in tenting offer greater privacy but require wider space and depth. Combined serial and parallel design allows the advantages of each, separating ill patients and increasing the number of simultaneous decontaminations.²⁶

Often built into the ED is another DECON room for one or two patients with the following features: outside access; negative-pressure exhaust air exchange; water drainage; water recess; seamless floor; non-pervious, slip-resistant, washable floor, walls, and ceiling; gas appliances; supplied air wall outlets for PPE use; high-input air; intercom; overhead paging; and an anteroom for DECON of isolated cases. PPE is recommended for use by military and fire departments during events involving hazardous materials. Hospitals use these devices and store a reasonable number of protective ensembles (i.e., gloves, suits, and respiratory equipment) usually near the ED DECON area. DECON areas are built with multiple supplied air outlets for PPE use to optimize safety and maximize work flexibility. A nearby changing area is available in some EDs. The changing area is laid out to optimize medical monitoring and to ease access to the DECON area.²⁷⁻³¹

Some capability to isolate and prevent propagation of a potential biologic agent has been designed into most EDs. Patients who present with undetermined respiratory illnesses are routinely sent to isolation. A direct entrance from the exterior to an isolation room is not usually available but has been a recent renovation in some EDs. Creation of isolation areas poses special design requirements for HVAC, cleaning, and security to ensure that infections and infected persons are contained. An isolation area should have compartmentalized air handling with high-efficiency filters providing clean air.³²⁻³⁵ Biohazard contamination is particularly difficult to mitigate. Keeping the facility “clean” and safe for other patients is an extreme challenge. Biologic agents of terrorism may resist decontamination attempts. Infected patients present a risk to staff. Few triage areas and ED rooms have been designed for decontamination. Surfaces must be able to withstand repeated decontamination. Sealed inlets for gases and plumbing have also

been considered.³⁶⁻³⁸ Patients who are isolated can be observed with monitoring cameras. Some isolation areas include a restroom within their space, which helps restrict patient egress.

General ED areas could have DECON capabilities built in. Floor drains have been included in some ED rooms for easier decontamination. Infection control is improved using polymer surface coatings that are smooth, nonporous, and tolerant to repeated cleaning, creating a virtually seamless surface that is easy to clean. These coatings can be impregnated with antimicrobial properties enhancing their biosafe capability. Silver-impregnated metal surfaces in sinks, drains, door handles, and other locations can reduce high bacterial content. Silver-impregnated metal has demonstrated antimicrobial effects.³⁹

Conventional ventilation systems use 15% to 25% outside air during normal operation, thus purging indoor contaminants. Air cleaning depends on filtration, ultraviolet irradiation, and purging. HVAC design should model demand for adequately clean air and also for isolation of potential contaminants.⁴⁰ The disaster-ready ED requires protection from external contaminations as well as contagious patients. A compartmentalized central venting system without recirculation has the ability to remove or contain toxic agents in and around the ED. Compartmentalized HVAC systems allow for the “sealing” of zones from each other. More desirable HVAC systems electronically shut down sections, use effective filtration, and can “clean” contaminated air. A compartmentalized system can fail, but it only fails in the zone it is servicing; smaller zones mean smaller areas lost to contamination. These systems are less vulnerable to global failure or spread of contamination. Modular HVAC units developed for field military applications have been added to existing ED isolation areas for use when needed to create safe air compartments.

PITFALLS

Cost may prohibit addressing issues like building more space or better ventilation, decontamination, and isolation facilities. If added space and facilities are not made more available, many lives may be lost during a disaster event. When monies are spent for terror readiness, EDs must continue to function day to day. EDs will be challenged to provide efficient routine care and also handle the consequences of a terror event or natural disaster. These competing functions could result in EDs that cannot handle routine care.

These design efforts could also lead to unnecessary increases in expenditures in anticipation of terror events that never materialize. To the extent that efforts to provide disaster care can be translated into solutions that address other more immediate hospital and ED problems, they will gain support. More access to information systems providing just-in-time training could inform staff not only of terror events but of mundane policy changes and unique patient needs such as bloodless therapy for Jehovah's witnesses, etc. Better information access could

also improve routine ED efficiency and communication with patients and families. However, these rationales may not prevail to fund disaster readiness. Decontamination equipment and areas may be used for commercial hazardous materials spills. Isolation areas could be more routinely used in an effort to contain suspected contagions, such as severe acute respiratory syndrome (SARS).

Lack of bed capacity in hospitals leads to ED overcrowding. Scalable EDs may offer temporary solutions in times of over-burdened hospital inpatient services. However, once reserve spaces are used to solve other over-capacity problems, those spaces may no longer be available for disaster operations. Thus, a new facility could "build" the capability of handling large surges of patients into adjacent spaces, only to lose it by filling these spaces with excess patients whenever the hospital is over census.

Finally, a terror event may be different from those for which we prepare. The rarity of terror events creates a need for us to test our disaster plans, skills, and capacities in drills. Drills may uncover design problems that can then be addressed but may only prepare us for anticipated threats.

CONCLUSION

Why pour such resources into building capacity that we hope never to use? Among the lessons learned from past disaster events is the need to develop disaster skills and build a disaster-response system from components that are in daily use. Systems that are used routinely are more familiar and more likely to be used successfully during terror events. Certainly the surge capacity of a "terror-ready" ED would be used for natural disaster response and in disaster drills. The surge space could also be used for over-census times, public health events, immunizations, and health screenings. A modern ED should serve as a community resource, deploy and test capacities regularly in disaster drills, and maintain "readiness" in a post-Sept. 11 world.

Chemical, Biologic, and Nuclear Quarantine

Patricia A. Nolan

As a society, we in the United States seek protection from harm through the exercise of police power as a basic function of constitutional governments “to provide for the general common defense and promote the general welfare.”¹ At the same time, we value individual liberty as the greatest good. This chapter examines the actions we can use to control the spread of a disease or toxin by controlling the movement of goods, animals, and people. These actions are embodied in the term *quarantine*. The emotional power of the term comes from the tension between our competing values of personal liberty and protection from harm. The word quarantine implies coercion, restricted movements, isolation from others, loss of property, and loss of liberty. We quarantine that which we seek to avoid or believe to be contaminated. In our use of police power (i.e., regulations, orders, law enforcement, and similar instruments) to restrict the movement of goods and people and to require examination, treatment, and confinement, we must also respect civil protections to limit our improper, excessive, or unethical use of this power.

In a terrorist event or a natural epidemic, principles of control, carefully applied, can reduce the number of casualties by preventing secondary cases. Data obtained through examining and monitoring of exposed persons can be used to identify and respond to subsequent cases, as well as to clarify the initial event.

The purpose of quarantine is to prevent the spread of a contagious disease in a population. Successful quarantine measures are based on the specific features of the biologic agent. Some elements of quarantine action may be appropriate in a terrorism event that involves biologic or chemical toxins or radiologic contamination. Quarantine is a set of legally authorized procedures instituted to accomplish the following:

- Identify what and who have been exposed;
- Determine which exposed people, animals, and/or goods are likely to be contaminated or infected;
- Prevent transmission by managing those who are contaminated or infected;
- Prevent subsequent exposures and contaminations.

Typical quarantine actions include the following:

- Identification of potentially infected or contaminated

- persons, animals, and goods;
- Initiation of protective measures to prevent further transmission of infectious agents;
- Initiation of protective measures to prevent exposed persons from becoming infected;
- Control of interaction of potentially or actually infected persons, animals, or goods with uninfected populations or goods.

Careful implementation of quarantine measures can assist in controlling fear and panic as well as controlling the spread of infectious agents or contaminants. At the same time, disasters require prompt decision-making and decisive action in the face of limited information. Healthcare personnel making quarantine decisions must have delegated authority from the government to act in ways that restrict liberties or take property. The critical safeguards in a disaster include formal orders for quarantine measures of persons, which are as specific as possible to the circumstances, opportunity for administrative or judicial review, and frequent, timely renewal of the conditions. For the protection of all, there are significant penalties for failure to comply with quarantine orders. These safeguards create a need for adequate records of the decisions made and the evidence used. Physicians should make it a point to know their responsibilities for reporting and controlling infectious diseases in the state in which they practice.

Consultation among law enforcement, emergency management, and public health agents is important in setting priorities among competing disaster management and antiterrorism demands. For example, cordoning off areas of contamination and preventing removal of goods may be less of a law enforcement concern than apprehending terrorists, yet failure to prevent movement of contaminated or infected goods may be devastating from a public health perspective.

QUARANTINE HISTORY

Our modern concepts of protecting society by isolating persons and controlling movement of animals and goods

to prevent the spread of contagious diseases can be traced to the Middle Ages. Leprosy was recognized as contagious, and lepers were separated from the community and isolated from society. As early as 583, authorities restricted the association of lepers with healthy people, building on the biblical sources in Leviticus.² In the mid-fourteenth century, authorities isolated victims of plague in their homes with their families until all had died or recovered. These periods of isolation varied in length, but a 40-day period became fairly standard.²

History is replete with instances of inequitable application of quarantine measures. The poor and the outcast were more likely to be confined, deprived of their livelihoods, and subjected to inhumane treatment as epidemics swept through. Modern epidemics, such as tuberculosis and HIV, reveal that better understanding of contagion does not always result in equitable responses. A preference for voluntary measures does not assure equity, especially if some groups have less access to medical care and other prophylactic measures.

Important elements of quarantine included requirements for the reporting of diseased persons and those in contact with them, civil or religious authorities empowered to decide who and/or what should be quarantined, and criteria for ending the quarantine. Quarantines have been enforced by armed force and imprisonment. As the nature of contagion became better understood, and as treatments and preventives were developed that reduced contagion, the definition of *quarantine* has been modified. Isolation and treatment of the infected; observation and control of movements of the exposed; vaccination and/or prophylactic treatment of the exposed; destruction or disinfection of animals, goods, and premises; extermination of disease vectors; and active case-finding and investigation are all now used to control the spread of contagious diseases.

We use governmental police power to ensure compliance with these control measures. In each state in the United States, specific statutes define the limits of the state's authority. As the views of civil liberties have shifted, the authority to impose quarantine became more limited and procedural safeguards were put in place. Many states revised public health statutes to codify the necessary procedures. In the first 5 years of the twenty-first century, many states revised statutes concerning emergency powers of the state in the event of terrorist attacks. The revision process has brought issues of civil liberties and the use of police powers to control the intentional introduction of infectious disease into sharp relief. Each state resolves the tension a little differently.

CURRENT PRACTICE

Quarantine measures are undertaken to separate sources of infection from susceptible populations. The same measures may be useful when extended beyond infectious agents to radiologic sources and toxic agents in terrorism incidents and mass disasters. Throughout our statutes there is a preference for voluntary cooperation with control measures, coupled with authority to enforce control measures when necessary.

In many statutes and descriptions, the terms *isolation* and *quarantine* are coupled. However, we can distinguish *quarantine* as control measures applying to those exposed to the agent of concern, and *isolation* as control measures applying to those known to be infected and capable of transmitting the agent. Thus, quarantine is the more expansive concept, applying to those who are not sick or even infectious at the outset. Isolation may require the more restrictive measures, since those persons are known to be infectious to others. In a population under quarantine, those who become infected and capable of transmitting disease need to be isolated from those who are exposed but may not be infected. In healthcare institutions, these distinctions become particularly important in sustaining the viability of the institution.

The general measures of quarantine include restriction of movement, periodic examination and testing, requirement of prophylactic treatment, closure of premises, and destruction of animals or goods. These are frightening concepts to many, especially in times of civil disorder related to terrorism or mass disasters. During an epidemic or after a terrorist attack, very large populations or geographic areas could be subject to quarantine measures, adding to fear and panic. Clear communication of the reasons for and the terms of quarantine measures are essential. The goals of actions include establishing trust that healthcare professionals and the government are taking the steps needed and applying them in an equitable manner. The clinician can play a role in controlling panic and gaining cooperation among the public in controlling spread of the agent.

In imposing quarantine in response to a terrorist event or a disease outbreak, we must emphasize voluntary compliance with quarantine measures, and we must use the least restrictive measures likely to be effective. The quarantine actions needed depend on characteristics of the biologic agent, the people and animals at risk, and the local environment. The quarantine officer has to use the best available evidence on the biologic agent; the time, place, and route of exposure; and the resources at hand or en route. The quarantine plan must establish a rapid, safe, and efficient means of determining who has been exposed, when they were exposed, and what their current health status is. The plan must set out the options for control measures and surveillance. The plan must also provide for reassessment and adjustment as new information is acquired.

To initiate quarantine, one must establish that there is a risk of transmission of an infectious agent so significant that liberties must be restricted, and that the specific measures imposed have a likelihood of preventing transmission. In the early stage of responding to a biologic attack, there may be little confirmed data and substantial confusion. The quarantine officer should set the decision parameters for control measures based on what is known and what is suspected. The most restrictive approach is reserved for infectious diseases known to be effectively transmitted from person to person by airborne, droplet, and fomite routes, such as plague, smallpox, severe acute respiratory syndrome (SARS), and measles. If exposure to these is suspected, the initial determinations of exposure and infectiousness should

be very sensitive, tolerating a high false-positive rate. As better data are obtained, adjustments in sensitivity follow.

In designing the screening system for determining who is infectious, who has been exposed, when they were exposed, and what their current health status is, consider the number of people to be examined, the time-frame necessary for controlling a particular infectious agent in the circumstances, and the risk that additional exposure to the agent could occur. Choose sites and facilities that can meet the security needs (e.g., access, parking, crowd control, and containment) that will protect vital healthcare assets and that will not interfere with other essential response actions. Consider the relationship between the quarantine functions and the population-wide actions such as mass immunization that may be planned.

The examination area should be set up to provide infection control, confidentiality, personal privacy, good lighting, and efficient movement of subjects and examiners. Design may vary substantially depending on the putative agent (e.g., addressing risks of contagion or dealing with potential symptoms such as vomiting, diarrhea, or skin lesions) and the numbers and skills of examiners. In a setting with few physicians, physician assistants, and nurse practitioners, history-taking and initial examinations may be completed by nurses, with clinician backup when a more detailed examination is required of those with “positive” findings or symptoms. Skilled volunteers, such as retired health professionals or student health professionals, may be recruited as well.

The first step in determining the need for isolation and quarantine is the finding of a history of exposure to an infectious agent that is transmitted from human to human or from animals or goods to humans. The interviewer needs a clear understanding of the parameters of exposure to make a determination that a person or animal is exposed and therefore subject to voluntary or involuntary quarantine measures. Confirmation of movements and actions that place the person or animal in proximity to the infectious agent is particularly important. The likelihood of exposure due to proximity varies with the nature of the agent and the exposing event.

People who are already terrorized will have difficulty determining exposure for themselves, so careful history-taking is essential. More than one question should be planned for each critical item to detect errors and dissimulation. The interviewer should clarify any contradictions and make a decision on what exposure, if any, has occurred for each person or animal. When obtaining information about a third party, such as a child, the interviewer should determine whether another person has information that needs to be considered.

If the putative exposure is to infectious persons or animals, the history must include all interactions within the longest period of infectiousness, not just the most recent interaction or the interactions after symptoms have developed. If the putative exposure is the result of being in a place, exact locations, times, and activities are important facts.

Quarantine measures restrict fundamental liberties. The decision needs to stand up in legal proceedings, yet

be efficient. History-taking forms that facilitate the recording of the key decisions will provide evidence and aid efficiency. The form should ensure that details about the exposure are recorded and that extraneous information is minimized. Recording exact answers enhances both the interviewer’s decision record and the interviewee’s understanding of exposures.

In attacks with very short exposure-to-symptom times, such as some poisons, toxins, or radioactivity, the history of exposure may be very limited, essentially addressing opportunity. Assessing vital signs and detecting symptoms becomes the central concern in such exposures, with prompt decontamination often the action of choice. Once it is determined that the risk of transmission is minimal, full attention is directed to treatment.

Once it is determined that a person or animal has been exposed to an infectious agent transmissible to others, the next requirement is an initial physical examination. The objectives of the initial examination include the following:

- Establish the current state of health
- Determine whether any symptoms of exposure to the putative agent(s) are present
- Determine a prophylactic management plan
- Establish the baseline for monitoring during quarantine
- Determine the level of restriction necessary to prevent further spread of the disease

Accurate recording is critical because of the legal concerns about quarantine. The administrative or judicial reviewer will need these data in assessing the quarantine measures imposed. Change in health status during prophylactic treatment and quarantine monitoring is critical to decision-making on isolation, further control of movement, and initiation, change, and discontinuation of treatment.

In addition to eliciting the current state of health, the examiner should determine the presence of health factors that increase the risk of infection (e.g., immune compromise, organ transplants, medications) and the presence or absence of symptoms of the putative agent. Allergies, medication use, and other possible contraindications to vaccine or prophylactic treatment should be elicited as appropriate to the circumstances.

The examiner should verify critical vital signs, most importantly the presence or absence of fever. When the putative agent causes shock or collapse, blood pressure should be monitored during the examination process. Determining the presence or absence of specific symptoms indicative of infection or contagion is the first task. This information is critical in protecting all persons being examined as well as examiners. The time of appearance of signs and symptoms of infection is essential in subsequent decisions regarding prophylaxis, immunization, and infection control.

Control of Individual Movement

The actual conditions of quarantine and isolation depend on many factors. The nature of the putative agent, how communicable it is, the initial symptoms of disease, the contagious period, and the routes of transmission all influence the decisions. Ordinarily, these decisions will be made by the local or state public health authority

and communicated to all examiners along with specific authorization to make quarantine and isolation decisions. The goal is voluntary compliance with necessary precautions. Many jurisdictions require a court order to initiate or enforce restrictions of movement or confiscation of property. If civil authority is seriously disrupted, local physicians may be faced with making decisions in a vacuum (see Pitfalls section).

The primary purpose of quarantine is to separate the unexposed population from the exposed population to prevent future exposures. The unexposed may be instructed on protective measures. In some circumstances, unexposed persons may be offered immunization or prophylactic treatment. A clinician acting in an individual capacity may be requested to provide vaccines or medications to unexposed persons not subject to past or likely future exposure (see Pitfalls section). For example, in the event of a smallpox outbreak, health authorities could decide to immunize whole populations if the resources were sufficient to do so without jeopardizing the protection of those already exposed or infected. More frequently, healthcare workers, caretakers of animals, and family members of persons under quarantine are candidates for prophylaxis by vaccine or medication.

Exposed persons and animals without signs or symptoms of infection are subject to quarantine. The nature of quarantine measures is dependent on characteristics of the agent and the outbreak, the cooperation and resources of the persons, the ability to confine or control animals, the capacity of the authority to monitor quarantine, and the level of risk of wider infection. For exposed *but not yet infectious* persons who can be monitored, confinement is often unnecessary. This strategy is dependent on early detection of infectiousness. The advantage is that individual liberty is only minimally compromised. The disadvantage is that maximum cooperation and significant monitoring is essential to detect "becoming infectious." The infectious agent involved is critical because a person may be infectious before symptoms appear or during a nonspecific prodrome. Many state quarantine laws prescribe the use of the least restrictive quarantine measures (Box 68-1).

Those who fail to observe the conditions of quarantine are subject to court-enforced orders of confinement and/or treatment. In a large-scale event, quarantine orders may be presented to all persons under observation, all persons receiving vaccines or prophylaxis, or all caregivers of infected persons to secure compliance and to provide the basis for enforcement action in the event that cooperation is lost.

Those who develop evidence of infectivity or contagiousness are subject to isolation and more stringent confinement. Conditions of isolation may include confinement at home (with or without additional precautions); confinement in a particular facility or unit; or restrictions in employment, public activities, etc. The isolation and quarantine of infectious persons must be maintained until the risk of transmission is *de minimus*. Isolation and quarantine may include requirements for treatment or immunization, and compliance with requirements may be relaxed once treatment is under way or immunization is effective.

BOX 68-1 EXAMPLES OF QUARANTINE MEASURES FOR DIFFERENT CIRCUMSTANCES

- Current evidence indicates that SARS is not spread by asymptomatic persons, but once fever develops, transmission may occur. Healthcare workers caring for SARS patients may be allowed to continue working and moving from home to work as long as fever is monitored at every shift. Persons exposed to SARS may be allowed to continue living in the community on daily fever monitoring with no restriction unless fever appears. Quarantine measures requiring confinement are imposed when fever is detected and remain in effect until the person is determined no longer infectious.
- Salmonella can be transmitted by anyone shedding the bacteria in stool. Most people with salmonellosis are advised to use proper hygiene measures to interrupt fecal-oral transmission. Because the interactions of small children increase fecal-oral transmission risks, children may be excluded from daycare settings. Inpatients are subject to enteric precautions to reduce transmission risks in institutions with many vulnerable patients. Because hygiene measures are often not followed, food service, childcare, and healthcare workers with salmonellosis may be excluded from working in food service or with young children or vulnerable patients until two consecutive stool samples collected 24 hours apart test negative for salmonella.
- If a bioterrorist or natural outbreak of severe, febrile respiratory disease is suspected, but no source has been identified, any person with fever and lower respiratory tract disease is suspected as a source of exposure until more information is obtained. Hospital emergency departments are required to set up isolation care sites and conduct any such patient directly to those sites for evaluation. Those requiring admission are isolated with respiratory precautions. Those not requiring admission are ordered into home confinement. All personnel in the chain caring for these patients are using personal protection equipment and are monitored on each shift for fever. Visitors and other staff at healthcare facilities are required to have their temperatures taken prior to admittance to the facility to protect patients and staff.

In a large-scale event, or when travel is interrupted (e.g., an airplane exposure) or people are dislocated (e.g., a flood), quarantine measures must include providing alternate shelter for people in quarantine. Shelter provisions must provide a means to segregate infectious persons under conditions of isolation as required. In planning for a response to a smallpox bioterrorism attack, many communities considered what facilities would be needed to house those being monitored and those being isolated and treated. Recent outbreaks of SARS and monkey pox have demonstrated the need to protect healthcare facilities and healthcare workers and the importance of quarantine measures that allowed early detection of second- and later-generation cases.

We have effective vaccines for some potential agents of bioterrorism and for many epidemic infections. Some vaccines are effective after initial exposure, either preventing

or modifying the disease and influencing the potential for contagion. In the case of smallpox, for example, intensive efforts to identify and vaccinate all contacts were the control measures that led to eradication. If a vaccine is available, persons or animals exposed but without active disease should be immunized. Other control measures, such as fever watch, exclusion from school or work, and/or periodic examinations must continue until a vaccine take is evident or a full incubation period has passed (Box 68-2).

Prophylactic treatment is used therapeutically to prevent the appearance of disease in a person or to modify its course. Prophylactic treatment may be effective in controlling the spread of infectious disease by preventing individuals from becoming infectious. If exposed persons receive prophylactic treatment, the quarantine measures should be modified to address any potential for transmitting infection without manifesting signs and symptoms. Surveillance may be directed to determining completion of the prescribed prophylaxis and reinstatement of controls if compliance is incomplete (Box 68-3).

Travel in airplanes, ships, trains, and buses where an infectious agent is thought to have been released or where a person with an infectious disease is identified presents special considerations. In the initial investigation period, groups of people thought to have been exposed to an infectious agent with a short incubation period may be detained for examination. The purpose of the quarantine is to determine whether any others are infected and to initiate surveillance of exposed persons. Attention should be directed toward making a decision about the index case as quickly as possible while the necessary examination of all others is taking place under infection control precautions, reducing both the risk of further exposure among the passengers and the risk of exposing other populations. The responsible jurisdiction may have

BOX 68-2 EXAMPLES OF VACCINE-RELATED QUARANTINE MEASURES

- Unimmunized children exposed to measles are excluded from school until one full incubation period after the last case. Children who accept immunization with live virus vaccine within 72 hours of exposure or with immune globulin within 6 days of exposure may return to school. Children immunized outside these timeframes are excluded from school until a full incubation period from the last exposure of that child has passed.
- Persons exposed to smallpox without fever or exanthemata may be vaccinated and continue normal activity while being monitored until a vaccine “take” is ensured (discharge from quarantine) or until fever and/or skin lesions appear (isolation required).
- Immunized domestic and farm animals exposed to rabies are revaccinated and confined for observation if owners are willing and able to restrict the animal’s contact with other animals and humans until an incubation period has expired. Unimmunized pets have to be quarantined in a controlled facility for 10 days, observed for onset of illness, and if well, vaccinated before being released from quarantine.

BOX 68-3 EXAMPLES OF PROPHYLACTIC TREATMENT AS QUARANTINE MEASURES

- Persons with household and face-to-face contact to pneumonic plague and those exposed through a terrorist act should receive prophylactic antibiotics as quickly as possible and be placed under surveillance for 7 days. If unprotected exposure continues, prophylaxis may need to be extended. Those who refuse or cannot receive prophylactic antibiotics must be placed in strict isolation and monitored closely for 7 days.
- Persons with tuberculosis may be required to remain isolated until antibiotics have effectively sterilized the sputum, at which time isolation ceases, but directly observed therapy continues for the full course of treatment.

responsibility for housing, feeding, and treating persons so detained. Although these are often international quarantines conducted by the U.S. government, not all such instances involve international travel (Box 68-4).

In an unfolding epidemic or outbreak, whether natural or manmade, control of movements of populations is challenging. Restricting the movements of large numbers of persons may quickly defuse an outbreak. However, confining people who will soon become infectious with others who have not yet been infected may increase the opportunities for contagion. A rapid response may encourage compliance with measures to provide large-scale prophylaxis and reduce panic if it is perceived as equitable and reasonable. The same action may interfere with compliance and increase panic if it is perceived as inequitable or poorly understood. Priorities must be set based on local laws and conditions, the infectious agent and modes of transmission, and national and international regulations.

Trust is a vital commodity. If the required restrictions are short term and involve options for treatment and/or immunization, then voluntary compliance is significant. During the 2003 SARS outbreak in Toronto, Canada, only 27 written quarantine orders were required.³ Even in the face of the unknown, compliance with measures perceived as reasonable can be high. As a situation drags on, issues become more complex, and maintaining compliance with complex regimens of disease control is more difficult.

PROTECTING COMMUNITY ASSETS

Critical issues need to be addressed to protect vital community assets. Key assets among these are healthcare institutions, schools, businesses, and agriculture and food production.

Healthcare Assets

Infected, exposed, and unaffected persons mingle in healthcare settings. In addition to promoting strict isolation of infectious persons and the adoption of stringent

BOX 68-4 EXAMPLES OF TRAVEL-RELATED QUARANTINE MEASURES

- A child on a long airplane trip may develop symptoms suspicious of measles. Data must be collected on the immunization status and current health status of all travelers. Data on the seating arrangements and movements about the plane of the child and other occupants are useful. Immunization can be provided to any unimmunized person. If immunization is unavailable or refused, detailed contact information for the next 3 weeks for any susceptible person is collected, as is precautionary information.
- In a more complex scenario, the diagnosis of measles is made after the debarkation and airline manifests must be used to find and notify fellow passengers.
- Travelers with suspected SARS provide recent examples. Temperature screening at embarkation and debarkation of travelers from areas with reported cases provide an opportunity to detect cases before passengers are dispersed to many destinations. The quarantine officers need data to decide whether to detain any passengers if there is a suspected case. Data are collected on the body temperature, the current health status, the seating arrangements, and movements about the plane of all travelers. Detailed travel plans and contact information for all nonfebrile travelers for the next 10 days are obtained in some instances. Before release from quarantine, travelers receive “fever watch” instructions and directions to report to medical care if fever develops.

infection control measures in emergency departments and hospitals, quarantine measures may include cohorting of patients and healthcare workers among institutions to reduce the introduction of infection into all institutions. Hygiene and barrier protection for staff, patients, and visitors should be considered. If the numbers of infectious patients overwhelm the isolation capacity of hospitals, setting up separate temporary facilities to care for infected persons may be used in outbreak control.

Measures to protect physician offices and clinics are very important. Hygiene (e.g., handwashing, equipment disinfection), barrier protection (e.g., gloves and masks), and isolation spaces (e.g., separate rooms or entrances) can increase safety in the office setting. Some examples of other important protective measures include the following:

- Telephone screening
- Home visiting
- Redirecting symptomatic patients to special facilities
- Reducing waiting times in communal areas
- Isolating symptomatic patients from other patients

Long-term care facilities serving the vulnerable and frail may be required to reduce movement in and out, limiting or prohibiting visitors, or monitoring the health of staff and visitors. Where feasible, long-term care and childcare facilities should immunize new admissions.

Schools

In a crisis, many parents declare that their first action will be to collect their children from school. Schools may be needed as space to provide mass distribution of prophylaxis or shelter for persons displaced by the outbreak or related events. On the other hand, schools provide a structured environment for children where they can be monitored for early signs of infection and receive directly observed prophylaxis. Daycare and alternative childcare arrangements present the same infection control issues as any congregate setting.

School events may involve only the children in a single school, and decisions on cancellation can be based on the health status of children in the school. Other events involve multiple schools, and decisions should be made on the basis of the health conditions in the wider community. We tend to be more ready to restrict school-related events than other mass gatherings, but the same considerations should apply to any mass gathering involving children.

Travel

The travel of infected persons may be governed by international regulations. In the event of a bioterrorism event or a large outbreak, instructions to exposed persons to postpone travel, to report to surveillance authorities, or to undergo directly observed prophylaxis or therapy may provide effective quarantine. Travel restrictions of this type may interrupt travel in mid-journey, creating a necessity for safe shelter and medical supervision. Private vehicle travel from an affected to an unaffected area by potentially infected persons is more difficult to control. If civil authorities are busy with law enforcement investigations and emergency response actions, the work of enforcing a quarantine of individual travelers may be left for the destination jurisdiction.

Mass Gatherings

Organized mass gatherings such as concerts, movies, and athletic events may be canceled based on the health conditions in the community. Conditions to be considered are the infectious agent and expected transmission routes, the number of exposed persons in the community, and the level of response to infection control measures.

Mass prophylactic treatment or immunization clinics present special cases of mass gatherings, where careful attention to identifying and promptly isolating infectious persons is vital. All mass clinics must be designed to reduce the risk of contagion, identifying potentially infectious persons and isolating them at the earliest possible time.

Business

During the SARS outbreaks in 2003, some businesses were closed because of infected workers failing to follow quarantine requirements. A larger number of workers were quarantined and kept from the workplace. In some cases, governments made special arrangements for compensation of those unable to work because of quarantine requirements.³ The potential for airborne transmission of the virus led to more stringent control measures than would be used if closer contact were required for transmission. Fear of contagion among coworkers may force closures even when exposed persons have followed quarantine instructions.

Individual businesses may be subject to quarantine because of other sources of infection. Warehouses, shipping businesses, and post offices may require quarantine because of contaminated goods. More difficult decisions involve marketplaces where vital goods are procured. In the 2003 SARS outbreak in Singapore, the government closed an entire marketplace because an infected person failed to obey the quarantine order.³ With airborne infections, transmission can occur in the supermarket or the mall. In general, emphasis on the control of the movements of infected persons may be more effective than closing the marketplace.

Agriculture and Food Production

A number of the important epidemic and bioterrorism agents can compromise food production even without directly affecting humans. Agricultural and food production may be curtailed because of infected or contaminated animals or plants. Animals exposed to infected animals present major quarantine problems. Issues include protection of other animals from direct exposure, prevention of contamination of the environment, protection of agricultural and food industry workers, and protection of the food supply. When domestic animals are involved, agricultural and public health authorities are consulted. Depending on the pathogen, the animals in a herd may be quarantined or destroyed. While decisions are pending, healthy animals need to be segregated from diseased animals. No movement in or out of an exposed herd can be allowed. Movements of people, equipment, vehicles, and other fomites must be controlled.

Destruction of animals can create additional hazards. Worker protection and carcass disposal methods must be designed to minimize exposure to the agent and prevent environmental contamination. Substantial investigation is needed to determine the breadth of quarantine by geography and species. Transport equipment and downstream food products may also be subject to quarantine.

Goods contaminated with transmissible biologic agents must be decontaminated or destroyed. While decisions are made about the actual contamination, quarantine measures to prevent access to or movement of the goods must include protection from human, animal, and environmental exposures, depending on the agent involved. All equipment used must be tracked in the event that destruction or decontamination is required.

PITFALLS

Balancing Civil Liberty with Quarantine

Quarantine and isolation restrict our civil liberties. In most healthcare settings, voluntary cooperation is sufficient, particularly when a patient is benefiting from treatment and shares in the effort to protect others from illness. In keeping with civil rights, the principle of “least restrictive measures” to protect the public is used, but the threat of law enforcement underlies these measures.

In the 1980s, the AIDS epidemic occasioned much discussion of the use of quarantine. Procedural changes were made in statutes in many jurisdictions to establish legal process to protect liberties. In the 1990s, concerns about confidentiality and privacy were prominent, placing real and perceived barriers in the way of reporting infectious disease and communicating about contacts to infectious disease. In the first decade of the twenty-first century, concern has turned to recognizing and containing terrorism. The law reflects these competing concerns and continues to change.

Advance planning for quarantine and isolation measures in various situations will help, but the decisions about a specific event are made with limited information under significant pressure. We must initiate action based on a high degree of suspicion and then narrow the response action as data improves. With the media leaning in and the lawyers poised, we still must use the most sensitive indicators available, risking false positives initially. In these circumstances, attention to equity and form is vital. Record-keeping and consistent reevaluation of circumstances, knowledge, and decisions are essential.

Obtaining Compliance

“Quarantine is a preventive measure and not a punishment”⁴ is an important reminder. The goal of the effort is to prevent the spread of disease and minimize terror and civil disruption. Good information repeated often is an essential component of the disease control effort. So is the appeal to duty, to concern for the community, and to self-preservation. Issues of compensation for lost wages, care for family members, and similar concerns of persons subject to quarantine cannot be ignored if we are to be successful in meeting the goal. Especially under the pressure of terrorism and demands for action, it is easy to move to coercive measures when appeals to finer instincts would gain much compliance. This can be self-defeating because people fearing confinement go underground and spread disease because they have taken none of the desired prevention measures.

Attention Fatigue

Healthcare professionals are notorious for inattention to infection control. Constant vigilance is necessary to maintain quarantine, isolation, and infection control measures throughout an epidemic. Initial disbelief, even if scientifically justified, can lead to a low index of suspicion. Even when an attack has occurred, attention to infection control wanders. After the first cases of deliberate anthrax

infections in 2002, many people took envelopes and packages containing white powders to police stations and emergency departments. Many became complacent after a few negative swabs and a few pranks. If one of those had contained anthrax spores, more people could have been exposed and infected. Hospital emergency departments could have been closed until the spores could be removed.

Communications

Single cases and a few contacts are a familiar problem for clinicians. Whole communities present many new stresses. Healthcare workers become key communicators to keep disease in check without undue disruption of civic and personal life. We are not all comfortable with this role. At the very least, the healthcare professional must be prepared to present findings and their significance for contagion clearly, to convey expectations to patients and those under quarantine, and to negotiate with those enforcing quarantine.

The physician or other healthcare worker making a quarantine decision must have clear authorization from the appropriate jurisdiction to do so. If civil authority is seriously disrupted, local physicians may be faced with making decisions without clear delegation. Consultation with the available law enforcement leadership is essential in such circumstances. The healthcare professional must create a record of data and decisions that will be available for subsequent civil court decisions.

Effective quarantine requires cooperation among the medical community and the affected populations. Clear instructions and information about the options available are essential. Threat of enforcement action provides an incentive to cooperate with restrictions on freedom. In every instance, we need to balance police action with the economic and social consequences. Judicial procedures may be especially important in bioterrorism because of the need to conduct law enforcement investigations and handle potential criminals in the health system.

Quarantine measures include ordered examination, treatment, and vaccination. Healthcare workers may need to be deputized to carry out these functions. Unwilling or uncooperative patients present additional threats. Practitioners need to be prepared to deal with law enforcement officers and to support them in handling difficult, potentially infectious patients.

Physicians, nurses, and other healthcare workers may be called on to put themselves in harm's way by working

with infectious persons. Once exposed, healthcare workers may be restricted to working with the infected, or not at all. Developing quarantine health facilities to care for the infected and sick presents an ongoing risk to healthcare workers and their families and may require additional limitations on liberty.

Physicians can expect a lot of questions about protecting self and loved ones from patients and the community. Should I leave the area; keep my kids from school or other activities; go to work? Do I need treatment, vaccines, or a prescription? In an unfamiliar situation, and with personal concerns of a similar nature, physicians need a framework for collecting essential information and providing useful advice.

Conflicting Goals

Physicians are accustomed to placing the needs of each individual patient first. Making decisions to require treatment or to refuse treatment to patients with lower-priority needs places a physician in a new relationship with patients. The new relationship presents ethical dilemmas, yet the pressure of the emergency situation leaves little time for reflection and consultation.

Many of the pitfalls result from this conflict in goals. Difficult decisions in preventing the spread of communicable diseases stem from the need to balance personal liberty and community protection. The decisions are made in the context of uncertainty. A high index of suspicion leads to more prompt decisions and more emphasis on protection of the community. To keep faith with the demand for liberty, quarantine decisions need to be reviewed frequently. Clear expectations of the length of quarantine and the accompanying disease control steps must be explained to the patient. *Maintain trust in the face of insecurity and uncertainty.*

Chemical Decontamination*

Barbara Vogt Sorenson and John Sorensen

Decontamination is defined as the reduction or removal of chemical (or biologic) agents by physical means or by chemical neutralization (detoxification) so agents are no longer hazardous.¹ The major objective of decontamination of victims exposed to a hazardous chemical is the prevention of further harm and the optimization of the chance for full clinical recovery.² An important secondary objective is to avoid spreading contamination to others and the healthcare facility (HCF). Although accidents from the manufacture, storage, or transportation of chemicals account for most instances of patient contamination, HCFs must now anticipate the intentional use of chemicals (including chemical warfare agents) to potentially contaminate large numbers of victims who may enter the facility individually or en masse with or without prior decontamination. This chapter focuses on the decontamination of patients/victims exposed to chemical warfare agents before entry to an HCF and the issues associated with preventing secondary or cross contamination of healthcare providers and their facilities. Also discussed are the problems associated with treating contaminated patients while wearing personal protective equipment (PPE).

Chemical agents exist in liquid, solid, or vapor form, with inhalation of vapors being the most likely route of exposure. Depending on the chemical's characteristics, physical properties, and exposure pathway, treatment for chemical warfare agent-contaminated patients is similar to other chemical casualties in the HCF environment. Terrorist-induced events are likely to result in psychological as well as physical harm. This is because a chemical attack would likely occur without warning, with an unknown substance, and in a location where large numbers of people are present or likely to pass through. These "outrage" factors elevate the perception of risk and fears for one's safety.^{3,4} Other factors—a sense of helplessness and fear of unknown consequences from the exposure to oneself and others—may also result in large numbers of the "walking wounded" converging on an HCF without prior decontamination.

Given the covert measures usually employed by terrorists, healthcare providers should routinely be alert for signs and symptoms of contamination on patients and take immediate steps to protect themselves and their facility from becoming secondary victims. This means that facility managers, especially emergency department directors, should communicate early with first responders about unusual incidents to ensure prompt notification about any potentially contaminated patients. The same personnel should have the authority to lockdown the HCF and reroute response teams and self-presenting victims to appropriate decontamination areas.

Decontamination is generally the task of first responders (e.g., firefighters and hazardous materials [HazMat] teams) trained to use PPE and to process victims through decontamination units at the site of the chemical release. After an accidental release, the chemical's characteristics (including toxicity, persistence, and health effects) are frequently known through information on material safety data sheets or from managers or employees at the release site. In a terrorist event, on the other hand, the chemical substance will likely be unknown, the dose uncertain, and the consequent health effects undetermined. If the victims include children and infants, input from pediatricians and poison specialists will be needed. All victims will require debriefing (even if the chemical agents remain unknown at the time) after decontamination and treatment.

Field decontamination procedures are carried out in both rural and urban settings by full-time first responders or part-time volunteers with or without special equipment or training. Field decontamination of the potentially exposed often occurs as a precautionary measure, especially when health effects are unclear. Working with the hypothesis that removal of clothing reduces the majority of contaminants, most field decontamination efforts involve clothing removal and showering either in a special decontamination unit (e.g., trailer on expedient setup) or by hosing off from firefighting hoses.⁵ The objective of field decontamination is to transfer a clean victim to an HCF without contaminating the conveying vehicle or exposing others. Given the large uncertainty of field decontamination effectiveness, most victims undergo another round of decontamination at the HCF to ensure the level of cleanliness needed to protect the facility, an issue that has prompted many complaints from victims. However, it is essential that the

HCF be able to lockdown as soon as the potential for contaminated victims arrival is detected to protect critical assets such as healthcare providers, the HCF, and the existing patient population.

The most important element of treatment after exposure to a chemical warfare agent is to immediately remove the agent through decontamination. Decontamination that is delayed or ineffective can escalate the number of casualties when very toxic substances, such as nerve agents, are involved. If injuries are life threatening, victims are sometimes transported with minimal attention to the decontamination unit before arrival at the HCF. This problem can be exacerbated if communications between the field response units and medical facility fail to describe the event so the HCF can take advance precautions, such as suiting up personnel in PPE, performing lockdown, and initiating decontamination setup. In a terrorist event, the number of victims transporting themselves to emergency departments could quickly overwhelm resources, as happened in the Tokyo subway incident.⁶

Treating a chemical warfare agent-contaminated patient is similar to handling patients contaminated by other hazardous chemicals, such as organophosphate pesticides, and requires similar precautions. Over 95% of surface contaminants can be eliminated by removing clothing and showering.⁷ Although the process is well known and easy to accomplish with ambulatory victims, injured patients require increased numbers of personnel and resources to perform decontamination.⁸

The three primary types of decontamination important to the healthcare provider are as follows:

- Personal decontamination (i.e., self- or buddy decontamination when one is exposed)
- Casualty decontamination (i.e., decontamination of casualties), and
- Personnel decontamination (generally, decontamination of noncasualties).

Personal decontamination may or may not involve PPE.⁹ More often, personal decontamination (i.e., disrobing and bagging clothing, then showering with copious amounts of soap and water) is needed after an unprotected healthcare provider is exposed while caring for a contaminated patient who presents to an emergency department without alerting the admitting staff. If PPE is worn, all equipment including outer garments, gloves, boots, and respiratory apparatus should be decontaminated after removal. This will avoid the unnecessary cost of replacing expensive and individually fitted PPE. Healthcare providers should also be instructed in the proper donning and doffing of PPE to prevent exposing themselves or others to contaminated clothing surfaces.

Decontamination of chemical casualties and other exposed personnel requires a substantial outlay of resources and personnel.^{10,11} Not all decontamination efforts will involve healthcare providers directly because HazMat teams are the general providers. However, medically trained personnel should provide overall supervision. The decontamination of each person should be monitored for adequate removal of agents and not left to the subjective evaluation of victims, especially children.^{12,13} This process requires sensitivity and tact when

handling civilian casualties, especially in the stressed environment of the disaster aftermath.

Decontamination Solutions

Many substances have been evaluated for their ability to remove contaminants from the skin. Compared with washing the skin with copious amounts of soap and water and irrigating the eyes with clean water, most have been found lacking. The most common problems are skin irritation, toxicity, ineffectiveness, and high cost. Although the military has used substances (such as special wipes) to determine whether the contaminant is removed, most healthcare providers must rely on subjective evaluations to assess decontamination effectiveness.

Disposal of contaminated solutions from decontamination of victims should follow the same procedures as disposal of other hazardous materials. If the contaminant is unknown or is suspected as benign at the time of decontamination, precautions such as holding secured drums of solution until a definitive result is obtained from later laboratory analysis can save the considerable expense of sending the wastewater to a HazMat disposal site. The U.S. Environmental Protection Agency (EPA) notes that in special circumstances where the protection of populations is critical, contaminated water from decontamination can be diverted to storm sewer or sanitary disposal.¹⁴ Although this is likely not an option for persistent biologic agents, most chemical agents would likely be dispersed in this way without causing further harm.

It is often assumed that normal decontamination procedures are performed outside the emergency department by trained HazMat personnel. However, during an emergency, those same providers will likely be involved in search and rescue activities, with decontamination of exposed victims a low priority. Many victims will likely self-evacuate to the nearest medical facility without advising emergency department personnel. After the Tokyo subway release of sarin, it is estimated that more than 10,000 victims presented to medical facilities on their own without any form of decontamination before arrival.⁶

Secondary Contamination

Because of the potential for secondary contamination, it is essential that medical personnel understand the need for and undergo training in the actual use of PPE. Surgical masks are not sufficient to protect against hazardous vapors from a contaminated patient's fluids or body parts.¹⁵ This is also a problem if the contaminant was purposely ingested and regurgitated in vomitus. Some persistent chemical warfare agents are not immediately symptomatic or visually evident on patient's skin, hair, or clothing. For example, sulfur mustard is a persistent oily substance producing signs and symptoms that can be delayed for 2 to 24 hours after exposure. It is also important that deceased victims of chemical agent events (even in body bags) be decontaminated prior to release to prevent secondary contamination of unsuspecting forensic or funerary workers.

A serious issue regarding chemical agents is the general absence of criteria to determine the effectiveness of decontamination efforts. Field decontamination performed by

HazMat personnel is generally considered gross decontamination and should not be considered adequate for admitting patients to a medical facility. This is a serious problem if the medical facility has not planned for decontamination of patients being admitted and healthcare providers respond without determining the cleanliness of patients.^{16,17} Reports of emergency departments being closed for several hours after healthcare providers were sickened by fumes from patients only field decontaminated suggest this could be a very real problem in large-scale disasters. Not only would the loss of healthcare providers create difficulties, certifying that the HCF was clean enough to reopen could take several hours or, in the worst cases, several days. One HCF found changing out filters in the cleaning process on a Friday required specially ordered filter media, and the supplier did not work weekends. Only after action by the state's health officer did the supplier comply with the request. In a major disaster that disrupts normal infrastructure channels and communications, deliveries could be delayed for several days.

Chemical agents that might be used in a terror event include a wide variety of substances, ranging from chemical warfare agents such as nerve and sulfur mustard agents to riot control and choking agents. (Some consider toxins such as ricin from the castor bean plant a chemical derivative, but most authorities characterize toxins as biologic agents because they are derived from living matter.) The individual chemical's characteristics and mode of release and the victim's own characteristics will determine how decontamination is performed. For example, most victims exposed but not symptomatic can accomplish decontamination on their own. But patients who are injured, wheelchair bound, elderly, or very young will require assistance. Decontaminating victims on litters often requires a team effort to coordinate the lifting required to move the victim from the dirty (hot) to clean (cold) zones.

An issue with most healthcare providers, especially in the emergency theaters, is the lack of training on wearing PPE while treating victims. Although PPE is becoming more available in emergency departments because of the Joint Commission on Accreditation of Healthcare Organizations' requirement to have an emergency response incident management system that is integrated with the community response system, periodic training in the actual use of equipment during patient treatment is still lacking. Having enough equipment for each person and providing the necessary training (8 hours for some PPE) is often restricted by budgets and the common misperception that a mass-chemical-casualty event will not occur in one's hometown. Since respirators must be fitted for individual use to prevent leakage around the face to protect the mouth and eyes, use of individual pieces of respiratory equipment by multiple persons is not acceptable. Each wearer must also be trained in the proper decontamination of the PPE and how to don and doff the equipment effectively. Otherwise, the facility, victims, and other healthcare providers will be placed at risk of secondary contamination.

Communication with patients and with other healthcare providers is difficult when wearing a full face-mask

respirator.¹⁸ Handling equipment and providing care is severely hampered when wearing the recommended 7 mL-thick gloves instead of the more common latex ones. Movements are often hindered by cumbersome outerwear, especially if the facility uses a common air line for the supplied air for respirators. Those who don't want to wear PPE and instead rely on common barrier practices should not be allowed into the arena because the threat of secondary contamination from victims is too serious to allow the practice. Appropriate training in PPE can alleviate the feelings of confinement and dread that often affect first-time users. Enacting policies and publicizing them within the facility will help eliminate those problems with noncompliant personnel during an actual event.

Specific stay and rest times while wearing PPE are mandated by the Occupational Safety and Health Administration (OSHA), especially in hot or cold environments. This adds to the total number of healthcare providers needed during the event. PPE and wear-time requirements dictated by state health authorities or OSHA may be more stringent than federal regulations and should be addressed in training sessions. Jurisdictional disputes over appropriate PPE and the training required should be addressed in reviewing yearly plans and in all Memorandums of Understanding (MOUs) and Memorandums of Agreement (MOAs) with other facility managers.

CURRENT PRACTICES

To prevent the spread of contamination, knowing when and how to decontaminate patients is critical. Decontamination usually requires multiple teams to fully decontaminate victims. Factors to be considered in planning for a decontamination facility at HCFs include the number of patients to be processed, the number of personnel in PPE needed, the frequency of rotating those personnel, and the availability of PPE for rotating shifts.^{19,20} This section discusses current decontamination practices at an HCF. This includes the physical layout of a decontamination area for handling both ambulatory and nonambulatory patients, mass decontamination techniques, and self/buddy decontamination procedures.

Physical Layout

Figure 69-1 shows one example of a casualty-receiving decontamination station. This can be situated in a field setting in an area safely distant from the accident site or at a hospital. The areas used for a station should be identified during the planning phase. A properly sited station will permit drainage from the decontamination process to be directed into a sump or a holding pond or container that can be emptied later during the recovery phase. The hot zone is the area considered to be contaminated. The cold zone is free from contamination. Plan for the cold zone to be upwind, uphill, and upstream from the hot zone. Walk-in patients and those who cannot be confirmed as receiving decontamination from a certified HazMat unit in the field go to screening and triage stations in the hot zone before proceeding

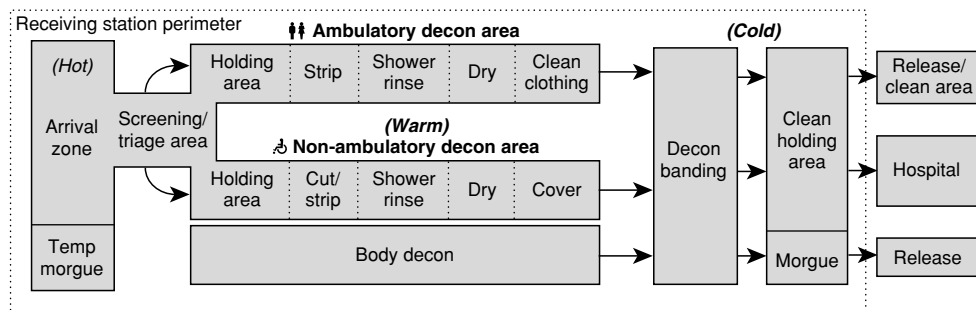

FIGURE 69-1. Layout of a decontamination station outside a healthcare facility. (From Federal Emergency Management Agency. *Don't Be A Victim: Medical Management of Patients Contaminated With Chemical Agents* [training video]. Oak Ridge, Tenn: Oak Ridge National Laboratory; 2003.)

through the decontamination line. Medical personnel should determine whether those decontaminated in the field should be decontaminated again or whether the patient can proceed directly to the triage area.

Site location and layout for decontamination should be predetermined and well known to operators. Maintaining secure perimeter control and clean work areas is important. All staff should be aware of the potential problems of cross or secondary contamination and should know how to process patients through decontamination stations. All of this requires planning and practice through live drills. At a HCF, the decontamination station could be temporarily set up in a parking lot outside the emergency department using a portable unit, or a more permanent decontamination facility could be constructed adjacent to the emergency department. Descriptions of permanent facilities are discussed by Macintyre and colleagues.⁸ Common features of most stations include separate lines for ambulatory patients and nonambulatory patients. Each is discussed in more detail below.

Ambulatory Patient Decontamination

The decision about who should proceed through the ambulatory line should be made by medical personnel. The “walking wounded” and others tagged *minimal* can usually be sent to the ambulatory decontamination area, where fewer personnel are needed to supervise the self-decontamination process.

Medical personnel may decide to decontaminate ambulatory victims' wounds and remove bandages before allowing victims to shower. Keep in mind that bandages can readily absorb liquid or aerosols, so passing a victim with bandages across the contamination control line to relatively unprotected personnel could create a secondary hazard. Open wounds should never be decontaminated with a normal soap-and-water solution. First, remove previously applied dressings and foreign bodies from the wound. Then, flush the wound and surrounding areas with water and a tincture of green soap. Carefully decontaminate around the wound by wiping outward, pack the wound, then seal with occlusive dressing before proceeding to full body decontamination.

Ambulatory patients should be instructed to remove all clothing and to bag personal effects. Contaminated clothing should not be removed over the head to avoid

their exposure to the eyes and mucous membranes, but should instead be cut away and discarded. The patient should then shower with copious amounts of soap and water from the head down, leaning the head back to reduce the chance of residue contacting the eyes, nose, or mouth. Encourage careful cleaning of warm, moist areas such as under the armpits and the groin, followed by a thorough overall rinse with clean water.

Once decontaminated, patients should don clean clothing—Tyvek disposables or scrubs work well. Patients then receive a standardized wristband indicating that decontamination has been completed and move to the cold zone staging area for screening and medical treatment. The best assurance a victim is free of contamination is certification of thorough decontamination. Most ambulatory patients will be capable of processing through the ambulatory decontamination lines, but some may need assistance. If possible, separate decontamination lines should be set up for males and females. When only two lines are possible, keep the second line for non-ambulatory cases, such as people with wheelchairs or walkers, those on stretchers, or anyone else requiring assistance or supervision.

Patients who were never in the path of a plume or in a contaminated area and who are without signs and symptoms of exposure should not have to be decontaminated. However, if some persons are still concerned about possible contamination, they should be instructed to remove the outer layers of clothing and take a quick 3- to 4-minute shower. Since much of the contamination, whether from liquid or vapor exposure, is completely removed by discarding clothing, that action followed by a rapid shower will likely eliminate 99% to 100% of the contaminant.

Nonambulatory Patient Decontamination

Nonambulatory patients displaying serious signs and symptoms of chemical exposure will be the first ones decontaminated in the nonambulatory area. Rapid decontamination is engaged, involving removal of clothing and a quick, high-volume shower focusing on exposed areas: skin and hair. This should take a maximum of 5 to 10 minutes per patient. Healthcare providers should follow universal precautions when treating these victims, and they may decide to more thoroughly decontaminate a patient if

severe signs and symptoms continue. Patients exhibiting moderate signs, or who have a confirmed liquid exposure, will be processed in the normal fashion once the rapid decontamination patients have completed the process. Those with minimal signs and symptoms will follow those with moderate exposures.

Normal decontamination of nonambulatory patients usually takes two to four staff members and 10 to 20 minutes. The casualty's backboard or stretcher should be elevated to limit the amount of runoff exposure to the patient. Each staff member focuses on a quadrant of the victim's body, perhaps using the waistline as a midline. Clothing is cut away or otherwise removed. Starting at the midline, spray or wipe the victim laterally or to the side or back of the victim. The sponge or brush used to decontaminate should be rinsed in the decontamination solution after each wipe. Once the front is finished, roll the victim to the side and proceed to decontaminate the back from the highest to lowest point.

Once the actual wiping process is complete, a liberal amount of solution should be used to rinse the patient, then the patient is dried. The process requires 35 to 50 gallons per patient, and fresh decontamination solution should be used for each patient. Once the patient is cleaned, roll him or her onto a clean stretcher or backboard and transfer across the hotline into the cold area.

Mass Decontamination

Alternatively, victims may be decontaminated in one or more groups; this is called *mass decontamination*. Chemical warfare agents can cause large numbers of casualties if dispersed in a vapor or aerosol, as manifested in the Tokyo subway incident. Such a situation could also occur in a high-profile event at a stadium, concert, or airport. The mass-decontamination process requires cordoning off several areas where a decontamination corridor can be set up with fire department aerials and/or deluge guns in close proximity. The nozzles are set at low volume so as not to inflict damage while maximizing the amount of water to which each victim is exposed. Ambulatory victims progress through the deluge so that they may be grossly decontaminated. In conjunction with removal of clothing, this will likely suffice to decontaminate those victims not exhibiting signs or symptoms of chemical agent exposure.

Another mass-decontamination method is to set up a sprinkler head near the exit point of the hot zone as a rudimentary decontamination shower. In this scenario, water delivered at 500 gallons/minute will produce 8 gallons/second. If the victim remains in the shower for 3 seconds on average, this equals 12 gallons—the amount used in a normal shower. In both scenarios, some clothing is left on, which reduces the effectiveness if vapor has penetrated to the skin.

Potentially contaminated runoff from mass-decontamination stations generally must be disposed of in compliance with local or state environmental regulations. The EPA has also published guidelines on this issue when conditions warrant otherwise.¹⁴ The agency concluded that based on the “good Samaritan” provision in Compre-

hensive Environmental Response, Compensation, and Liability Act, Section 107d, first responders should undertake any necessary emergency action to save lives and protect the public and themselves. Section 107d states that no person will be liable for costs or damages resulting from actions taken or not taken rendering care, assistance, or advice under the National Contingency Plan or at the direction of the on-scene coordinator. This does not preclude liability for damages resulting from negligence. The EPA recommends that once imminent threats to human life are addressed, reasonable attempts should be made to contain wastewater and prevent environmental insult.

Self- and Buddy Decontamination

If resources cannot be mobilized quickly enough to perform systematic and assisted decontamination, it is crucial to have a plan to instruct members of the public potentially exposed to a chemical agent to either perform self-decontamination or assist another to decontaminate (“buddy decontamination”). Instructions should inform people to remove and bag all clothing and personal items such as watches and jewelry and thoroughly wash with copious amounts of soap and water followed by a clean water rinse. People should then don clean clothes and follow official instructions. Eyeglasses can be decontaminated by soaking in household bleach and then rinsing with clean water. Although self- and buddy decontamination will not suffice for entry into the HCF it will minimize health impacts to the exposed person and help avoid cross contamination.

PITFALLS

Decontamination of victims of a hazardous chemical release is fraught with problems, many of which can be alleviated with appropriate planning. Appropriate PPE is expensive, and maintaining the appropriate level of trained personnel for 24-hour operations will strain budgets and resource allocations.²¹ Mass decontamination of victims of a chemical warfare agent release will likely exhaust even the most well-prepared medical facility. If the event is terrorist instigated, there is also the possibility of the perpetrator(s) initiating a secondary hazard or hiding among the casualties. This increases the stress on healthcare providers accustomed to dealing only with a person's medical issues. If the victims include a large number of fatalities, instructions for handling the deceased must be clearly detailed to prevent secondary contamination among medical personnel.

Communications can be problematic. Communications may be difficult between healthcare providers and HazMat responders when the substance is unknown or widespread. Wearing protective respirators complicates communication between patients and healthcare providers. The situation is exacerbated by the potential conflict in agenda between crisis and consequent management teams. Deciding what takes priority—crime investigation or medical care—can be problematic, especially if the

event is labeled an act of terrorism. Victims exposed to high levels of chemical warfare agent especially need immediate care to offset immediate and potentially fatal effects, a need that may not be readily apparent to crime scene investigators.

An issue not often considered by healthcare providers is the special decontamination needs of the more vulnerable populations such as elderly persons, children and young adolescents, or immune-compromised persons. Children may compose a significant portion of casualties in a terrorist attack because of their higher breathing rates, thinner skin, larger surface-to-mass ratio, smaller fluid reserves, and lower circulating blood volumes.^{21,22} Such groups may also be more vulnerable to negative psychological effects.²³ Likewise, elderly persons may have underlying health problems such as asthma that exacerbate the health effects from a chemical release. Decontamination solutions and areas for disrobing and showering may not be heated. Care should be taken to avoid the necessity of treating victims for exposure (e.g., hypothermia). Having access to personal records of victims may be impossible in mass care situations, and healthcare providers may need to rely on subjective evaluations of stressed victims.

Lack of victim privacy when media personnel are on the scene has also been a problem.²⁴ Graphic photographs and videos of victims being decontaminated are sought by media outlets but only increase the stressful situation for victims.²⁵ Securing external perimeters of areas for triage and decontamination of victims while the HCF is in lockdown may prevent such intrusion but may delay essential treatment as well. Innovative news correspondents may pose as victims to gain entry and access to victim's stories. Medical facilities that plan to use expedient items such as large trash bags for patient wear after decontamination should be aware that privacy can and will be a major issue for victims already subjected to unfamiliar decontamination procedures.

Preplanning for chemical agent incidents is still not universal.²⁶ Although planning for and providing resources for responding to a terrorist event has been advocated by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) in cooperation with OSHA, studies of healthcare preparedness have found many facilities not in compliance.

The casual openness and use of volunteers at many entries to HCFs present significant vulnerabilities for contamination of the HCF, healthcare providers, and volunteers. A few HCFs provide separate waiting rooms for other reasons than maintaining a space for isolation of contaminated victims. Although this method of receiving patients is not likely to change soon, HCF managers and supervisors should consider reorganizing the environment to more easily adjust to the unexpected influx of contaminated patients after a disaster.

The number of pitfalls that can hinder effective decontamination efforts may seem overwhelming; however, with planning, management support, and appropriate resources and training, such events can be managed with less chaos and confusion. The most important factor is protection of the healthcare provider and the HCF to optimize the care provided to victims.

Radiation Decontamination*

George A. Alexander

Merriam Webster's Collegiate Dictionary, 10th edition, lists 1936 as the year of the earliest known use of the word *decontaminate* in English.¹ *Decontaminate* is defined as follows: "to rid of contamination (as radioactive material)." To better appreciate the meaning of the word, one should first understand the concept of radiation contamination. Contamination occurs when material containing radioactive particles is deposited on skin, clothing, or any surface area of an inanimate object. A person contaminated with radioactive material will continue to be irradiated until the radioactive material (source of radiation) is eliminated or removed. Interestingly, radiation does not spread in a person; instead, it is the radioactive contamination that can spread. *External contamination* of a person may occur if radioactive material is deposited on external body surfaces or clothing. *Internal contamination* occurs if radioactive material is inhaled, ingested, injected into, or absorbed through wounds. The environment can also become contaminated if radioactive materials are uncontained or spread about.

Comprehensive concepts of radiation decontamination are presented in this chapter. The aim is to provide a framework in which to understand the principles of radiation decontamination and their application in controlling exposures to radioactive contamination. The chapter provides a brief historical perspective of radioactivity, summarizes current practices of radiation decontamination, and highlights obstacles to the execution of an optimal radiation decontamination response plan.

HISTORICAL PERSPECTIVE

Radiation injury to human cells was first recognized within months after Roentgen's discovery of X rays in 1895.² In 1896, Becquerel discovered natural radioactivity—the emission of fast electrons from the nuclei of salts of uranium.³ This mode of radioactive decay was termed *beta decay*. This discovery eventually led to another dis-

covery and isolation of radium by Marie Curie in 1898.⁴ In 1899, Rutherford described radioactive decay by the emission of alpha particles (helium nuclei).⁵ And, in 1900, Villard was the first to describe electromagnetic radiation release during radioactive decay known as gamma radiation.³ The three major forms of radioactivity are alpha (α), beta (β), and gamma (γ), named for alpha particles, beta particles, and photon energy, respectively.

After their discovery, X rays and radioactive materials were used with little regard for their biologic effects. The consequences of careless handling and use of radiation sources soon became apparent. Many of the early workers who pioneered the medical applications of ionizing radiation experienced firsthand the deleterious effects of radiation. Curie's discovery of radium led her to receive the Nobel Prize for chemistry in 1911 and brought about the introduction of radium use in medicine and industry.⁵ Internal contamination from radium caused injury to many workers of the radium watch dial-painting industry in the 1920s.⁶

In the early twentieth century, the understanding of atomic physics increased rapidly and culminated in the nuclear era. The development of manmade radioactive isotopes during and after World War II was a factor in the establishment of the nuclear industry that had a workforce of several hundred thousand people. Only 97 cases of clinical radiation injury had occurred in this population by 1969.⁶ Knowledge of radiation-monitoring procedures was an integral component of the civil defense programs of the 1960s directed against the threat of nuclear weapons use and thermonuclear war. Most of what is known today about radiation decontamination came about after the atomic bomb explosions of World War II and has evolved from three primary areas: therapeutic radiation exposures, radiation accidents, and military preparedness training directed at nuclear weapons-related injuries. The military experience has provided some of the most comprehensive and useful information on radiation decontamination.⁷⁻⁹

CURRENT PRACTICE

Basic techniques of radiation decontamination derived from the military can be applied to nonmilitary settings

*The views expressed in this chapter are those of the author and do not necessarily represent the official policy or position of the National Cancer Institute, the National Institutes of Health, or the U.S. Department of Health and Human Services.

depending on the situation and resources available. Radiation is given off by radioactive particles, most of which appears as dust or debris as in the case of a detonation of a nuclear weapon or radiologic dispersal device. For decontamination purposes, radiation is generally thought of as a solid. Four categories of decontamination are recognized⁷: (1) personal decontamination is decontamination of one's self; (2) casualty decontamination denotes decontamination of patient casualties; (3) personnel decontamination generally means decontamination of workers who are not patients; and (4) mechanical decontamination includes procedures to physically remove radioactive particulates.

Radiation decontamination is not an emergency. Decontamination of casualties is a labor-intensive task. The process demands the dedication of a significant number of personnel and large amounts of time. Appropriate planning and training are a necessity. The demands may require a major contribution of resources.

Monitoring Instruments

A variety of instruments are available for detecting and measuring radiation. Radiation monitoring entails the measurement of radiation fields in the vicinity of a radiation source, measurement of surface contamination, and measurement of airborne radioactivity. Such monitoring methods are also known as radiation surveys. Radiation survey meters are used to evaluate radiation contamination of patients, equipment, or the environment. Old civil defense instruments such as the CD V-700 and CD V-715 survey meters can be used. The CD V-700 meter is used to detect low-intensity gamma and most beta radiation. It can only measure up to 50 mR/hour. The CD V-715 meter is used to measure high-intensity gamma radiation. It can measure up to 500 R/hour; however, it cannot detect beta or alpha radiation. These instruments are also called *Geiger counters* or *Geiger-Mueller meters*.

Newer portable and compact radiation monitor units with digital readouts and alarm systems are commercially available to measure alpha, beta, and/or gamma radiation. Because alpha radiation travels a very short distance in air and is not penetrating, radiation survey instruments cannot detect alpha radiation through even a thin layer of water, blood, dust, paper, or other materials. Most beta emitters can be detected with a survey instrument such as a CD V-700, provided the metal probe cover is opened. Since gamma radiation or X rays frequently accompany the emission of alpha and beta radiation from radioactive isotopes, the latter constitute both an external and internal hazard to humans. Gamma radiation is readily detected with survey instruments.

Radiologic Assessment

In the period immediately after a detonation of, for example, a nuclear or large RDD, there will be considerable uncertainty about the nature and extent of radioactive contamination. It is imperative that radiation measurements be obtained as soon as possible to implement proper protective actions against potential radiologic hazards. On-scene radiologic assessments can be easily

and rapidly performed using exposure rate measurements. However, assessments of long-term consequences require knowledge of the specific radioactive isotopes and more specialized skills.¹⁰ An RDD that contains nuclear spent fuel as a radiation source will probably release one or a few radioisotopes on detonation. This simple source is easier to measure and characterize than mixed radiation sources potentially released from nuclear reactors or weapons.

Prehospital Decontamination

State radiation safety or health departments should provide field teams to assist in radiation monitoring at the scene of a nuclear or radiologic incident. The radiologic evaluation of injured patients should be performed by persons with radiation health and safety training under the supervision of on-scene medical personnel.¹⁰ Patient decontamination performed by emergency responders should be brief. The goal should be to remove all gross radioactive dust or debris from body surfaces. If clothing and shoes are contaminated, they should also be removed. These measures may benefit the patient by eliminating sources of radiation exposure and reducing the cumulative absorbed dose the patient would have received. Depending on the severity of injuries and the extent of radiation exposure, these simple decontamination methods may be life-saving while the patient is en route to more definitive care at the nearest hospital emergency department.

Hospital Decontamination

To prevent or minimize the occurrence of radiologic contamination of the hospital facility and hospital staff, a decontamination area should be established outside the hospital, preferably downwind from the clean treatment area or hospital entrance. A patient arrival/triage area should be downwind from the decontamination area. Wind direction is vital since re-suspension of radioactive dust may occur downwind from the contaminated area. Outdoor patient decontamination is always performed upwind from the patient arrival/triage area.⁷ Ideally, the decontamination area should be set up to take advantage of the prevailing wind. The setup should be adaptable. Consideration must be given to the security of the decontamination area. An outdoor shower system may also be considered for use of mass decontamination. Portable vacuum units with high-efficiency particulate air filters have reportedly been used to facilitate rapid decontamination outdoors.¹¹

An entry control point is necessary to identify and manage movement of clean and contaminated vehicles to the decontamination site. Control of patient and staff movement is critical to ensure that contaminated ambulatory patients and staff do not accidentally contaminate clean areas. A hotline should be established and secured. Any people or equipment leaving a contaminated area must undergo radiologic monitoring to make sure that radioactive contaminants do not enter clean areas. In addition, a radiation emergency area, a location for indoor decontamination, should be part of the radiation emergency plans in the event that patients contaminate the hospital.¹¹

Hospitals with nuclear medicine departments have an added resource—a gamma camera. A gamma camera is a perfect device for detecting nuclear fission products from either nuclear detonations or nuclear power plant reactor accidents.

Patient Decontamination

Removal of outer clothing and rapid washing of exposed skin and hair removes 95% of contamination.⁷ Standard patient decontamination is normally performed under the supervision of medical personnel.¹⁰ Moist cotton swabs of the nasal mucosa from both sides of the nose should be obtained, labeled, and sealed in separate bags. These swabs can be used as evidence for inhalation of radioactive particles. A 0.5% sodium hypochlorite solution can be used to remove radioactive contamination from intact skin. Radioactive material removed from the patient should be preserved for later analysis to identify the specific radioisotope. Maintain care not to irritate the skin. If skin becomes erythematous, some radioactive isotopes can be absorbed directly through the skin. Surgical irrigating solutions, such as normal saline or lactated Ringer's solution, should be used liberally in wounds, the abdomen, and the chest. These solutions should be removed using suction instead of wiping or sponging. For the eyes, only abundant amounts of water, normal saline, or eye wash solutions are recommended. If feasible, skin wash water should be contained and held for disposal. Contaminated tourniquets are changed with clean ones. Wounds should be covered after adjacent skin is decontaminated to prevent skin contaminants from entering the wound.

Wound Decontamination

During initial decontamination in the receiving/triage area, bandages should be removed and all wounds flushed. If bleeding persists, apply fresh bandages. Highly energetic gamma emitters can present an immediate hazard to contaminated wounds. Particulate matter contaminating a wound should be removed if possible. Alpha and beta emitters left in a wound can cause extensive local injury and may be absorbed into the systemic circulation, where they will be redistributed as internal contaminants; this can cause additional internal organ injury from irradiation. After adequate decontamination of the wound is achieved, it should be copiously irrigated with saline or some other physiologic solution. Aggressive surgery such as amputation is not necessary and should never be used to manage radioactive contamination of a limb. Partial-thickness burns should be extensively irrigated and cleaned with mild solutions to prevent irritation of burned skin. In full-thickness burns, the presence of radioactive contaminants requires specialized surgical treatment.

Mechanical Decontamination

Radiologic contamination may involve one or more radioactive elements. This section addresses the specific decontamination of six common radioactive elements.⁸

The decontamination principles discussed here are also applicable to radiologic contamination by other elements with chemical properties similar to those discussed below.

Cesium

The most common radioisotope of cesium is cesium-137. It emits beta and gamma radiation, decaying to stable barium-137. Cesium-137 is widely used in gamma sources. It occurs in these sources as cesium chloride pellets. Cesium chloride is a soluble salt. The contamination from a sealed-source leak absorbs water, becomes damp, and creeps. Contamination from a sealed cesium source is best decontaminated by wet procedures unless the contamination is on a porous surface, in which case wet procedures should be preceded by vacuuming. Cesium is known to adsorb from a solution onto glass surfaces. Decontaminating a liquid cesium-contaminated surface is best accomplished by wetting the surface, absorbing the solution with a rag or other absorbent material, and rinsing the area several times with water. If the contamination persists, use a detergent solution and scrub with a brush.⁸

Cobalt

The most common radioisotope of cobalt is cobalt-60, a beta and gamma emitter. Metallic cobalt-60 is commonly used in sealed gamma sources. Particles of cobalt dust adhering to small articles are readily removed by ultrasonic cleaners or by dipping the article in a dilute solution of nitric, hydrochloric, or sulfuric acid. Cobalt dust contamination that exists over a large area is best removed by vacuuming. Sealed cobalt sources may leak as a result of electrolytic action between the cobalt and the container. The result is often a soluble cobalt salt, which creeps and spreads. This is best decontaminated with a detergent or an ethylenediamine tetraacetic acid solution, followed by treatment with mineral acids. Contamination from solutions containing cobalt may be treated with water.⁸

Plutonium

The most common isotope in which plutonium may be present as a contaminant is plutonium-239, an alpha emitter. Plutonium contamination may be the result of a nuclear weapons accident, in which case the plutonium will be scattered as a metal or oxide in a dust form. Both forms of plutonium are insoluble. Aging of plutonium-239 contamination is impractical since it has a 24,000-year half-life. Plutonium contamination that covers a small area is best decontaminated by vacuuming. If contamination remains, the area should be washed with a detergent solution. Any contamination that remains can be sealed in a protective coating of paint, varnish, or plastic. Plutonium oxide or metal dust spread over a large area, such as a field, is best decontaminated by removing the top layer of soil and disposing of it as radioactive waste. Personnel should wear respiratory protection when decontaminating or removing the soil.⁸

Strontium

The most common radioisotope of strontium is strontium-90, a beta emitter. The daughter particle of strontium-90 is yttrium-90, which is also a beta emitter. Strontium-90-yttrium-90 is commonly used in sealed beta sources. Generally, it is present as a chloride or carbonate. The chloride is hygroscopic; it absorbs water and creeps out of the container. This contamination is best decontaminated by vacuuming, followed by a treatment with water, a complexing agent solution (i.e., substance capable of forming a complex compound with another material in solution), and a mineral acid, in that order. Contamination resulting from a strontium-containing solution is best decontaminated by absorbing the solution with rags or other absorbing materials and washing the area with a detergent solution. If strontium contamination persists, the top layer of the surface should be removed by abrasives or other removal procedures and a sealing coat should be placed over the surface.⁸

Tritium

Tritium is the radioisotope of hydrogen and is a weak beta emitter. If it is released to an area as a gas, the best decontamination method is to flush the area with air. Since inhalation tritium can present an internal hazard, personnel entering an area containing tritium gas should wear an appropriate self-contained type of breathing apparatus. Objects in an area exposed to tritium for any great length of time may absorb the gas and should be disposed of, if possible. They may be degassed, under a vacuum, by flushing with helium or hydrogen. A surface that is monitored as clean may become contaminated again in a matter of hours by percolation. There is no practical way of removing tritium oxide (T_2O) from water due to its similarity to natural water.⁸

Uranium

The most probable source of uranium contamination is a nuclear weapon accident in which the fissionable uranium is spread as a metal or oxide dust. The common isotopes of uranium contamination are uranium-235 and uranium-238. This metal or oxide is insoluble and is best removed from a contaminated surface by brushing or vacuuming, followed by a treatment with mineral acids or oxidizing acids, and then the area should be sealed. Large-area uranium contamination is best decontaminated by removing the top layer of the surface or by sealing it.⁸

Equipment and Building Decontamination

In most instances of equipment and building contamination, a mixture of normal household cleaning practices will remove the radioactive material. Vacuum cleaners that can handle wet material and have high-efficiency particulate air filters are suggested.

Personal Protective Equipment

Members of on-scene field radiologic decontamination teams and hospital-based teams should have appropriate protective equipment to meet all requirements for radiation decontamination. Emergency medical services and hospital personnel responsible for patient decontamination should also be appropriately equipped to protect themselves from the hazards of radioactive contamination.

Respiratory Protective Devices

There are two types of respiratory protective devices: air-purified respirators, which remove contaminants from breathing air by filtering or chemical absorption, and air-supplied respirators, which provide clean air from an outside source or from a tank. Most air-purified respirators (i.e., protective masks) afford excellent protection from inhalation of radioactive material. Radioisotopes such as radon and tritium gas will pass through these filters. However, short exposures to these gases are not considered medically significant. The device providing the greatest factor of safety for a particular radiation incident should be used.

In nuclear weapons accidents or terrorist incidents, most nuclear weapons will contain high explosives in varying amounts—even as much as hundreds of pounds. Detonation of high explosives in nuclear weapons will cause a major radiologic threat—the release of plutonium-239.¹² When associated with a fire, metallic plutonium may burn, producing radioactive plutonium oxide particles and serious inhalation and wound deposition hazards. In these situations, use of self-contained breathing apparatuses should be considered.

In RDD incidents in which radioactive contamination is associated with fire and dangerous chemical fumes from burning metals and plastics, use of self-contained breathing apparatuses should be considered. Such devices enable radiation response/decontamination workers to enter a contaminated or oxygen-deficient environment, up to the limits of the respirator. They should be used when it is necessary to enter a highly contaminated environment to rescue persons, for example, from RDD incidents or nuclear power plant accidents.

Protective Clothing

Anticontamination suits are commercially available for use in nuclear and radiologic disasters. Chemical-protective clothing provides excellent protection against radioactive contamination while also offering protection from chemical and biologic agents or hazards. A wide variety of chemical-protective clothing is available to protect the body, including gloves, boots, coveralls, and total-encapsulation protective suits. Standard hospital barrier clothing that is used in universal precautions is adequate for protection of hospital personnel who provide emergency evaluation and treatment to limited numbers of radiologically contaminated patients. In these instances, hospital personnel should be decontaminated after the patients' emergency treatment and decontamination.

Radiation Dosimeters

There are a variety of detectors used to measure a person's level of radiation exposure.¹³ Film badges, thermoluminescent dosimeters (TLDs), pocket dosimeters, or other devices should be used by radiation decontamination personnel, emergency responders, and hospital medical providers who are involved in any nuclear accident or terrorist incident.

Film badges are the most common dosimeter in use. They are worn on the outer clothing and are used to measure gamma, X-ray, and high-energy beta radiation. A badge consists of a small piece of photographic film wrapped in an opaque cover and held in a metal frame. It can be worn as a ring or pinned to clothing. Radiation interacts with the atoms in the film to expose the film. At periodic intervals, the film is removed and is developed to determine the amount of radiation exposure. A film badge provides a permanent record of radiation exposure.

TLDs are used for measuring gamma, X-ray, and beta radiation exposures. They can be worn as rings or body badges. They contain small chips of lithium fluoride that absorb ionizing radiation energy and displace electrons from their ground state. The electrons then become trapped in a metastable state but can be restored to their original ground state by heating. When heated, the electrons return to their ground state and light is emitted. A TLD readout instrument is used to heat the chips and measure the emitted light. The amount of light emitted is related to the dose of radiation absorbed by the TLD and to the radiation exposure dose of the individual. TLDs are beginning to replace film badges.

A pocket dosimeter is a direct-reading portable unit shaped like a fountain pen with a pocket clip. It is worn on the trunk of the body and is generally used to measure X-ray and gamma radiation. It should be used in conjunction with a TLD rather than in place of TLD use.

The pocket dosimeter consists of a quartz fiber, a scale, a lens to observe movement of the fiber across the scale, and an ionization chamber. The quartz fiber is charged electrostatically until it reaches zero on the scale. When the dosimeter is exposed to radiation, some of the atoms of air in the chamber become ionized. This causes the static electricity charge to leak from the quartz fiber in direct response to the amount of radiation present. As the charge is lost, the fiber moves to some new position on the scale that indicates the amount of radiation exposure.

The main advantage of the pocket dosimeter is that it can be read immediately by the wearer, even while working in a radiation-contaminated environment, instead of waiting for processing of a film badge or TLD. However, since pocket dosimeters lose their electrical charge over time, they may give a false indication of radiation exposure. When practicable, use of two dosimeters can prevent false interpretation of a person's exposure. One should assume that the lower reading is the actual exposure.

Basic Radiation Safety

During a nuclear or radiologic disaster, it is vital that emergency medical responders, decontamination team personnel, and hospital healthcare providers adhere to the basic principles of radiation safety. These actions will help to prevent or minimize the risk of these persons becoming radiation casualties due to exposure to radioactive contaminants. The three basic principles of radiation protection are time, distance, and shielding.

Time

The longer the exposure to radioactive contaminants, the greater is the possibility of radiation injury. There is a direct relationship between the exposure dose received and the duration of exposure. Reducing exposure time in a contaminated area will reduce the radiation exposure. The maximum acceptable exposure time can be calculated based on the exposure dose rate measured using radiation survey meters at a given incident scene and the maximum dose that is needed to accomplish radiation decontamination or other task. In practice, the dose received in completing a task may be spread over several workers so that no one person's exposure exceeds guide levels.

Distance

The inverse square law states that the dose from a radiation point source decreases with the square of the distance from the source. For example, doubling the distance from the source of radiation, the exposure would be decreased to $(\frac{1}{2})^2$, or one fourth, of the original amount. In nuclear or radiologic incidents, the radiation source may not be equivalent to a point source and so the inverse square law can be used as an approximation. In most instances, the approximation should be adequate. Maintaining a safe distance is especially critical. The larger the distance from a radiation source, the lower the dose.

There are certain emergency response operations that cannot be performed without some exposure of workers. In these situations, all unnecessary exposure to radiation should be avoided, even if it means barring workers from entering contaminated areas. These hazardous areas should be barricaded or roped off to form a restricted area that cannot be entered by non-radiation workers or bystanders.

Shielding

Shielding is generally used to safeguard against radiation from radioactive sources. The more mass placed between a source and a person, the less radiation the person will receive. This should be the guiding principle. Proper shielding from a source requires knowledge of the type of radiation hazard.¹³ Different types of shielding are required for alpha, beta, and gamma radiation. Light clothing will provide protection and prevent contamination of the body from alpha radiation. Light metals such as aluminum are preferred for shielding from beta emissions. A sheet of aluminum can stop most beta

radiation. Plexiglas is another shielding material that is effective against beta particles. Since gamma radiation is more penetrating than alpha and beta particles, higher-density materials such as lead, tungsten, steel, and concrete are ideal for shielding gamma rays. As the thickness of these materials increases, the intensity of the gamma radiation will decrease.

PITFALLS

Obstacles preventing the delivery of proper radiation decontamination procedures in response to a radiation catastrophe include the following:

- Lack of adequate radiation decontamination planning by emergency medical and hospital responders for possible nuclear or radiologic accidents and/or terrorist incidents;
- Lack of commitment of resources for radiation decontamination preparedness by emergency and hospital disaster planners;
- Lack of consultation and involvement of medical or health physicists in planning radiation decontamination plans and protocols;
- Lack of coordination with local and state radiologic health and safety agencies;
- Lack of understanding by medical providers and assigned decontamination team personnel of the basic science of radioactive isotopes and principles of radiation injury;
- Lack of adequate training in radiation decontamination techniques;
- Lack of recognition of the importance of radiation safety by emergency medical response personnel;
- Lack of proper radiation safety equipment and monitoring devices and instruments.

chapter 71

Introduction to Natural Disasters

Debra D. Schnelle

This text is designed as a comprehensive study of disaster medicine that also includes ready-made resources for the practitioner of disaster medicine. Part I, Overview of Disaster Management, serves as a definitive informational text for the professional working in the field of disaster management. The goal of Part II is to provide a quick reference for an exhaustive list of possible disaster scenarios. This introductory chapter provides an analytical framework common to all disasters, so that each scenario can be understood within a common frame of reference. The analytical framework offers definitions and provides a structure for the study of natural disasters in general.

This framework is the result of more than seven years of work conducted by the Steering Committee of the Task Force on Quality Control of Disaster Management, which is under the oversight of the World Association for Disaster and Emergency Medicine (WADEM) and the Nordic Society for Disaster Medicine. These organizations recently published their work, *Health Disaster Management Guidelines for Evaluation and Research in the Utstein Style*,¹ which provides much more detail concerning the concepts summarized here.

Natural disasters are a part of the human experience, and as the size of human societies increases, it appears that the *impact* of natural disasters on human society is growing, for the following four reasons¹:

- Disasters are continuing to increase in frequency
- Disasters are affecting more citizens of the world community
- The economic costs associated with disasters are increasing at an alarming rate
- More people are moving to areas subject to natural hazards, for example, along hurricane-vulnerable coasts (many living in vulnerable mobile homes) and areas near earthquake faults or in flood plains

Unfortunately, the uncertainties of a natural disaster—how and when it will occur, what “type” of disaster will occur, and the ability of the affected population to withstand the effects of the disaster—all combine to create a “threat” not easily understood by any single professional perspective, specialty, or discipline. After each disaster, expert sources release a plethora of “reports” that recount personal experiences or consensus agreements from the experts on the lessons learned from the disaster.

Unfortunately, few of these reports or evaluations appear to lead to sustained improvements in the response to natural disasters.

Important information is lost, errors and inefficiencies are perpetuated, and, in many settings, vulnerability continues to increase. Often, the impact of an intervention is assessed by *quantifying the output and not the outcome*. It is clear that some relief and assistance efforts not only are ineffective in meeting defined needs, but also actually are counter-productive and impair potentially beneficial responses and measures. More than 50% of the medical supplies sent to Bosnia during the recent conflicts not only were inappropriate or useless, but also cost the Bosnian government 34 million dollars to dispose of them.¹

Examples such as this indicate the need for common definitions and a common conceptual framework for understanding natural disasters and systematically improving the quality of interventions designed to mitigate the natural disaster’s impact on society.

The analytical framework outlined in the following is an adaptation of the conceptual model developed by WADEM; it is presented in detail in *Concepts of Operation of Health Service Support in an NBC Environment*.² Although the analytical framework in this textbook focuses on the chemical, biologic, radiologic, and nuclear (CBRN) threat, the adaptation remains broadly consistent with the WADEM conceptual model, due to the scope encompassed by the WADEM efforts and its rigorous development of definitions.

To begin, the word *disaster* has almost as many definitions as there are disasters—or the number of disciplines involved in disaster management. However, both the World Health Organization (WHO) and the United Nations (UN) present the following definition¹: a natural disaster is “the result of a vast ecological breakdown in the relationships between man and his environment, a serious and sudden (or slow, as in drought) disruption on such a scale that the stricken community needs extraordinary efforts to cope with it, often with outside help or international aid.” This definition is particularly useful because it differentiates between the *event* that caused the disaster and the *damage* associated with the disaster. From this definition, an understanding emerges that “all disasters are related to a specific hazard. . . .”¹

Hazards are classified by type in three classes: natural (e.g., seismic, climactic); manmade (e.g., a result of technology, such as the release of CBR substances; explosions; or fire); and mixed (a combination of natural and manmade). Section Seven of this textbook focuses on natural disasters, but the framework and definitions apply to all of the sections in Part II.

Events, then, are the realization or delivery of a hazard and can be characterized by onset, intensity, duration, scale, and magnitude.¹ *Damage* is defined as harm or injury that impairs the value or usefulness of something, or the health or normal function of persons. *Impact* is defined as the actual process of contact between an event and a society or a society's immediate perimeter.¹ These definitions can be understood separately or as different phases of the disaster (Fig. 71-1). A society exists in a state that can be characterized by its major functional components (medical, public health, sanitation, shelter, food, energy supplies, etc.).¹ Hazards may exist or be common in this environment, such as hurricanes, earthquakes, tornadoes, or floods.

When these hazards are realized, the event occurs, producing damage of varying degrees and types. The impact resulting from the infliction of the damage on a society is "dependent upon the vulnerability and preparedness of the environment and the society for that event."¹ This definition of a disaster as a progression from situation, to hazard, to event, to damage, and then to impact leads to the understanding that effective disaster response consists of intervening between these states to minimize the impact of the event to the greatest extent possible (see Fig. 71-1).

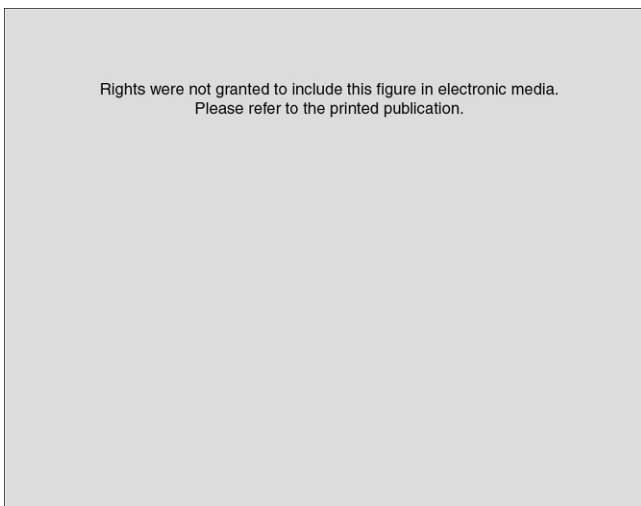

FIGURE 71-1. Phases of natural disasters and appropriate interventions. (From North Atlantic Treaty Organization, Nuclear, Biological, Chemical/Medical Working Group. Concepts of Health Service Support in an NBC Environment. Oct 2003.)

The first intervention is risk assessment—a comprehensive analysis of all possible hazards. WADEM defines hazard assessment as “identification and scaling of latent conditions that represent a threat.”¹ The second intervention—planning and preparedness—is the most effective means of “prevention” to a natural disaster.¹ *Planning* is defined as¹:

The process used to develop contingencies in preparation for an event that is likely to occur at some time. Planning includes warning systems, evacuation, relocation of dwellings (e.g., for floods), stores of food and water, temporary shelter, energy, management strategies, disaster drills and exercises, etc.

Preparedness is defined as “the aggregate of all measures and policies taken by humans before the event.”¹

The third intervention is mitigation and in this context refers to the mitigation of the damage *after* an event.² The fourth intervention is *response*, defined as “an answer to a defined need or request.”¹ Finally, the fifth intervention is recovery, or “the restoration or replacement for all of the damage of an event.”¹

All of these interventions serve one or more of the following objectives¹:

- Reduce the likelihood of damage that results from an event
- Minimize the damage
- Improve the resilience and capacity of the society and thus reduce the impact of the event
- Direct the recovery from the damage

Each of the following chapters in this section focuses on a particular type of natural hazard and describes the most common events associated with that hazard. Practical considerations for the hazard assessment and planning/preparation interventions are presented as preincident actions, and the mitigation, response, and recovery interventions are presented as postincident actions.

Finally, unique considerations, pitfalls, and case presentations are offered to place each of these natural disasters within the common framework presented in this chapter.

Hurricanes, Cyclones, and Typhoons

Eric Sergienko

DESCRIPTION OF EVENT

Cyclonic weather throughout the tropics has caused hundreds of thousands of deaths and billions of dollars of property damage in the last 100 years. Cyclones can occur in the Atlantic, Western or Eastern Pacific, or Indian Oceans. They can occur at any time of the year.

Tropical cyclones start as waves of warm air. In the Atlantic, these typically start as waves coming off of the Sahara. A tropical cyclone forms over the ocean, and then increases in strength and size, depending on the moisture and heat that it derives. As it moves over the ocean, it draws energy from the warm water, pulling it up into an organized weather system. Water must be at least 26.5°C (80°F). Rapid cooling of the atmosphere, enough to create thunderstorms, liberates the heat from the ocean and allows a cyclone to develop. There must be adequate moisture at about 5 km above sea level for the thunderstorms to continue. And this must occur far enough away from the equator (about 500 km) for the Coriolis effect to occur, resulting in the rotation of the storm. Finally, there must be a near-surface disturbance to create a vortex. If vertical wind shear between the surface and the upper troposphere occurs, this can prevent a cyclone from occurring or can significantly weaken an existing storm.

As the wave becomes organized, it may be classified as a tropical disturbance. These appear to have an organized convection (e.g., squall lines or multiple cell thunderstorms) and a discrete identity for at least 24 hours. They may not have increased winds, and they do not have a closed circulation or eye formation.

Tropical depressions generate sustained surface wind speeds of less than 17 m/s (34 knots, or 39 mph). Depressions are poorly organized, but they do have closed circulation. They do not have the classic “eye” formation that is seen with more organized storms.

Tropical storms generate winds that range from 17 m/s (34 knots, or 39 mph) to 32 m/s (63 knots, or 73 mph). At this intensity there is a distinct organization to the storm with rain bands forming outward from the center. On achieving this level, the storm is assigned a name. Names can be retired if they are associated with a devastating storm. Of the 60 or so tropical waves coming off of Africa in a year, 10 will become named storms.

Tropical cyclones that generate sustained surface winds greater than 32 m/s have titles associated with the location from where they originate: hurricanes (From the Carib language, meaning “eye of the god”) form in the mid-Atlantic, Caribbean, or Northeast Pacific oceans. Typhoons form in the Western Pacific. Cyclones form in the Indian Ocean.

The typical season for Atlantic and Eastern Pacific hurricanes is from June to November. Although typhoons can develop any time of the year, they are more common from May until December.

Tropical cyclones are classified by the strength of their sustained winds. The Saffir-Simpson scale rates cyclones on a scale from 1 to 5 (Table 72-1). In addition, super-typhoons are typhoons that maintain wind speeds greater than 140 knots.

Movement of a cyclone is generally east to west as the storm forms in the tropics. It is kept in the tropics by a subtropical ridge. The storm gradually moves away from the tropics and becomes extratropical, finally dissipating in the regions outside the 45th parallel. The weaker the subtropical ridge, the earlier it turns away from the equator and dissipates.

Although the intensity of the winds is predictive of damage, equally important is how rapidly a storm moves through an area. A slow-moving storm will allow for a greater degree of damage than a fast-moving storm. Also one has to consider the amount of rainfall associated with the cyclone, which can lead to significant flooding and landslides. In addition, a storm surge associated with tropical storms causes further flooding and damage to coastal areas. Finally, a tropical storm can spawn tornadoes and waterspouts that can cause additional damage.^{1,2}

The worst natural disaster in the United States occurred in 1900 in Galveston, Texas, when a storm surge of 15.7 feet flooded the island, which has a maximum elevation of 8.7 feet. Eight thousand people, one-fifth of the population, died. The most deadly natural disaster in the western hemisphere was Hurricane Mitch in 1998, which resulted in approximately 12,000 deaths in Central America, predominantly from flooding and mudslides. Similarly, more than 500,000 deaths occurred when a cyclone coming off the Bay of Bengal in 1970 caused flooding in Bangladesh and India³. Economically, Hurricane Andrew caused more than \$20 billion worth of damage.^{4,5} In 2005, Hurricane Katrina devastated the gulf coast of the United States and

TABLE 72-1 SAFFIR-SIMPSON HURRICANE SCALE

CATEGORY	SUSTAINED WINDS (MPH)	DESCRIPTION	DAMAGE	EXAMPLE
Tropical storm 1	39-73 74-95	Minimal	No real damage to buildings; damage to unanchored mobile homes	Allison, 1995
2	96-110	Moderate	Damage to building roofs, doors, and windows; considerable damage to mobile homes; flooding damage; trees down	Bonnie, 1998
3	111-130	Extensive	Some damage to small residences and utility buildings; mobile homes destroyed; coastal flooding, causing destruction of smaller buildings and damage to larger ones; flooding inland	Opal, 1995
4	131-155	Extreme	Complete roof failure on small buildings; major erosion; flooding well inland	Hugo, 1989
5	156 and up	Catastrophic	Roof failure on residences and industrial buildings; complete building failures possible; major flooding on shoreline structures	Andrew, 1992

Adapted from National Weather Service National Hurricane Center. The Saffir-Simpson Hurricane Scale Available at: www.nhc.noaa.gov/aboutsshs.shtml.

resulted in the evacuation of New Orleans. As of this writing, the full extent of the destruction in terms of loss of property and life is not fully known, but clearly Katrina was one of the worst hurricanes in U.S. history.

PREINCIDENT ACTIONS

Planning for a tropical storm involves preparations for all of the threats associated with the storm: high winds, flooding, landslides, and storm surge.

Preparations for tropical weather should be an ongoing activity starting at the onset of the tropical storm season. Whereas some preparations should be made at the start of the season, others can wait until storm activity is anticipated. Typical hospital emergency management plans are organized based on a timeline that starts at the beginning of the storm season and continues through the arrival of storm-force winds to the post-storm recovery efforts.

Some planning should start with the construction or remodeling of the hospital. Hospitals in areas where storms occur should be constructed to withstand high winds and flooding. Storm shutters should be used to protect all exterior openings. Redundant power sources should be considered, with a final backup being small portable generators capable of powering essential equipment in an individual unit. Redundant communications systems with civil defense and emergency medical services are essential because multiple system failures can occur.

Another consideration for medical facilities, regardless of size, is the evacuation of patients and staff farther inland and away from the predicted storm track.

Therefore, the facility's evacuation annex should include relocation of patients to a distant facility.

At the start of the storm season, sandbags should be available to barricade low-lying doors susceptible to flooding. Damage control equipment should be available. Plywood sheeting for blown-out windows, 2 × 4 boards for reinforcing doors and other structures that may be stressed by prolonged winds, and vacuums that can handle water (wet/dry vacuum) are essential. Facility engineers and damage control parties must be designated as essential personnel and receive training on mitigation of storm damage. Generators should be fully fueled and maintained.

Before a storm, employees should be alerted to bring in personal items that may be required for a prolonged stay in the medical treatment facility. This should include food, bedding, and medications. Employees who are in the facility during the storm should ensure that their families and residences are prepared before the storm.

Enough durable and expendable medical equipment and pharmaceuticals should be stocked to allow for unsupported operations for up to 72 hours. Disposable equipment (e.g., suture sets) should be considered if sterilization systems should fail. Alternative means of cleaning, such as alcohol-based hand sanitizers, should be obtained. Food and water must be stocked to feed and hydrate staff, patients, and family of patients. The fuel tanks of vehicles, both personal and hospital-associated, should be filled. Waste systems may be damaged, so alternative means of disposing liquid and solid waste, including biohazardous material, must be considered.

Traditionally, pregnant women, who are either at least 36 weeks' gestation or are in the third trimester and

expecting complications with delivery, have been advised to report to the hospital before the storm's arrival. Precipitous labor may occur due to decreased barometric pressure, although this has never been validated.

During the Storm

Generally, damage control predominates during the passage of a tropical cyclone over a medical facility. In an intense storm, there will be minimal movement outdoors, so new patients will not be arriving in large numbers.

If emergency medical services are required to perform a rescue during high winds, it is advisable to use military vehicles (such as Hummers) or at least heavy four-wheel drive vehicles rather than a standard ambulance. Because of its high profile and relative low weight, a traditional ambulance is at risk of being blown over or flooded away. Further, it is beneficial to send two vehicles in a convoy rather than sending a vehicle by itself.

Communications will deteriorate during the storm. Cellular systems will go down as repeater cells are destroyed. The same is true for handheld radios beyond line of sight as their repeaters are damaged. Landline analog phones seem to be the most rugged, and amateur radio operators can serve as a backup.

Deaths during the storm will occur due to multiple causes. The largest cause of death in flat areas is flooding. Oftentimes, these deaths involve the drowning of persons trapped in vehicles. In areas with hills, landslides may be the most prominent cause of death. Drownings from swimming, boating, or surfing in storm waters do occur despite warnings to the contrary. Deaths that can occur post-storm may be indirectly due to power outages as people are electrocuted when power lines are re-energized and from the use of candles, which can lead to house fires. Equally frustrating are deaths related to carbon monoxide caused by the use of generators or charcoal stoves/grills without proper ventilation.^{6,7}

POSTINCIDENT ACTIONS

A rapid needs assessment for the hospital and the community should be performed. Repairs required for maintaining hospital operations should be done. Durable and expendable medical equipment destroyed or damaged during the storm should be noted, and replacement equipment should be ordered. Typically, power will be out, so consideration should be made for patients with medications that require refrigeration. "Social" admissions may be needed to maintain patients' health status. Post-storm morbidity in the community is associated with disruption in the infrastructure and attempts to restore normal function. Those with chronic medical problems or patients who require regular routine medical procedures such as dialysis experience an exacerbation due to the stresses of the uncontrolled environment and/or loss of medications and durable medical equipment. Injuries occur during cleanup of storm damage and may include lacerations, concussions, and plantar puncture wounds. Illnesses are associated with lack of safe water sources or

proper food handling and the inability to dispose of waste. In developing countries, cholera and other diarrheal diseases often occur. Finally, anxiety and posttraumatic stress can occur among survivors.^{8,9}

MEDICAL TREATMENT OF CASUALTIES

There may be a greater likelihood to admit patients who are unable to take care of themselves at home until the community's infrastructure has been re-established.

There also is a tendency to use antibiotic wound prophylaxis and to administer early updates of tetanus post-storm due to the increased concern over wound contamination and the inability to properly clean the wound. It may be more appropriate to use delayed primary closure.¹⁰

It may be difficult to obtain ancillary or laboratory studies in a hospital that is stressed by a surge in patients or damaged radiology or laboratory spaces. Consideration for prioritizing studies may be necessary in these situations.

Foodborne and waterborne diseases are possible, even in developed countries. Most of these are spread through fecal-oral contamination. Public health actions may prevent an outbreak. Notices to boil or chlorinate water should be posted. Both depression and posttraumatic stress disorder (PTSD) are common after large storms. In one survey after Hurricane Andrew, the incidences of depression and PTSD among survivors were 36% and 30%, respectively. Although there is significant debate over what methods are most effective in minimizing the psychological sequelae of a disaster, cognitive therapy and supportive psychotherapy may be useful, along with short-term use of antianxiety and sleep medications. Recognition that healthcare providers could be part of the disaster and may need intervention is also important in maintaining a functional disaster response.^{11,12}

UNIQUE CONSIDERATIONS

The hospital in the midst of a tropical cyclone is just as prone to being damaged or rendered unusable as any other building in the area. Consideration must be given in the pre-storm period to evacuate all patients who are able to be transported. Essential staffing should be maintained during the storm, including keeping providers in house. The bulk of hospital staff should be available after the storm since that is the time the majority of new patients will arrive.

PITFALLS

1. Failing to plan for catastrophic weather when located in a zone that experiences such hazards: Storm preparation and planning, including tabletop exercises, should be done yearly to ensure that the hospital is adequately equipped and trained for cyclonic weather.

2. Failure to evacuate, when possible: Smaller community hospitals should consider this as part of their routine for larger tropical storms. Moving critically ill patients will free up beds for incoming casualties and minimize the number of staff needed in-hospital during the storm. Larger hospitals in coastal or flood prone areas should also consider this option.¹³
3. Failure to have redundant systems: Both power and communications systems tend to fail during cyclonic weather.
4. Thinking that the worst is over when the storm has passed: The post-storm period is just as likely to produce injuries, illness, and fatalities.

CASE PRESENTATION

Supertyphoon Pongsona struck the island of Guam in the Western Pacific on Dec. 11, 2002. Pongsona started as a tropical disturbance to the east of Chuuk. As it progressed across the Pacific, it became increasingly more organized and powerful. The majority of computer models initially predicted the storm would pass south of Guam. An outlier model predicted a direct hit. Both the military and government of Guam issued statements for higher conditions of readiness. As the storm continued to track toward Guam, aircraft and ships moved out of its path. The eye of the storm made landfall over the north end of the island. Although the official wind gauge was destroyed by the typhoon, the wind gusts were estimated to be greater than 200 mph, with sustained winds of 150 mph. In addition, the storm track went over the island at a speed of approximately 6 knots. This sustained wind over an unusually long period led to significant structural damage. Most nonreinforced structures were destroyed. The pediatric intensive care unit of the island's civilian hospital, Guam Memorial Hospital, was destroyed, and the adult intensive care unit was significantly damaged. Naval Hospital Guam experienced significant water damage, and the emergency department's equipment storage room was destroyed. The emergency medical services system lost several ambulances, which were blown over by the storm.

In addition, during the storm, several people trapped in buildings were rescued, and thunderstorms caused a fuel depot to ignite. Three deaths were attributed to Pongsona. In the post-storm environment, the emergency departments of both hospitals were overrun with patients with minor traumatic injuries that had occurred during the storm. Resource sharing, including personnel, was used to maintain critical care. Critically ill patients were transferred to the naval hospital. Within 72 hours, an expeditionary medical squadron that was deployed from an air base in Japan had co-located with Guam Memorial Hospital. Two additional disaster medical assistance teams deployed to the island from the U.S. mainland. Initially, acute injuries were treated, but largely these teams were involved in the care of routine medical problems.

Earthquake

Bruce M. Becker

DESCRIPTION OF EVENT

At 11:40 AM on Dec. 7, 1988, a massive earthquake struck northwestern Armenia. The epicenter was between the cities of Spitak and Stepanavan. Leninakan, a larger and more populous city, located 35 miles south of Spitak, was also severely affected. The earthquake registered 6.9 on the Richter scale and was followed by multiple aftershocks that lasted for days. Because the earthquake occurred in the late morning of a weekday, in the winter, and in a mountainous region of Armenia, most adults were at work or home and most children were inside at school. The majority of buildings in the affected cities and towns were destroyed. Water, sewage, and gas lines running under the city streets were ripped apart. Natural gas leaking from broken pipelines caught fire, and soon much of Leninakan was a burning conflagration. Many people were trapped inside the collapsed buildings and suffered from smoke inhalation. In other sites, broken water mains flooded buildings and streets. In Leninakan, a large clock tower still stands, partially destroyed in the town square, with its iron hands frozen at 11:41 AM. The clock has not been fixed but remains as a memorial to the earthquake. Roads were destroyed, blocking access to these cities and the towns between them. People who survived the initial quake, escaping from collapsing buildings, returned again and again to try to rescue their friends and relatives from the rubble. By the night of Dec. 7, 1988, almost 500,000 people were homeless in the earthquake region, squatting by fires in the streets and fields and trying to arrange temporary shelter. At the time of the earthquake, Mikhail Gorbachev was preparing to visit the United States. International news media attention was focused on the former Soviet Union. When Gorbachev interrupted his visit to attend to the disaster area, the news media quickly focused on the Armenian earthquake, providing tremendous coverage. This coverage initiated one of the largest international acute disaster relief efforts ever mounted.

To this day, the number of casualties is unknown. The region had recently been the site of a large immigration of Armenians from other republics of the former Soviet Union and from Nagorno Karabakh, an Armenian terri-

tory that had been annexed by Azerbaijan, a hostile neighbor. (Soon after the quake, Nagorno Karabakh became the site of a civil war and uprising.) Estimates of casualties from the earthquake and its aftermath ranged from 30,000 to 75,000 people dead and hundreds of thousands injured. Because roadways were the only means of transportation into Spitak and Leninakan, and because these roadways were compromised by the earthquake, there was a significant lag time between the disaster's impact and the arrival of local response. Medical infrastructure in the city was completely destroyed or rendered inoperable, and many of the healthcare workers, including physicians and nurses, were killed or injured. Relief workers were forced to rely on air transportation. The Leninakan airport was small and inadequate, and very soon its runway became so congested that relief planes could not land. Within 48 hours of the quake, the weather had worsened, with rain and snow falling, putting the now homeless residents of these destroyed cities at risk for hypothermia.

The destruction of infrastructure was almost unimaginable. Almost 400 schools and universities were destroyed along with 85 hospitals and clinics. Fifty-eight villages, 90 collective farms, and 200 large state farms were destroyed. The psychological effects were even more far reaching. The average survivor lost between 10 to 15 relatives, their homes, jobs, and all of their possessions. The country's nuclear reactor, a Chernobyl-style facility, had been built on the same fault line that caused the earthquake. Amazingly, it was not affected; however, the government immediately shut it down, thus cutting electricity to most of the country. It did not resume operating for years. Soviet and international relief efforts were extensive. Almost 5000 tons of drugs and consumable medical supplies were delivered to Armenia. Thousands of Soviet physicians and other medical relief workers and hundreds of international workers poured into the country to provide aid. Most remained for about 2 weeks. Five years later the cities of Leninakan (renamed Gyumri after the fall of the Soviet Union and the extirpations of Lenin and Stalin from all city names) and Spitak remained in rubble, with few hospitals and clinics rebuilt or restored to providing functional medical services.

PREINCIDENT ACTIONS

Preincident actions in earthquake-prone regions fall into two categories. The first focuses on structural preparations and engineering and design issues intended to strengthen and improve buildings to decrease the likelihood of massive destruction in the face of an earthquake event. These engineering decisions may also focus on the positioning, strengthening, and layout of utility pipes, roadways, and power plants and the relative proximity of potentially dangerous structures, such as factories producing or storing toxic materials and fuel storage facilities, to fault lines and potential earthquake epicenters. The fault system in northwest Armenia had been well defined in the past; nevertheless, very few appropriate engineering and structural preparations had been put into place. The older buildings in Armenia, especially in the northwest, were made from huge blocks of a native Armenian stone called *tufa*, which is volcanic but strong. In fact, one of the last standing buildings in Gyumri was the great Armenian apostolic church, which was made completely of huge blocks of tufa. Most of the housing constructed in the decades before the earthquake, however, was much shoddier. This was the result of two forces acting in concert: an unprecedented demand for housing triggered by the large-scale immigration to the region from other parts of the Soviet Union, as previously described, and the deep and inherent corruption of the Soviet system itself. It was well known that collective farms and industries paid almost no wages to workers, especially during the last years of the regime, as it began to fall apart economically and politically. Those who were successful either initiated private business enterprise or became involved in corrupt practices, such as acquisitioning sturdy building materials from the government for construction of large apartments and then selling the materials on their own while using cheaper-grade concrete or concrete thinned with sand with few reinforcement bars to construct dwellings. The result of these building practices was the construction of edifices with little capacity to resist earthquakes. When the temblor struck Dec. 7, 1988, most of the newly constructed and tall apartment buildings in Gyumri and Spitak crumbled to the earth like so many sand castles washed away by an incoming tide.

The second set of preincident actions for a country or region with populous regions and cities in the area of large earthquake faults is the development and implementation of a disaster response plan that should include training medical providers and stockpiling equipment to facilitate rapid action in the event of an earthquake. The former Soviet Union's medical structure was reactive, rather than proactive, and slow to accept conceptual changes from the West. There was no emergency medicine in Armenia before the earthquake and only a very primitive prehospital care system. Search and rescue teams and earth-moving equipment, which are vital for appropriate search and rescue operations after an earthquake, were not readily available. The medical system was so economically devastated in the years before the fall of the Soviet Union that even some of the most basic

equipment for medical procedures was not available in medium to large cities in republics across the former Soviet Union. Therefore, when the earthquake struck, there were virtually no resources available to provide disaster response to Gyumri, Spitak, or the villages in between. The few surviving local health workers organized the small amount of undamaged medical equipment available and were able to mount a small immediate local response. Many healthcare workers responded from Yerevan, the capital city; however, as previously noted, transportation was very difficult—there is only one road into the earthquake region from the south, and much of it was destroyed by the earthquake. Search and rescue teams and equipment came first from the former Soviet Union and then from other countries; personnel, machinery, and supplies had to be flown into the airport in Yerevan and then trucked to the earthquake zone. This delay proved deadly for people trapped in the rubble of falling buildings, many of whom perished.

POSTINCIDENT ACTIONS

One of the most important concepts in disaster response today is that of command and control. There has to be a central authority that oversees the disaster response and controls the communications; logistics; requests for and distribution of resources; distribution of information; allocation of search and rescue teams and equipment, medical equipment, surgical equipment, primary care and subspecialty healthcare physicians, and allied healthcare workers; and construction of temporary healthcare facilities. This central authority is also responsible for the control, preparation, and distribution of other vital public health elements of the relief efforts, including sanitation, water, shelter, food, clothing, and psychosocial support. Large-scale international disaster responses, such as those mounted in Armenia after the earthquake, are well intentioned and successful in providing lifesaving interventions; nevertheless, they are inefficient and resource intensive. One problem that responders sometimes encounter is that many of the teams from different countries do not share a common language or common system in their approach to the response. They may have different equipment and drugs that cannot be shared across systems and are often unknown to healthcare practitioners in the host country. This lack of coordination can lead to extensive duplication of some services and the lack of other services completely. Some of this was magnified in Armenia because of the latent tensions between Armenia and Russia, in the wake of the dissolution of the former Soviet Union. There was a lack of trust of intentions on both sides that impeded the pace and efficiency of the response effort. Disaster responders from different countries are often reluctant to submit to a central command and control or Incident Command System that is being directed by administration and personnel from a country other than their own.

The tremendous amount of media attention that was focused on Armenia immediately after the earthquake was both a blessing and a curse. It engendered

a tremendous amount of international response, bringing healthcare workers, allied health personnel, search and rescue teams, fire rescue personnel, structural engineers, psychologists, and others from all over the world to Armenia with a huge amount of relief supplies. On the other hand, of the almost 5000 tons of drugs and medical supplies eventually delivered, less than 30% were usable by healthcare workers in Armenia. More than 10% of the drugs delivered were expired or about to expire, and an equal percentage of the medical equipment sent was outdated, broken, or not functional. Twenty percent of all materials delivered as foreign aid had to be destroyed by the Armenians by the end of 1989 at considerable cost.¹

In the ideal postimpact phase of an earthquake, the fire chief or fire rescue commander (of Spitak, Gyumri, Yerevan, or Armenia) would have initiated a command center and set up an Incident Command System. All other healthcare workers, search and rescue workers, structural engineers, and others involved in the rescue effort would have been dispatched through and monitored by the command center. All supplies, drugs, and other equipment would have been inventoried, sorted, and distributed through the command center, which also would have controlled the apportioning of casualties and would have maintained a database of all persons uncovered, discovered, or otherwise affected in the earthquake area. Such an orderly response is rarely seen in the postdisaster phase, especially in countries already suffering from economic, political, and social upheaval. Certainly this was the case in Armenia in 1988.

MEDICAL TREATMENT OF CASUALTIES

Medical casualties in the impact and postimpact phases of an earthquake disaster fall into three categories: acute, subacute, and chronic. Acute injuries from the impact of an earthquake, as clearly witnessed in the cities of Armenia, are caused by collapsing buildings, falling rubble, fire, and dust inhalation. Most people caught in collapsing buildings, especially structures greater than two stories, are killed instantly or trapped in pockets. Some of those trapped have body parts pinned under extremely heavy loads, timbers, or stone. Even when rescued, they will often have crush syndrome and acute renal failure. Others are caught up in the flash fires that accompany the rupture of natural gas pipes and suffer extensive body burns or smoke inhalation, leading to severe morbidity and mortality. A third group of patients suffers acute and chronic respiratory disease from the inhalation of the large amount of particulate matter that is aerosolized by the collapse of concrete and stone buildings and mixed with smoke from the generalized fires throughout a region. Depending on climatic conditions, hypothermia can also be a consideration.

The cities affected by the earthquake in Armenia were located in a mountainous, snowy region; the earthquake occurred in winter. Five hundred thousand people were homeless, and of those, many had minor to moderate orthopedic and soft tissue injuries. One of the

unique acute medical problems associated with earthquakes is crush syndrome. In some ways, the timing of the Armenian earthquake was quite fortuitous, considering the large incidence of crush syndrome and secondary renal failure. The American Society of Nephrology was having its annual meeting Dec. 11, 1988. The official Soviet request for dialysis was made to the nephrologists at that meeting and the international nephrology community responded.² Hospitals in Yerevan had 10 antiquated dialysis machines. The system was overwhelmed by the almost 400 patients with acute renal failure from crush syndrome who were extricated from the rubble of the earthquake. About 150 of these patients were flown to Moscow for dialysis treatment. Many others were treated by machinery sent by the international nephrology community rendering humanitarian assistance in response to the earthquake.³ This acute response also had positive long-term outcomes for Armenia in that an extensive sustainable dialysis program was set up in the postearthquake days and continues.^{4,5}

Subacute injuries and medical illnesses after the impact of an earthquake often include those that patients sustain while attempting to rescue other victims trapped in the rubble. These injuries are quite common since many of the buildings in a zone devastated by an earthquake are rendered structurally unstable and are subject to further collapse if people attempt to enter them to perform hand excavation and rescue; aftershocks are common. There are also many new hazards created by the collapse of building structures and the rupture of underground utility pipes and underground or above-ground electric wires. These secondary injuries are less severe than those sustained during the earthquake; nevertheless, they require appropriate intervention if patients are to heal properly without infection and long-term disability. Illness in the subacute phase includes exacerbation of chronic medical problems no longer being treated with appropriate medications or equipment destroyed during the disaster. These illnesses may include diabetes, hypertension, coronary artery disease, and pulmonary disease. Asthma and chronic obstructive pulmonary disease often flare in response to deteriorating air quality and the rapid spread of acute respiratory illness through a population weakened by compromised nutrition; sleep deprivation; and lack of clothing, housing, and food; and stress. Smoke from fires caused directly by the disaster as well as smoke from open fires used for cooking and keeping warm exacerbate these problems. Other infectious disease entities of concern include gastroenteritis from the consumption of spoiled food when refrigeration is not available and contaminated water from ruptured water mains and surface water contaminated by toxins and fecal run-off.

Chronic medical problems are seen in the weeks and months of the postimpact phase of an earthquake and include the ramifications of chronic disease entities untreated or partially treated during that time and the infectious complications of a population displaced into temporary and congested housing lacking proper food, clothing, and shelter. In addition, disruption of the social milieu may lead to psychiatric illness, including

posttraumatic stress disorder (PTSD) and depression. PTSD and depression may persist for months to years after the impact.^{6,7} In fact, treatment for these problems both in children and adults has been ongoing for years after the Armenian earthquake.⁸⁻¹⁰

UNIQUE CONSIDERATIONS

There are several considerations that are unique to the disaster medical response to an earthquake.

1. A small but salvageable number of persons is often trapped by falling building debris in an earthquake. Rapid deployment of appropriately trained search and rescue teams with dogs and high-tech listening devices is necessary to locate and save these people. Search and rescue equipment was very limited initially in response to the Armenian earthquake. It was on-scene after considerable delay during the rescue effort. Consequently, most people trapped in the rubble in Gyumri and Spitak died.
2. The most common injuries in an earthquake are traumatic injuries to the head and body, including closed head injury and orthopedic injuries. Disaster medical response teams must be prepared to handle these neurosurgical, orthopedic, and soft tissue injuries to provide appropriate medical treatment to casualties. Crush syndrome is more common in earthquakes than in any other disaster. The response team should have appropriate intravenous solutions and the equipment and skills to evaluate tissue compartment syndromes, perform fasciectomy, and treat crush syndrome. Laboratory capacity is necessary to monitor renal function and provide dialysis if necessary.
3. Other injuries commonly seen in earthquakes, especially in urban areas, are burns; inhalation injuries from smoke; and exacerbation of chronic or subacute respiratory illness, including asthma from the inhalation of dust, smoke, and debris. Disaster medical response teams must be prepared to treat patients with these problems.
4. Earthquakes massively destroy infrastructure, rendering hospitals and medical clinics inoperable and unusable. Basic utilities are also usually devastated, including gas lines, water mains, sewage facilities, and electrical power plants. The disaster response team must be prepared to provide these basic services, including water, shelter, and energy as well as temporary equipped medical facilities. Even if hospitals and clinics remain standing after an earthquake, they may be structurally unusable and extremely dangerous to enter.
5. The earthquake site is quite dangerous for rescue workers. Building debris, loose wires, and leaking gas, water, and sewage are common. Rescue workers entering buildings to perform search and rescue operations or to unearth buried casualties are often putting themselves at risk if the buildings are structurally unstable. Aftershocks are common after the initial impact of an earthquake and can trigger the collapse of structures that remain standing.

PITFALLS

1. Not implementing search and rescue operations early. Search and rescue personnel with heavy earth moving equipment can be very effective if mobilized in a timely fashion and are available proximate to the impact of the earthquake. These operations have discovered and unearthed survivors trapped in the rubble; however, this part of the disaster response is very cost-intensive and, generally, the number of victims saved is small relative to the total number of casualties that requires intensive short- and long-term medical care.
2. Identification and treatment of crush syndrome. Crush syndrome is common in patients pinned under small or large amounts of debris and trapped for extensive periods, leading to necrosis of the pinned extremities. Rescue workers should be fully educated and carry protocols on how to respond properly to patients who potentially have crush syndrome and incipient renal failure. The response team needs to have access to dialysis and nephrology consultation.
3. Even though major orthopedic injuries, crush syndrome, hemodialysis, and other major medical subspecialty interventions are interesting and often grab media attention, the most important part of the medical response to earthquakes is couched within public health and primary healthcare. The major issue facing most survivors of an earthquake is the restoration of infrastructure, including water, shelter, food, sanitation, and basic medical facilities with primary healthcare services. Any relief effort that ignores these issues will only have a short and expensive impact for a small number of patients without any sustained impact on the short-, medium-, or long-term health of the affected population.
4. Early attention to anxiety and psychological stress imposed by the disaster can ameliorate the long-term disability and impaired functional capacity associated with PTSD, chronic anxiety, and depression on the population. Disaster medical response teams must engage psychologists and psychiatrists to participate actively from the very beginning of the response.
5. Although human nature calls for an immediate active *intervention*, the best disaster medical response to an earthquake demands a rapid and immediate *assessment* with communication of information back to planning entities removed from the disaster site so that appropriate allocations of equipment, medicines, medical personnel, search and rescue teams, and other resources can be made.
6. Disaster systems concepts such as an Incident Command System and Command and Control must be imposed on any disaster response to avoid ineffective and inefficient interventions resulting in duplication, waste, miscommunication, and unnecessary further loss of life.

Tornado

Michael D. Jones and James Pfaff

DESCRIPTION OF EVENT

Tornadoes are one of nature’s most violent storms. In an average year, about 800 tornadoes are reported across the United States, resulting in 80 deaths and over 1500 injuries.¹ A tornado is a violently rotating column of air extending from swelling cumulonimbus clouds to the ground. The most violent tornadoes are capable of tremendous destruction with wind speeds of 250 mph or more. Damage paths can be in excess of 1 mile wide and 50 miles long.²

Tornado severity is graded using the Fujita-Pearson Tornado Scale (Table 74-1). This scale ranges from designations of F0 to F5. Originally designed as a measurement of structural damage caused by a tornado, the scale is now often used to describe the wind speeds associated with a tornado. Measurements of actual tornado wind speeds are not usually available, and the assignment of a Fujita designation may vary for any one tornado, even among experts. Still, this scale is the preferred method for rating the severity of these storms. The great majority of tornadoes are rated F0-F1 with wind speeds under 113 mph, causing only mild structural damage and rarely leading to significant injuries or death. Only 1%-2% of tornadoes each year are designated as F4-F5 (wind speeds greater than 206 mph), but these rare mon-

strous storms cause over 50% of the tornado-related fatalities in the United States each year.³

Tornadoes occur with equal frequency in all countries of the world that have land mass in the middle latitudes, but the unique landscape and weather patterns of the United States cause it to have the most intense tornadoes of any country. Between 1950 and 2003, over 4663 deaths and 80,376 injuries were reported as directly related to tornadic storms in the United States. In addition to the loss of life and the frequent injuries, tornadoes were responsible for over \$20 trillion in property and crop damage between 1950 and 2003.⁴ Tornadoes come in all shapes and sizes and can occur anywhere in the United States at any time of the year. In the southern states, peak tornado season is March through May, whereas peak months in the northern states are during the summer.² Because of the consistent high frequency of tornadoes seen in the region including northern Texas, Oklahoma, Kansas, and Nebraska, this area has become known as “Tornado Alley.”⁵ The probability that any one particular city in North America will be struck by a tornado has been calculated as once every 250 years.⁶ This probability is much higher for communities in Tornado Alley. For example, Oklahoma City has been struck by significant tornadoes 26 times in the past 100 years.⁷

Tornadoes strike with little or no warning. Because of investments in research and observation systems such as the NEXRAD Doppler radar, interactive computer systems, and other forecasting technology, the lead time for tornadoes has nearly doubled from a national average of 5 minutes in the early 1990s to nearly 11 minutes today. Major storms are often picked up or spotted and warnings made more than 20 minutes before the tornado touches down.¹ In the United States, all severe weather watches and warnings are issued by the Storm Prediction Center (SPC) in Norman, Oklahoma. The SPC is a division of the National Weather Service (NWS). The SPC issues a *tornado watch* when their forecasting systems indicate there is a region where tornadoes and other kinds of severe weather are possible in the next several hours. This is the time to turn on the TV or radio to the local weather channel and quickly review tornado disaster plans. The SPC issues a *tornado warning* only when a tornado has been spotted or when Doppler radar has detected a thunderstorm circulation that can spawn

TABLE 74-1 FUJITA-PEARSON TORNADO SCALE

CATEGORY	WIND SPEED (MPH)	TYPES OF DAMAGE INFLICTED
F0	40-72	Small trees uprooted, broken tree limbs
F1	73-112	Roofs damaged, mobile homes uprooted
F2	113-157	Roofs removed, mobile homes demolished
F3	158-206	Roofs and walls torn down, all trees uprooted
F4	207-260	Homes leveled, foundations moved
F5	261-318	Buildings destroyed, cars thrown >100 meters

a tornado at any moment.⁸ When a tornado warning is issued, immediate action to ensure safety during a tornado should be undertaken. Despite the improved surveillance and severe weather warning systems, communities that hope to prevent unnecessary death and injury from tornado disasters must prepare long before the warning sirens are sounding.

Pre-Incident Actions

The most important preincident action is to develop a tornado disaster plan and to rehearse that plan regularly. Such rehearsals should be especially frequent in communities within Tornado Alley. The Federal Emergency Management Agency (FEMA) has published a *State and Local Guide for All-Hazard Emergency Operations Planning* (SLG 101), which can be downloaded from their Web site.⁹ The SLG 101 has an appendix addressing specific issues for tornado planning.

Communication

Command/Control

Designate a clear command and control structure involving police, fire, EMS, and local hospital emergency rooms with capability for these entities to communicate on radio devices that do not depend on the local power grid for functionality.

Warning Systems

Make certain all public buildings, trailer home parks, nursing homes, and all hospitals have 24/7 access to local weather reports and a method for receiving severe weather watch and warning information from the SPC. Active warning systems (weather alert sirens, weather alert radios, and loudspeakers) are more effective than passive warning systems (conventional radio and TV).¹⁰

Injury Prevention

Warning/Shelter

Timely warning of an approaching tornado and appropriate sheltering have proved to be the most important factors in preventing injury and death in the face of tornadoic storms.¹¹⁻¹³

Focused Education

Public health education regarding tornado warning systems and safe sheltering during tornados should be provided to the populations most at risk. These include:

1. People in mobile homes
2. The elderly, very young, and physically or mentally impaired.
3. People who may not understand the warnings because of a language barrier.^{1,9}

Sheltering Guidelines

FEMA, the Centers for Disease Control and Prevention (CDC), and the NWS have published guidelines detailing

the safest sheltering actions to take in case of a tornado warning. These are summarized in Table 74-2.

Emergency Medical Response

Hospital Power/Water Supply

Medical facilities are not immune from tornado damage.¹⁴ Electrical power and clean, running water are essential to medical care following a tornado. All hospitals should have plans for short-term back-up power and water supply should the main power and water lines be damaged.

Trauma System Triage/Transport

An organized trauma system with a centralized communication system has been shown to be highly effective and efficient in ensuring that the sickest patients go to the highest level care facilities following a tornado disaster.¹⁵ Even with such a system in place, a significant minority of patients will require transfer from community hospitals to higher-level trauma centers. Agreements for such transfers should be worked out before a mass casualty incident occurs. Aeromedical transport has been shown to be of great benefit when they come to rural hospitals, or when the normal urban roadways are damaged or closed because of the disaster.¹⁶

Traffic Control at Hospitals

Traffic control has consistently been reported as a problem in and around emergency departments following a tornado disaster. Disaster plans should include

TABLE 74-2 SHELTERING GUIDELINES IN CASE OF TORNADO WARNING

In General:

1. Stay away from windows.
2. When a warning is issued, move to the safest area immediately.
3. If possible, put on a helmet.
4. Get under a sturdy piece of furniture and cover yourself with a blanket, pillows, or mattress.

IF YOU ARE:	YOU SHOULD:
Outside	Get inside a building. If stuck outside, stay away from cars and trees. Lie down in a ditch or culvert and cover your head and neck with your hands.
In a mobile home	Leave the mobile home. Go to a community shelter. If no shelter is available, see "Outside" above.
In a car	Move the car off the road. Leave the vehicle. Do not seek shelter under an overpass. If stuck outside, see above.
At work or school	Go to the designated interior room or hallway away from windows, and get under a sturdy piece of furniture.
In a house	Go to the basement. If there is no basement, go to an interior room or hallway away from windows, get under a sturdy piece of furniture, and cover yourself with a blanket.

directions for hospital security or local police to secure the access and egress routes from local hospitals. These agencies should understand where to direct the walking wounded, privately owned vehicles, and EMS vehicles for appropriate triage and evaluation.¹⁷

Healthcare Provider Training

The majority of patients arriving at hospitals following a tornado disaster will arrive by private vehicles. Some of these patients may have severe injuries. Healthcare personnel should be trained in proper spinal immobilization and vehicle extraction techniques in order to avoid further injury to these patients who have not benefited from prehospital medical care.^{8,17}

Postincident Actions

Search/Rescue

Reports of tornado disasters—including the 1970 tornado in Lubbock, Texas and the 1996 tornado in Topeka, Kansas—support the intuitive idea that the most severely injured victims and the majority of those killed will be found in the core area of the tornado strike.⁸ Severely injured victims are likely to be thrown by the tornado, struck by flying debris, or found in buildings with the greatest structural damage. An aerial survey using fire, EMS, or police helicopters can greatly assist rescue efforts by defining the regions of greatest damage and guiding search teams to locations where the most injured patients are likely to be found. Such surveys may be hindered by severe weather still lingering in the region. Search-and-rescue teams and first responders should protect themselves from hazards such as downed power-lines, gas leaks, and potentially unstable building structures. This is especially important since most tornado fatalities are not prevented by rapid EMS transport. Most patients that die in tornado disasters do so at the scene prior to EMS arrival.⁸ Multiple reports of tornado disasters confirm that very few patients that arrive at the hospital alive die during hospitalization.^{8,15,18,19}

EMS Triage

EMS units should be deployed carefully along the area of the tornado strike. Early responding units will likely become overwhelmed with casualties and must be supported by other units or aeromedical transport systems that can move the severely injured patients to the area hospitals and resupply the units in the field. Casualty collection points should be set up using mobile EMS vehicles or public buildings such as schools or churches. These collection points should be carefully selected to avoid radio blackout zones so that the medical command/control personnel can stay in close contact with the providers in the field to coordinate evacuation resources. If aeromedical transport is to be used, personnel must be trained in selecting and marking safe landing zones for the helicopters.

Hospital Triage

As in any mass casualty situation, it is imperative that open and precise communication channels are in place to allow triage personnel, emergency department physicians, and operating room personnel and surgeons to communicate as casualties arrive. Casualties following a tornado usually arrive in a bimodal fashion, with the least severely injured arriving first, usually within 5 to 30 minutes after the disaster. The severely wounded will arrive by EMS transport and by privately owned vehicles usually 1-4 hours after the tornado strike.^{17,20} Plans should be designed to allocate appropriate resources to the least injured without overwhelming personnel and space that will be needed by critically injured patients.

Monitor Ongoing Weather Alerts

It is not uncommon for multiple tornadoes to touch down in a region over a period of several hours. The emergency response teams and emergency departments should have access to NOAA weather alert radios and should constantly monitor the storm. Heavy flooding and/or hail may alter the medical response as well.

Medical Treatment of Casualties

Types of Injuries

The majority of injuries from tornado disasters are complex, contaminated soft-tissue wounds. Fractures are the second most common injury and the most common cause for hospitalization.^{8,10-12,15,19-20} Many fractures are open and require surgical wash-outs and reductions.²¹ Head injuries are the most common fatal injuries following tornado disasters.^{20,22} Nearly 50% of patients seen in emergency departments following tornado disasters will have soft tissue wounds as their chief complaint. Many of these wounds will be severely contaminated with mud and debris.^{8,9,22} Wound infections caused by gram-negative bacteria such as *Escherichia coli*, *Klebsiella*, *Serratia*, *Proteus*, and *Pseudomonas* are common in wounds sustained during tornadoes.²³⁻²⁵

A clean water supply, good lighting, large numbers of suture repair kits, and ample wound care materials are essential resources for emergency departments in a tornado response. In the case of water line damage, emergency departments must have access to a short-term emergency water supply. Some have suggested that without clean water, emergency departments should not even attempt to treat patients following a tornado but instead act as triage or command/control headquarters.^{8,26} An emergency supply of high-powered flashlights should be kept in all emergency departments and the batteries checked regularly. Car headlights have been used as a temporary lighting mode in tornado disasters that caused loss of power to hospital centers.

At 6 PM on May 15, you are working in a community hospital on the outskirts of Kansas City and your triage nurse comes running into the emergency department (ED) screaming “A huge tornado has been spotted just 5 miles from here. The news says it’s headed right into the metropolitan area!!!” Because of the frequency of tornadoes in the region, your head nurse knows the drill and immediately activates the hospital tornado response plan. Suddenly the power goes out in the hospital. Thanks to the backup generator, the lights, monitors, and computers are back up within minutes.

One of the new techs is assigned to watch three local news stations on the TVs in the waiting room and keep the head nurse posted on any new weather advisories or other public emergency announcements. This tech is also provided with a battery-powered weather alert (NOAA) radio that is kept in the emergency department for use during weather-related disasters. The operating room (OR) is notified of the possibility of mass-casualty incoming traumas, and the in-hospital radio system is tested to ensure adequate communications between the ED and the OR. All on-call physicians are alerted of the impending mass casualty and asked to respond ASAP. A call is made to the local police asking for assistance in organizing a controlled traffic pattern into and away from the ED. The hospital public affairs director is alerted via beeper and asked to organize a press-briefing area away from the ED.

Over the next 5 hours your hospital receives some 200 tornado-related patients. Almost 70% of these patients arrive by private vehicle and must be triaged by ED and hospital staff. Thanks to recent training, all victims of blunt trauma or other high-risk injuries are carefully immobilized and c-collars are placed by the triage personnel.

Again, thanks to the well-rehearsed hospital and regional disaster plan, you are able to provide appropriate care for all of these patients. During your shift, you and your colleagues treat 70 patients with soft tissue injuries, including

30 lacerations, 2 corneal abrasions, and 38 contusions. Halfway through the shift the city water is shut off because of tornado damage to several of the main lines. Luckily the hospital has an emergency hot and cold water supply that allows for continued appropriate cleansing of your patients wounds, most of which are highly contaminated with soil and other debris.

Almost 50 of the 200 patients are not physically injured but just don’t know where to go and need direction to the emergency shelters in the area being set up by the Red Cross and other relief agencies. Twenty-six patients present with head injuries ranging from mild concussions to skull fractures and ICH. Three of these patients require emergent transfer to the regional tertiary care facility for neurosurgical intervention. The local fire and EMS system provides two air ambulances, which make these transfers possible despite extensive damage and congestion on the local highways between your facility and the receiving hospital. During the shift you and your colleagues manage 18 patients with fractures and dislocations, 14 patients with blunt trauma to the chest and abdomen (one of whom has a pneumothorax requiring tube thoracotomy and 6 of whom are sent to the OR for emergent operative procedures), 18 sprains/strains, and one patient with a penetrating injury to the neck resulting in spinal cord injury. (This patient is also transferred via air ambulance to the regional tertiary care facility.) In all, you admit 35 patients with tornado-related injuries. Four of these go to the regional trauma center, four go to your ICU, six go to the OR, and 21 go to ward beds.

Driving home after your shift you contemplate the magnitude of the disaster you have just witnessed. You realize how grateful you are for all those “mandatory” disaster response drills the city has required you to reluctantly participate in over the past several years. You shudder to think what might have happened had you, the hospital, and your staff been totally unprepared for the events of the past 12 hours.

Unique Considerations

Most tornado-related deaths occur prior to arrival at the hospital. Rapid EMS transport may not affect mortality from tornadoes.

Soft tissue wounds from tornadoes should be considered highly contaminated, and delayed primary closure may be a prudent approach to wound management.

PITFALLS

Up to 50% of soft tissue wounds and contusions from tornado disasters are sustained during search-and-rescue efforts.

Flood

Sylvia H. Kim

DESCRIPTION OF EVENT

Floods are the most common natural disasters. They cause greater mortality than any other natural disaster.¹ Worldwide, floods account for approximately 40% of natural disasters. In the United States, approximately 146 deaths are caused by floods each year, the majority associated with flash floods.² Floods cost the nation \$3.8 billion each year.³

Floods continue to be the No. 1 natural disaster in the United States in terms of lives lost and property damage. In 1889, more than 2200 deaths were due to flash flooding from a dam break in Johnstown, Penn. In 1976, a 19 foot wall of water near the Big Thompson River near Denver, Colo., killed 140 people camping nearby.⁴ More recently, in 2001, Tropical Storm Allison resulted in 41 deaths, \$2 billion in property damage, and decades of research lost by scientists at the Texas Medical Center.⁵

Floods may be caused by an abundance of rainfall; melting snow; or the expanding development of wetlands, which reduces absorption of rainfall. Flash floods occur within 6 hours of a rain event, after a dam or levee fails, or after the sudden release of water from an ice or debris jam. Flash floods are the No. 1 cause of natural disaster-related death.³

Most communities in the United States can experience flooding. In fact, flash floods occur in all 50 states.⁶ Communities at greatest risk are those in low-lying areas, near water, and located downstream from a dam.⁴ In October 1998, flooding in Central Texas resulted in 31 deaths. Of the 16 incidents of vehicles being driven across flood waters, 11 (69%) occurred in areas with a prior history of flooding.⁷

PREINCIDENT ACTIONS

Hospitals should determine whether they are located in a flood-prone area. The National Weather Service issues flood watches and warnings, which are organized by state, and publishes these listings at www.nws.noaa.gov. These projections are based on precipitation and lake and river levels.⁸ Flood watches are posted 12 to 36 hours before possible flooding events. Flood watches indicate a hazardous event is occurring or will occur

within 30 minutes.³ A flood watch should be used for early evacuation planning.

Evacuation routes should be planned and practiced. For planning purposes, flood hazard maps are available from the Federal Emergency Management Agency at www.fema.gov/mit/tsd. The usual routes of access to and from the hospital may be flooded, therefore alternative routes should be planned in advance. As with any natural disaster, transport times will likely increase, and hospital personnel should expect ambulance arrival without prior dispatch. There will be greater reliance on alternative means of transport, including aeromedical and marine units.⁸ In one extreme case, flood waters isolated a community in Grand Forks, N.D. A temporary shelter for medical care that was capable of laboratory tests, radiology and other ancillary services was established.⁹

An emergency communications system should be available. Communication lines among hospitals, prehospital staff, and patients may be affected by floods. Telephone lines, 911 dispatch lines, and emergency medical service communication with hospitals may be impaired. Create a plan for redundant communications capabilities, including two-way radios and dedicated channels, cell phones, and Internet connectivity.¹⁰ An emergency communications system plan should be in place to request further staffing, services, or evacuation assistance.

Floods are long-term events and may last days to weeks, or longer.⁶ Therefore, disaster supplies should be available and include a portable battery-operated radio, flashlights, batteries, first aid kits, nonperishable food, and water.⁴

POSTINCIDENT ACTIONS

During a flood, battery-operated radios or televisions should be used. The National Oceanic and Atmospheric Administration (NOAA) Weather Radio broadcasts warnings from the National Weather Service 24 hours a day. Hospitals not equipped with the special radio receiver to pick up the signal can obtain timely information at iwin.nws.noaa.gov/iwin/nationalwarnings.html or from television and radio.

Hospital staff and patients should immediately be evacuated according to a pre-established disaster plan. If no

plan is in place, seek shelter at higher ground. Avoid walking or driving through flood water. The force from 6 inches of flood water can cause one to fall. Cars can easily be swept away by just 2 feet of flood water.⁴ Research from the Georgia flood in 1994 showed that 71% of flood deaths were associated with submersion in vehicles.²

MEDICAL TREATMENT OF CASUALTIES

Approximately 0.2% to 2% of flood survivors will require urgent medical care.¹ The main cause of death during floods is drowning, with victims typically found some time after the flood recedes. Because it is often difficult to reach victims during the acute phase of a flood, it is relatively uncommon for near-drowning victims to present to emergency departments.¹¹ Fast-flowing flood waters carry cars, trees, and other large debris that can result in trauma, including orthopedic injuries and lacerations.^{1,11} In addition, there have been reports of flood waters displacing snakes and other animals, resulting in increased animal bites.^{12,13} Also, the preponderance of water during the event and still water postevent results in an increase in insect bites and vectorborne illnesses. Flood waters also may contaminate the local water supply and sewage system.^{1,13}

The Centers for Disease Control and Prevention¹³ analyzed data from emergency departments in 20 hospitals during Hurricane Floyd in North Carolina during September and October 1999. The medical examiner found that 52 deaths were directly related to the storm. Four causes of injury/illness accounted for 63% of all emergency room visits during this period: orthopedic and soft tissue injury (28%), respiratory illness (15%), gastrointestinal illness (11%), and cardiovascular disease (9%). The majority (24/52, or 67%) of deaths was due to drowning, primarily associated with vehicles. There were 19 cases of hypothermia and 10 cases of carbon monoxide poisoning. There was also an increase in suicide attempts, violence, dog bites, and arthropod bites compared with the same period the prior year. Finally, five deaths occurred among prehospital personnel.¹³

Not surprisingly, drowning is the primary cause of death during floods. Patients who are submerged in cold water for 40 minutes have been successfully resuscitated to attain complete neurologic recovery secondary to the neuroprotective effects of hypothermia.¹ Therefore, cardiopulmonary resuscitation should be performed as soon as possible after securing the scene. Cervical spine injuries should be suspected, and immobilization should be maintained.¹⁴ The patient should be rewarmed using external and internal rewarming techniques, as indicated. Resuscitation efforts should be continued until the patient's temperature is 32° to 35°C (90° to 95°F); at that point, decisions regarding the utility of continuing resuscitation are made.¹⁵

Flood waters carry a large amount of debris, such as cars and tree limbs, and result in traumatic injuries. Orthopedic injuries should be reduced, splinted, and managed accordingly. Most injuries during floods that require urgent medical attention include lacerations,

rashes, and ulcers. These wounds are contaminated and should be conservatively managed by irrigation and healing by secondary intention. Among those lacerations that are closed primarily, the majority require reopening secondary to infection.¹

Floods cause water contamination and an increase in vectorborne illnesses. Water contamination often results from damage to the water purification and sewage systems. Contaminated water sources result in waterborne disease transmission, including *Escherichia coli*, *Shigella*, *Salmonella*, and hepatitis A virus. The large areas of stagnant water that typically remain days or weeks after the initial flood event create a breeding medium for vector-borne illnesses.

Flood waters may also result in the spread of chemicals stored above ground. In addition, temporary shelters to house those displaced by flooding may result in crowded and unsanitary living conditions, increasing the incidence of gastrointestinal illness among other infectious illnesses.¹

The force from flood waters may also down power lines, flood electrical circuits, and submerge electrical equipment, increasing the risk of fires and electrical hazards.^{4,8}

Finally, victims of floods, as well as other natural disasters, are at an increased risk of mental illness and substance abuse. In one study, there was an increase in suicide rates of 13.8% compared with predisaster rates.¹⁶ As of this writing we are beginning to see evidence of this in the flood regions resulting from Hurricane Katrina that struck the Gulf Coast of the United States in 2005.

UNIQUE CONSIDERATIONS

Floods are the most common natural disasters and affect all 50 states. Flood waters can remain for days, weeks, or longer. As a result, flood-related injuries and illnesses may continue to present over a long period of time. Drowning is the No. 1 cause of death and is often related to vehicles attempting to cross flood waters. Deaths also occur among healthcare providers, but increased natural disaster training may decrease this occurrence. In addition to drowning, flood victims are at an increased risk for hypothermia, contaminated wounds, and waterborne infections. Water and sewage treatment facilities may be damaged by flood waters and result in water contamination.

Most communities in the United States can experience flooding. Flash floods occur in all 50 states and most countries. Areas at greatest risk are low-lying, near water, and located downstream from a dam.⁴ For planning purposes, flood hazard maps should be obtained in advance and evacuation routes planned accordingly. In the event of flood warnings, evacuate early because a vehicle can be swept away with the force from as little as 2 feet of water.

PITFALLS

- Failure to plan flood evacuation routes before a flood event
- Delayed evacuation by those in a flood watch area

CASE PRESENTATION

While seeing patients in your emergency department, one of your staff members informs you that she just heard a flood watch for the local area over the radio. What should you do next?

- Failure to know who is in command of disaster operations in the local area
- Closing contaminated lacerations
- Failure to continue resuscitation of a patient who is hypothermic
- Notify the unified command/management structure and obtain directions
- Listen to a radio or television for local flood information
- Obtain your emergency kit and emergency communication (including battery-operated radio)
- Be prepared to evacuate patients and staff and know the evacuation route
- Communicate with other facilities to determine who has the capacity to accept your patients

Tsunami

Prasanthi Ramanujam and Thea James

DESCRIPTION OF EVENT

Tsunami is a series of waves formed by displaced water due to disturbance of the sea floor that enters the coastal areas, causing serious damage. *Tsunami* (pronounced tsoo-nah-mee) is a Japanese word that literally means “harbor wave.” Tsunamis are appropriately named so because they are silent and unseen in the ocean waters, but are fierce on the shallow coastal waters. They are commonly referred to as tidal waves or seismic sea waves. This is entirely misleading because neither of these terms fully characterizes tsunamis. Tidal waves are caused by the gravitational pull of the moon, sun, or planets, whereas seismic sea waves are the result of earthquakes. Tsunamis can also be caused by nonseismic activity and usually occur due to the following three major geologic movements:

1. **A fault movement on the sea floor occurring during an earthquake:** When tectonic earthquakes (those associated with the crustal deformation of earth) occur in the ocean floor, the harmony of the ocean is disturbed. This results in the displacement of the water mass, creating a wave. When a large area of the sea floor is involved, tsunami waves are created. Tsunamis can occur in any oceanic region of the world but are more common in the Pacific coast. The zone of Earth where tsunamis terrorize the Pacific Island coast is called the “Ring of Fire.” This zone of extreme seismic activity circles the Pacific Ocean from south of Chile to the coast of North America and westward along the Aleutian Islands arc, extending south to Japan and the Philippines, westward to Malaysia and Indonesia, and eastward through New Guinea, the Southern Pacific Island groups, and New Zealand.¹
2. **A landslide:** This begins above the sea, plunges into the water, or occurs under water and creates a violent disturbance in the waterfront as the landslide disseminates into the ocean floor, generating a tsunami.
3. **A sub-marine explosion:** This is the result of a volcanic eruption, creating a mechanical force that lifts the water column, which generates a tsunami. Landslides and cosmic-body impacts thrust the water from above, as the energy and force from falling debris are transferred to the water, stirring up a tsunami wave.²

Categories of Tsunamis

There are three categories of tsunami. Depending on the area affected, they are categorized as local, regional, or Pacific. Local tsunamis are confined to small areas and are commonly caused by coastal or sub-marine landslides and volcanic explosions. Regional tsunamis are the most common and are undersized because of deficient energy or lack of a favorable geographic location. Pacific-wide tsunamis are less common but have the potential for causing major damage.¹

Characteristics of a Tsunami

Once tsunamis are generated, the energy propagates a horizontal wave through the ocean, similar to ripples formed by tossing a rock into a pond. A series of waves, called a *tsunami wave train*, spreads outward in all directions from the source of activity. The waves follow each other in 5- to 90-minute intervals.² The original tsunami then divides into two types: one goes to the nearest coast (a local tsunami) and the other one travels into the deep ocean (a distant tsunami).¹ The speed at which the waves travel varies depending on the ocean depth, which implies that the local tsunami travels at slower speeds than the deep ocean wave. Tsunamis in deep water may travel as fast as 500 mph, compared with the normal wave speed of around 60 mph. Despite traveling at such great speeds on the open ocean, at that depth, they only reach one or two feet, producing a small uprise of the sea surface, often going unnoticed by sea travelers. However, as a tsunami comes closer to the coast, the wave height increases due to a decrease in ocean depth. People who have survived tsunamis describe them as giant “walls of water.” On shore, the initial sign of a tsunami depends on what part of the wave first reaches the land: a wave crest causes a rise in water level, but a wave trough causes a recession.² The terminology used to measure the height of water above the referenced sea level is called *run up*.³ Tsunamis may reach a maximum run up on shore of 10, 20, and even 30 meters. Unlike many descriptions of tsunami-like monster waves, the waves come onto the shore more like uncontrollable fast tides, and much of the damage inflicted is caused by their strong currents and debris.

The small number of tsunamis that form vertical walls of turbulent water near the shore line are called *bores*.¹ Once a tsunami hits the shore, some of its energy reverts into the ocean. In some cases, a tsunami can generate a particular type of wave called an *edge wave*, which swings back and forth along a coastal shore, resulting in successive multiple waves.³

PREINCIDENT ACTIONS

Once tsunamis are formed, they cannot be stopped; hence, strategies to lessen their effects are crucial. Salient features of a preparedness program include improving awareness and mitigation of the hazards. The foremost step is to increase knowledge among decision-making authorities, emergency personnel, and the public. Mitigation involves steps to decrease the impact of the event at the time of occurrence. The features recommended by the 1995 National Oceanic and Atmospheric Administration's (NOAA) Tsunami Hazard Mitigation plan⁴ are as follows:

- 1. Identifying an approaching tsunami and attempting to reduce false alarms:** The Pacific Tsunami Warning Center (PTWC) is an operational center for the Tsunami Warning System in the Pacific coast (TWSP). It has been the international warning center since 1965, when a formal arrangement was made. PTWC is able to locate seismic activities that are potentially tsunami-generating in the Pacific coast or surrounding areas by continuously obtaining seismographic data from more than 150 stations around the Pacific and other international agencies running such stations and networks.^{5,6} This method is not fool-proof; false alarm rates are extremely high. To improve the accuracy of reporting, Japan and NOAA have planted multiple bottom-pressure sensors that detect a tsunami traveling overhead. This information is communicated to the shore via satellite links using a buoy in the ocean. If the extent of destruction is determined to be wide, entire Pacific coastal areas are given a warning. Regional warning centers exist, which are responsible for the issuing warnings to specific countries and their coastal areas. For example, the Japan Meteorological Agency provides tsunami warnings to Japan and also to Korea and Russia for events occurring in the Sea of Japan or East Sea. The Center Polynésien de Prévention des Tsunamis provides warnings to French Polynesia and Chile. In the United States, West Coast/Alaska Tsunami Warning Center (WC/ATWC) provides tsunami warnings to the U.S. West Coast and Canada, and PTWC provides tsunami warnings to Hawaii and all other U.S. interests in the Pacific.⁶
- 2. Utilization of resources for communication and evacuation:** Local preparedness planning consists of determining safe evacuation pathways, setting up shelters, critical facilities, and strengthening structures that cannot be relocated and are in the path of inundation of a tsunami. As preparations are being undertaken, alerting systems are used to spread the information

and to communicate effectively about the evacuation measures. Local tsunamis pose major challenges. They are associated with earthquakes that cause damage to the infrastructure, leading to difficult evacuation plans. This is further complicated by a tsunami arriving minutes after events like earthquakes leaving less time for emergency response. Planning committees have made recommendations for this setting. They include disseminating an inundation map obtained using computer-generated simulations to plan mapping of the critical zones and to predict the areas prone to devastation. Other strategies are improvising warning systems and notifying the public immediately after earthquakes of the likelihood that a tsunami will result.⁴

- 3. Support for state and local agencies' long-term tsunami mitigation program:** Multistate projects have been proposed, along with individual state programs, to raise the public's level of awareness and preparation for an event. Apart from federal and state actions, various organizations exist to help coordinate federal, state, and local emergency management agencies; the public; and the NWS (National Weather Service) tsunami warning system. This helps maintain the safety of the public by increasing awareness. The various guidelines at the community level include:
 - Establish minimum community standards, which depend on the size of the community. Create a 24-hour operations system, with the ability to receive, disseminate, and activate warning systems in the community. There also should be communicative abilities between other emergency centers and tsunami warning centers.⁷
 - Disseminate information to the public using means such as NWS (NOAA weather radio), television, and a statewide telecommunications network located at public buildings.⁷
 - Improve awareness and preplanning among the community by conducting awareness programs in schools, hospitals, and community meetings. Define the areas in the community for shelter, provide hazard zones and evacuation maps, and conduct practice evacuation drills in schools.⁷

POSTINCIDENT ACTIONS

Preventing a disaster from happening is paramount, but when it is impossible to avert the natural disaster, timely applications of management strategies gain importance. The postincident action phase is composed of emergency response activities that transition into rehabilitation phase activities that culminate in the reconstruction phase. Emergency response efforts actually evolve from the final stages of the preincident phase and have many overlapping features. Examples include (a) evacuation of people to safe places, which in the case of a tsunami can be inland or to a higher altitude, and (b) provisions for emergency shelter and temporary lodging to people who are displaced after the event. The next stage begins

with the dispatch of search and rescue teams to look for injured people who need medical assistance. Because damage to water pipes in the affected areas is likely, provision of short-term food and water is essential for the displaced population. Water disinfection and purification become important after the disaster to prevent epidemics from water contamination. Public announcements regarding safety standards for water storage and disinfection, even after flooding, should be made as a preventive health measure. Epidemiologic surveillance in areas affected by flooding is important because overcrowding among the displaced population and overflow of industrial, agricultural, and sewage systems can pose serious health hazards. Subsequent management steps consist of reestablishing communication with remote areas, restoring infrastructure by re-opening roads, clearing debris, and repairing damaged housing and public buildings. The final phase consists of providing employment by creating opportunities, offering technical assistance to industries and for agricultural recovery, and encouraging activities that help rebuild the area.^{8,9}

MEDICAL TREATMENT OF CASUALTIES

Mass casualties can exceed system capabilities during disasters. This becomes a burden on the local system until outside help arrives. Steps to hasten the delivery of treatment to the injured include triage, on-site stabilization, and transportation to the local hospital. The goal of triage is to prioritize injured patients by identifying those whose injuries are critical and in need of prompt medical attention and arranging for either on-site treatment or quick transfer. Patients who have minimal likelihood of survival from major injuries despite optimal care are provided only comfort measures. There are two different systems of triage for mass casualties, and they are qualitative and quantitative. The former system is based on the patient's injury relative to others who are injured and to available care and requires timely reassessment. The latter is based on a clinical score for the patient at time of initial presentation to predict outcome. Triage begins with arrival of the emergency medical personnel on-scene. This is followed by relative assessment of the demand on available supplies. If the numbers overwhelm available help, the need for additional services is rapidly communicated to the emergency dispatch center. Triage set up begins with designating the most qualified medical person to be the provisional triage officer. With the arrival of more help from outside, this role should be taken by the most knowledgeable person with triage experience. Various adjuncts to triage help with the identification of which triage category the patient is placed in and with enforcing the use of a classification system, such as immediate, delayed, minor, and expectant, depending on the injury severity and prognosis. Priority one triage, based on the initial clinical picture, includes patients with impending airway issues, such as asphyxia, respiratory obstruction, sucking chest wounds, tension pneumothorax, maxillofacial wounds with impending air-

way compromise, shock, and major medical problems. Delayed triage, or priority two, includes patients with visceral, vascular, facial, spinal cord, and genitourinary injuries; thoracic injuries without asphyxia; and victims with less chance of survival. Once patients are triaged, a decision must be made as to whether to transport them to a nearby hospital or provide on-site care by setting up the necessary facilities. This decision is based on the number of available qualified transport personnel. If the system is overwhelmed by the number of patients awaiting rapid transportation, advanced-field medical treatment may be necessary. If rescue personnel or patients are in an unsafe environment, rapid transport becomes a necessity. Emergency communications should be used to alert local hospitals about the mass casualty situation and the need for resources to handle multiple-trauma patients. Hospitals, in turn should, report to the disaster operations center the current status on bed availability, the number of casualties they have received, and the availability of supplies to manage the crisis.⁹

UNIQUE CONSIDERATIONS

- Tsunami is rightfully called the harbor wave because its effects are devastating on coastal areas.
- Tsunamis are not one single wave but consist of a wave train and travel at great speeds in the ocean.
- Unlike other tides, tsunamis are caused mostly by seismic activity, which adds to the damage caused by a tsunami.
- Tsunamis are unique in that their propagation involves the entire depth from the ocean surface to the bottom, accounting for their tremendous energy.¹
- The issuance of a tsunami warning means that evidence exists for a potentially destructive tsunami and evacuation is strongly advised. On the other hand, a watch status means that a tsunami may have been generated, the wave travel time is more than 3 hours, and evacuation is needed if the watch is upgraded to a warning.¹
- For tsunamis of distant origin, the danger areas are 50 feet above sea level and within 1 mile of the coast.
- For tsunamis of local origin, potential danger areas are those less than 100 feet above sea level and within 1 mile of the coast.⁸

PITFALLS

- Tidal wave is a misnomer for tsunami because the latter can be extremely dangerous with devastating effects.
- Tsunami run up (height of the water above sea level) varies with the geography of the land, leading to different degrees of damage along the coastline.
- Local tsunamis can follow a seismic activity very quickly, leaving less time for incident preparation.
- False alarms during the preincident phase can pose a major drain on available resources.
- Early return of people to their settlements without anticipating the wave train or to witness the tsunami can result in significant morbidity and mortality.

Papua New Guinea is a group of islands including the eastern half of the island of New Guinea between the Coral Sea and the South Pacific Ocean, east of Indonesia. On July 17, 1998, at 6:49 PM local time, these islands experienced an earthquake with a magnitude of 7.1 near the northwest coast. This was soon followed by three dreadful tsunamis that killed about 2182 people and left more than 10,000 people in the villages of Sissano, Warupu, and Arop homeless. The tsunamis affected a 40-km coastline of a narrow strip of land, largely a swamp area between the ocean and a lagoon that was home to 15,000 tribal people who subsisted on farming and fishing. About 20 minutes after the first earthquake, the trough of the first tsunami arrived with a 7- to 10-meter crest that destroyed the village and swept the debris into the lagoon 500 meters inland from the coast. The destruction was enormous and included three schools, a health center, mission buildings, churches, bridges, and the government administration center. Common injuries included multiple bony and soft tissue injuries, development of gangrene, near-drownings, and loss of lives from impalement onto tree stumps.¹⁰

The tsunami of southeast Asia on Dec. 26, 2004, deserves mention for the death and devastation it caused in the region. An undersea earthquake with a magnitude of 9.0 on the Richter scale in the Indian Ocean originated off the western coast of Northern Sumatra. This fourth-largest earthquake since 1900 resulted in the generation of a tsunami, which affected the coastal regions of Indonesia, Thailand, Sri Lanka, and South India. Waves were as tall as 50 feet and traveled more than 1 mile inward in some areas. Damage also was recorded in South Africa, about 5000 miles from the epicenter. The estimated number of deaths

in the affected region was about 300,000 and the displaced population about 1.5 million. The waves also inflicted major environmental damage on the regions. There was infiltration of fresh water supplies, spread of solid and liquid wastes, damage to ecosystems, and much more. The economic damages are unquantifiable and included loss of industrial infrastructure on the coastline, destruction of fishing fleet, and a breakdown of the tourism industry. The devastation has created a lot of awareness in the region about tsunamis and has created a need for establishing warning systems in the Indian Ocean.¹¹

Multiple case reports from different parts of the world have resulted in improvements to existing disaster mitigation plans. Lessons learned from historic events include the following:

- Establish a global communication network that recognizes and warns the population in high-risk areas about possible tsunamis
- Quickly sense an approaching tsunami after ground-shaking and loud oceanic noises.¹⁰
- Identify areas of land between a lagoon and the ocean as high-risk areas for inundation, thereby avoiding rebuilding after a tsunami¹⁰
- Train the local population to handle the immediate disaster needs in case of a tsunami strike until further support systems can be deployed
- Recognize that mangroves are a source of floating debris that can cause more physical damage and that lagoon areas are less of an impediment for tsunamis, exposing more inland to destruction¹⁰

Heat Wave

Alison Sisitsky

DESCRIPTION OF EVENT

A heat wave is a prolonged period of heat and humidity. The duration of heat plays an important role in how people are affected. Illness tends to occur within 2 days of excessive heat. However, there are certain populations who are at increased risk, and may exhibit symptoms earlier. The elderly, very young, those with preexisting diseases, those taking various drugs/medications, and urban dwellers are more susceptible to heat-related illness.

Each year, hundreds of people die from heat-related illnesses. The Centers for Disease Control and Prevention estimated that from 1979 to 1997 there were 7000 U.S. deaths attributable to extreme heat. There were 600 deaths during the Chicago heat wave of July 1995. The next summer, during the 1996 Summer Olympics in Atlanta, Ga., 1059 people were treated for heat-related illness. Of those who died, 89% were either spectators or volunteers.¹

There are four mechanisms by which the human body is able to dissipate heat. Radiation is the passive transfer of heat by electromagnetic waves. This accounts for 65% of heat transfer. Evaporation is the transition of liquid into gas. This only occurs when the outside temperature reaches 95°F, and it accounts for 30% of heat transfer. Convection is heat loss to air and water vapor molecules that surround the body. It only accounts for 10% of heat transfer. Finally, conduction is heat transfer via direct physical contact. It is only responsible for 2% of heat transfer.²

Heat waves are among the most common emergencies and are the leading environmental cause of death in the United States, followed by cold-related deaths during winter months (Fig. 77-1).

PREINCIDENT ACTIONS

The most important action in preventing illness during a heat wave is public education before the heat wave begins. The National Weather Service issues alerts when a potential heat wave is near. The heat index (HI) is the temperature the body feels when heat and humidity are combined. For example, if the air temperature is 90°F and the relative humidity is 60%, the HI is 99°F.¹

Educating the public allows people to protect themselves from excessive heat exposure. If the following recommendations are adhered to, the risk of heat-related illnesses could be reduced. Reduce strenuous activity or reschedule outdoor activities until the coolest time of day. Dress with lightweight clothing and light colors. Avoid restrictive hats that will block sweating and evaporation of heat. Drink large amounts of water or other nonalcoholic beverages. Avoid alcohol intake. Spend as much time as possible in air-conditioning and avoid direct sun exposure.³

POSTINCIDENT ACTIONS

In the prehospital setting, remove the patient from the heat. Disrobe the patient and apply ice packs to the neck, axilla, and groin. In addition, placing a wet sheet over the body will encourage heat loss from the body to the environment. Intravenous fluid should be started. If the patient has an altered mental status, consider administering glucose, thiamine, and naloxone.

Always assess vital functions, and obtain an accurate core temperature with a rectal probe. Laboratory evaluation should include a complete blood count to assess for leukocytosis as well as electrolyte levels and a urinalysis. Hypernatremia can exist with severe dehydration. Acute renal failure and myoglobinuria may be present with rhabdomyolysis. If heat stroke is suspected, liver function tests and coagulation studies are needed to assess for hepatic necrosis or disseminated intravascular coagulation.

Further diagnostic tests should include an electrocardiogram in an elderly patient or anyone with cardiac risk factors, head computed tomography for patients with an altered mental status, and a chest x-ray for evidence of respiratory distress.^{4,5}

MEDICAL TREATMENT OF CASUALTIES

Immediate cooling should include spraying the disrobed patient with cool mist; fanning mist with bedside fans; and applying ice packs to the neck, axilla, and groin.

FIGURE 77-1. Heat fatalities. Between 1995 and 2002 in the United States heat-related deaths outnumbered both hurricane- and cold-related deaths. (Graph adapted from data collected at <http://www.disastercenter.com>.)

Immersion in cold water is effective if the patient's condition is stable, but it is difficult to manage patients who have any evidence of cardiovascular compromise.

For patients whose hyperthermia (temperature >104°F) persists, iced peritoneal lavage and cardiopulmonary bypass should be considered.

While active cooling is taking place, hydration should be started with 0.5 to 1 L of normal saline. Pediatric patients should receive a 20-mL/kg bolus.

Medications to consider include analgesics for muscle cramps; benzodiazepines for seizures or severe shivering; and glucose, thiamine, and naloxone for altered mental status.

Patients with evidence of heat stroke (hyperthermia, anhidrosis, and altered mental status) should be admitted to an intensive care unit. Patients with heat exhaustion (hyperthermia [temperature >104°F], central nervous system dysfunction, dehydration, nausea/vomiting, and diaphoresis) or the elderly should be admitted for electrolyte abnormalities and evidence of rhabdomyolysis.^{4,5}

UNIQUE CONSIDERATIONS

Patients at extremes of age are at increased risk of heat-related illnesses. Children have an increased body surface area to mass ratio, which increases their risk. Hydration of pediatric patients consists of a 20-mL/kg bolus of intravenous fluid. If hypoglycemia is present, give 2 mL/kg of D25W over 1 minute intravenously.

Elderly patients are at increased risk secondary to underlying medical conditions and medications that worsen heat illness. Taking a thorough history and a physical examination will help guide therapy.

Risk factors for serious heat injury are outlined in Table 77-1.^{2,4,5}

PITFALLS

Consider other causes of hyperthermia in patients with altered mental status. The differential diagnosis includes

TABLE 77-1 RISK FACTORS FOR SERIOUS HEAT INJURY

Dehydration
Obesity
Heavy clothing
Poor physical fitness
Cardiovascular disease
Skin diseases (burns, eczema, scleroderma, psoriasis)
Febrile illnesses
Hyperthyroidism
Alcoholism
Drug use (cocaine, amphetamines, opiates, LSD, PCP)
Poor socioeconomic conditions
Medications (antipsychotics, anticholinergics, calcium-channel blockers, beta blockers, diuretics, alpha agonists, sympathomimetics)

CASE PRESENTATION

Today is the local marathon. There are 2000 runners participating in the event. The local temperature is predicted to reach 99°F. The race started 2 hours ago and medical control is calling with questions. Not only do they have runners with symptoms of heat-related illness, many of the spectators are symptomatic. Currently, they would like to bring three patients. Patient 1 is a 40-year-old male with vomiting and severe abdominal pain who was unable to finish the race. Patient 2 is a 4-year-old female spectator who had a syncopal episode while waiting for her mom to finish the race. Patient 3 is an 85-year-old female who was providing water for the participants, but became diaphoretic and short of breath and is now unresponsive. While you are online with medical control, the triage nurse is handing you a note with five expected patients that were called in. How can you prepare to treat these people, and what care do they need?

alcohol withdrawal, neuroleptic malignant syndrome, malignant hyperthermia, toxicities (anticholinergics, salicylates, PCP, cocaine, amphetamine), infectious sources (tetanus, sepsis, encephalitis, meningitis, brain abscess, typhoid fever, malaria), endocrine abnormalities (thyroid storm, diabetic ketoacidosis), status epilepticus, and cerebral hemorrhage.

For patients with hyperthermia, do not forget to consider an acute cardiac event or a severe electrolyte abnormality.

Consider other causes of altered mental status, including hypoglycemia, thiamine deficiency, or opiate overdose.⁶

Winter Storm

Alison Sisitsky

DESCRIPTION OF EVENT

Heavy snow, high winds, and freezing rain can combine to create winter storms. The National Weather Service provides public information related to the severity of the storm expected. The various types of winter storm are blizzard, heavy snow, sleet, and ice storm. A blizzard is a combination of low temperatures, snow, and wind speeds up to 35 miles per hour resulting in less than a quarter mile of visibility. Heavy snow is 6 or more inches of falling snow in less than 12 hours. Sleet is frozen raindrops that bounce when hitting the ground. Finally, ice storms occur when rain hits the ground and freezes. The ice can accumulate on roads and power lines, causing damage and creating dangerous electrical hazards.¹

The incidence of winter storms is approximately 105 per year in the continental United States. Causes of death related to winter storms include traffic accidents, overexertion, and exposure.² Of these deaths, 70% occur in automobiles, and 25% occur out in the storm.¹

PREINCIDENT ACTIONS

Before a winter storm hits, the most important action is to prepare the public. This includes educating the public about when to expect a storm, how to find out if one is coming, and how to handle the possible dangers associated with it.

The National Weather Service will issue alerts on the radio and television within 24 hours of a possible storm. The alerts are graded from watch to advisory to warning. When dangerous weather is predicted, a watch is issued. During the storm, an advisory is issued that alerts the public to dangerous winter weather. When a warning is issued, the weather is very dangerous and could be life-threatening.¹

The public should have a winter storm plan as well as various supplies. Every home should have extra blankets and warm clothing, including coats, gloves, hats, and water-resistant boots. A disaster kit should be assembled. The American Red Cross recommends a first aid kit, a battery-powered weather radio, extra batteries, canned food, can opener, bottled water (1 gallon per person per day for 3 days), and extra warm clothing. In

addition, cars should be winterized in the late fall, including placing a disaster kit inside the car.¹

When a winter storm warning is issued, the public should follow these general rules: stay indoors but if one must go outside, wear several light layers of clothing, a hat, and gloves; protect the skin from wind chill; walk carefully on snow and ice; and avoid overexertion when removing snow.

If one gets stuck in a car, it is advised to stay inside the car after placing a bright cloth on the antenna. To stay warm, start the car and use the heater for 10 minutes every hour. Continue to move the arms and legs while sitting in the car to keep the body warm.¹

Prehospital treatment consists of keeping the patient warm with minimal movement if the patient is hypothermic. Assess vital functions, remove cold or wet clothing, and apply dry blankets. Refer to hypothermia treatment described later in the chapter. It is not recommended to begin cardiopulmonary resuscitation if a pulse is palpable and transport time is brief.

POSTINCIDENT ACTIONS

Remove the patient from the cold environment as soon as possible. Remove all wet and cold clothes to prevent further heat loss.³

The medical conditions to consider in a patient caught in a winter storm are hypothermia (mild, moderate, and severe), frostbite, carbon monoxide poisoning, and overexertion injuries.³

It is important to keep roads clear of snow and ice as soon as possible. Driveways and sidewalks around the hospital also must be clear to keep patients safe upon arrival.

MEDICAL TREATMENT OF CASUALTIES

Assess vital functions, and determine core temperature. Blood should be evaluated for possible complications, including lactic acidosis, rhabdomyolysis, and bleeding diatheses. A toxicology screen is recommended as well. An electrocardiogram should be obtained to evaluate for

prolongation of the intervals, elevation of the J point (Osborne wave) (Fig. 78-1), and dysrhythmias.³

Mild hypothermia is when the core temperature is between 32° and 35°C. Patients with mild hypothermia may experience tachypnea, tachycardia, shivering, or mild altered mental status. Passive external rewarming should be initiated after removing wet clothing. Blankets or any other insulation should be adequate to assist endogenous thermogenesis. Moderate hypothermia is when the core temperature is between 28° and 32°C. These patients may have decreased heart rate and cardiac output and generalized central nervous system depression. They are at risk for renal failure, atrial fibrillation, and bradycardia. Paradoxical undressing may be witnessed. Immediate passive and active external rewarming should be initiated. Warm blankets, heating pads, and warm air should be applied to the patient to decrease further heat loss. The heat should be applied to the patient's torso to prevent core temperature afterdrop. The goal is to prevent extensive peripheral vasodilation that occurs naturally after the patient is removed from the cold and is rewarmed. Cold blood is shunted to the core, causing decrease in body temperature as well as hypotension, poor cardiac perfusion, and risk of ventricular fibrillation.⁴⁻⁶

Severe hypothermia is when the core body temperature is below 28°C. Patients with severe hypothermia are at risk for hypotension, bradycardia, ventricular fibrillation, pulmonary edema, and coma. Move these patients carefully to avoid inducing ventricular fibrillation. Active internal rewarming is necessary in these patients and can be done with the external techniques previously described. Humidified oxygen and warm intravenous fluids are minimally invasive ways to warm the severely hypothermic patient. The peritoneal cavity, pleural spaces, and bladder can be irrigated with 45°C fluid.

Pleural irrigation should be reserved for those without a cardiac rhythm to avoid inducing ventricular fibrillation with chest tube placement. Blood warming by hemodialysis and cardiopulmonary bypass are acceptable means to raise the core body temperature. Protocols for aggressive and invasive rewarming procedures should be developed in cooperation with other departments involved in these processes prior to an incident requiring such measures.⁴⁻⁶

Arrhythmias related to hypothermia were formerly treated with bretylium, but this medication is no longer available. Arrhythmias should be treated according to advanced cardiac life support (ACLS) guidelines and may be refractory until the patient is normothermic.⁵

Cold-induced tissue injuries are common during winter storms. Risk factors include altered mental status, advanced age, malnutrition, and peripheral vascular disease. Tissue injuries range from mild (frostnip) to severe (frostbite). Frostbite is local injury from contact with temperatures below 2°C. The first phase of frostbite is the initial freeze injury when cell damage occurs. The second phase is the reperfusion injury that occurs while rewarming. The full extent of the injury may not be obvious on initial presentation. Do not rub or manipulate the frozen part. Treatment should consist of rapid rewarming in a water bath kept between 40° and 42°C. The affected extremity should be immersed for 15 to 30 minutes. Blisters should be left intact, and a sterile dressing with antibiotic ointment should cover any that have burst. Other remedies include aloe vera and ibuprofen. Tetanus status needs to be updated. Patients should be advised to avoid smoking as well.^{3,7,8}

Carbon monoxide poisoning should be considered in patients with headache, dizziness, nausea, vomiting, confusion, seizures, or coma. Apply 100% oxygen, and consider hyperbaric oxygen therapy if the patient's condition is stable and a chamber is easily accessible.

FIGURE 78-1. Electrocardiogram of a hypothermic patient with characteristic J waves after the QRS complexes.

Arterial blood gas and carboxyhemoglobin levels will help guide therapy.⁹

Epidemics of carbon monoxide toxicity may be encountered when heat and electricity are cut off for prolonged periods due to storms. The indoor use of heat generation utilizing fossil fuels contributes to cases (as was seen in the 1999 ice storms in upstate New York).

UNIQUE CONSIDERATIONS

Extremes of age are risk factors for cold-induced illnesses. As one ages, the shivering mechanism may not be adequate, and therefore there is an increased risk of hypothermia. Infants have a large body surface to mass ratio and can lose heat quickly. The elderly and children may be unable to carry out actions to warm themselves.

Medications such as barbiturates, benzodiazepines, chlorpromazine, and tricyclic antidepressants can increase the risk of hypothermia.

PITFALLS

- Always assess the entire patient.
- Think of other causes of altered mental status and consider giving naloxone, thiamine, and glucose.

CASE PRESENTATION

Yesterday, the National Weather Service issued a winter storm warning. A blizzard is expected to hit this morning. Snow began falling late last night, and local schools are closed. Emergency medical services have just arrived with a homeless man found unresponsive under a bridge. He is naked, feels frozen, and has a thready pulse. They have intubated him in the field and started intravenous fluid, but they cannot get a blood pressure reading. What else can be done to save this patient?

- Do not forget to evaluate for hypothermia in the patient who presents with frostbite.
- For patients with frostbite, do not rub the affected part. Monitor the rewarming bath temperature to avoid extremity refreezing. Obtain surgical consult for severe frostbite that involves structures below the subcutaneous tissues. Warn patients about the dangers of reexposing the area to cold temperatures.
- For patients with hypothermia, always obtain an accurate rectal temperature. Remember that arrhythmias are best treated with rewarming. Do not handle the patient roughly because it may induce arrhythmias. Continue to resuscitate patients until the core temperature is at least 32°C. Continue fluid resuscitation, and watch for core temperature afterdrop.^{3,5}

Volcanic Eruption

Gregory Jay

DESCRIPTION OF EVENT

Volcanic eruptions have the potential to produce significant loss of life and far-reaching medical and socioeconomic disruption. More than 270,000 volcano-related fatalities have been recorded since 1700, with the number of fatal eruptions averaging two to four events per year.¹⁻³ Eighty percent of the world's active volcanoes are located around the Pacific Basin where continental and seafloor plate subduction occurs.^{1,4} In 1990 approximately 10% of the world's population lived within 100 km of an active volcano.¹ With the continued growth in world population and urbanization, the risk of trauma and death from volcanic eruptions will only increase.

The violence or force of a volcanic eruption determines the characteristic of injuries produced. A volcanic eruption is the ejection of gases and solid material from a vent or hole in the Earth's surface. Outgassing, or release of volatiles dissolved in magma, provides the motive force for an eruption. While magma rises to the Earth's surface, the decreasing pressure on molten rock allows volatiles and gases in the melt to be released.⁵ The higher the silica content of the melt, the more viscous and polymerized it remains, stabilizing volatiles and gases.¹ When pressure is suddenly released on magma with a high dissolved volatile concentration, rapid and explosive outgassing may occur. This produces the typical violent or explosive eruption during which lava bombs and plumes of ash are ejected. When magma has a low silica content, outgassing occurs more gradually, and a more gentle, or effusive, eruption ensues.⁶ The volcanoes located along plate subduction zones tend to produce more violent eruptions because of the high silica and dissolved volatile concentration in their magma.¹

A variety of physical and chemical hazards are associated with volcanic eruptions. Lava is responsible for very few fatalities. The flow is often slow and can be easily avoided. Pyroclastic flows are responsible for the most deaths.² A pyroclastic flow is a mass of hot volcanic ash, lava fragments, and gases that erupts from a volcano and moves rapidly down its slope at speeds of up to a few hundred miles per hour.⁶⁻⁸ Rocks and debris within the flow may be hurled at great speed, causing severe secondary blast injury. Pyroclastic flows are extremely destructive and fatal to nearly all life in the

area through which they travel. The temperatures in a pyroclastic flow may be as high as 600° to 900°C, causing severe, if not fatal, burns.⁶

Pyroclastic flows may extend a great distance from the site of an eruption. Flows commonly travel up to 15 km from a vent; during the Mount St. Helens eruption in 1980, flows reached 17 miles.⁷ Pyroclastic flows often occur multiple times during an eruption and have also been reported in the absence of violent eruption.^{9,10}

Another common cause of volcanic eruption-related fatalities is tephra. Tephra includes all of the solid fragments of magma and volcanic rock ejected from a volcano during an eruption.^{6,8} Ejecta can cause severe head injury, burns, and blunt trauma.¹¹ Tephra fragments less than 2 mm are termed *ash*, 2- to 64-mm fragments are called *lapilli*, and fragments larger than 64 mm are often called *lava bombs* or *blocks*. Lava blocks and bombs generally follow a more ballistic trajectory after ejection, landing a few meters to several kilometers away from the site of eruption. The path and final point of impact is dependent on the initial "muzzle velocity" of the fragment.⁶ Ballistic fragments are a serious hazard near a vent, but become a more minor hazard as distance increases from the site of eruption. Air resistance also prevents ballistic fragments less than a few centimeters in diameter from being hurled more than a few hundred meters from a vent.⁶

Ash clouds pose a potential health hazard. Small particles of tephra rise on convection currents within a hot eruption cloud and may drift for hundreds of kilometers downwind from the active volcano.⁶ Tephra deposits tend to become finer grained farther downwind because the coarser particles of ash and lapilli fall nearer the volcano.⁶ In very large eruptions, tephra accumulations may reach several meters in depth, and the associated lapilli and ashfall may be heavy enough to induce darkness at midday.⁶ Although the mean diameter of tephra grains decreases with distance from a vent, the percentage of respirable ash, particles less than 10 μm in diameter, does not necessarily increase.⁶

Currently very little research is available regarding the respiratory effects of volcanic ash. There was concern about the development of acute silicosis from exposure to ash with high silica and cristobalite content.^{12,13} However, no cases of acute silicosis were reported in

studies of eruptions at Soufriere Volcano in Montserrat and of the Mount St. Helens eruption in 1980, where high concentrations of cristobalite and silica were recorded in ash samples.^{12,13} These studies did note a slight increase in bronchial reactivity and wheeze in children during the Montserrat eruptions and a doubling of asthma- and bronchitis-related emergency department (ED) visits, compared with the previous year, during the Mount St. Helens eruption.^{13,14} It is believed that no cases of acute silicosis were reported because people were not exposed to high enough concentrations of silica-laden ash for a long enough duration to develop the condition.¹³ The risk of silicosis from prolonged ash exposure may be more substantial, but it is difficult to quantify.¹³

During ashfalls, the amount of total suspended particles (TSP) in the air is a useful predictor of ED visits for some respiratory conditions. The number of ED visits for respiratory complaints during the Mount St. Helens eruption was highest when the TSP concentration was greater than 30,000 µg/m³.¹⁴ The number of ED visits did decline with decreasing TSP levels, but it did not return to normal levels until 3 weeks after peak TSP levels were recorded.¹⁴ The increase in ED visits during high TSP levels was greatest for asthmatics.¹⁴ (An important factor to remember is that rain significantly reduces TSP levels.¹⁴)

Volcanic gases also pose a potential health threat. To determine the hazards from volcanic gas, the composition of the volcanic gas emissions and the prevailing weather conditions should be assessed.^{6,15,16} Water vapor is the most abundant volcanic gas released, followed by carbon dioxide and sulfur dioxide.^{5,6} Volcanic emissions may also include smaller amounts of hydrogen sulfide, hydrogen, carbon monoxide, hydrogen chloride, hydrogen fluoride, helium, and trace amounts of other gases.⁵

The volcanic gases that pose the greatest threat to people, animals, and agriculture are sulfur dioxide, carbon dioxide, and hydrogen fluoride.⁵ Sulfur dioxide may produce an irritant effect in the upper and lower airways, on mucosal surfaces, in the eyes, and on the skin.^{5,17} Few studies have been performed to assess the health risk of volcanic gas emissions. One study, performed in Hawaii, of volcanic sulfur dioxide emissions was inconclusive in respect to its effect on reactive airway disease.¹⁸ Sulfur dioxide does produce acid rain, which may react with zinc in galvanizing on sheet metal roofs and release heavy metals into drinking water and catchments.¹⁶

Hydrogen fluoride also induces an irritant response in the upper and lower respiratory tracts, but it is of greatest risk to livestock secondary to ingestion. Ash becomes impregnated with hydrogen fluoride, and upon ingestion, the fluoride produces fluorosis and death of the animal.⁵ Fluorosis is a theoretical risk to a human population posteruption, but it can be avoided by cleaning ash off of food before ingestion and checking the fluoride levels of local drinking water.

Carbon dioxide is the second most common gas released during volcanic activity. Carbon dioxide is odorless, colorless, and heavier than air, thus it will collect in low-lying areas. Breathing air with a carbon dioxide concentration greater than 20% to 30% can rapidly induce unconsciousness and death through asphyxiation.⁵ If a substantial release of carbon dioxide has occurred or is sus-

pected, venturing into depressions or cellars in the area should be avoided. The carbon dioxide and air boundary can be sharply demarcated, with one step placing a person within a lethal concentration of carbon dioxide.⁵

The other gases tend to be released in much smaller quantities during an eruption. An important consideration is hydrogen sulfide. It is a highly toxic gas that is relatively dense and may collect in depressions and low-lying areas.⁶ Hydrogen sulfide gives off a “rotten egg” odor and can cause eye and upper respiratory tract irritation, pulmonary edema with prolonged exposure, and death through cellular asphyxiation.^{5,17} It is important to determine the emissions spectrum of a volcano to ensure that larger concentrations of dangerous trace gases are not present.

Volcanic debris flows, termed *lahars*, and mudslides can be very destructive. Loose fragments of rock mixed with water from rainfall, melted snowpack, or another source forms a thick slurry that travels down the mountain side or valley at speeds that may be greater than 50 km per hour.^{6,19} The high sediment concentration of the flow destroys buildings, bridges, and other structures, which would usually survive a flood.⁶ People caught in the flows almost universally perish.⁶

Lahars also occur when a volcano is quiescent. Both the heavy rainfall from hurricanes and the disruption of volcanic debris and sediment by earthquakes have produced lahars and mudslides.^{20,21} Lahars may also be formed by lake breakouts. This happens weeks to months after an eruption when a river blocked by a mudslide or other volcanic deposit overflows the newly formed dam. Erosion of the blockage and the walls of the river channel downstream from the initial surge of water allows tremendous volumes of sediment to be incorporated into the flow.²² This is termed a *cold lahar*; in comparison, the lahar formed by hot volcanic debris may remain hot far downstream.⁶

Volcanoes pose a unique threat in regard to gas release in the absence of visible eruption. In 1984 at Lake Monoun in Cameroon, 73 people were killed by carbon dioxide released by lake water turnover.²³ A similar event occurred in 1986 at Lake Nyos in Cameroon, a crater lake. Approximately 1700 people in low-lying areas were killed by a massive release of carbon dioxide.²³ Carbon dioxide is believed to have gradually accumulated in the deep waters of the lake. Rain or a landslide may have been responsible for the lake water turnover and gas release at Lake Nyos.

Other risks associated with volcanic eruptions are lightning, tsunamis, and earthquakes. Lightning discharges and lightning strikes from ash clouds occur during eruptions and have caused electrocution injuries.²⁴ Please see the chapters on tsunamis (Chapter 76) and earthquakes (Chapter 73) for further information about these forms of disaster.

PREINCIDENT ACTIONS

The following are important preincident questions to ask:

- Is there a volcano in close proximity to your medical facility that may be at risk of eruption? To determine

this, contact the U.S. Geological Survey or an equivalent authoritative source.

- Does your facility have a mass casualty plan in case of an eruption? Refer to the section on the basics of disaster management (Part 1 of the book) for assistance in developing an organized strategy for dealing with mass casualties.
- Does your medical facility need to be evacuated in the event of an eruption? Medical facilities were evacuated during the eruption of the Rabaul Volcano in Papua New Guinea in 1994 because it was in the fallout zone.²⁴ If your facility is in a valley or plain with a history of lahars or mudslides, it may need to be evacuated.
- Is a disaster plan prepared, and has it been practiced to allow the timely notification and evacuation of your hospital and the populations at risk? Preparation is crucial, considering that the majority of the deaths during an eruption occur within the first 24 hours.² Please refer to the basics of disaster management of this book (Chapter 1) for assistance in creating a disaster plan appropriate for your facility.
- If your facility may require evacuation during an eruption, is there an evacuation plan prepared and coordinated with the appropriate nearest medical facilities outside of the potential fallout zone?
- Does your facility have appropriate supplies and personal protective equipment? Your facility may benefit from having detectors for sulfur dioxide, hydrogen sulfide, carbon dioxide, and carbon monoxide available in case of gas release.¹⁵ Special masks may be needed for protection from gases and dust. Particulate masks do not provide adequate protection. Based on experience from the World Trade Center disaster, the New York Committee for Occupational Safety and Health has recommended the use of National Institute for Occupational Safety and Health (NIOSH)-approved air-purifying respirators of N-100 or N-95 grade.²⁵ Other useful protective equipment would include hard hats or helmets and heat-resistant clothing.¹¹
- Does your facility have adequate internal resources for continued short-term operation if isolated by disruption of local infrastructure? If not, do you have a plan for communication and procurement of needed assistance?

POSTINCIDENT ACTIONS

1. Activation of disaster plan with appropriate allocation of resources.
2. Distribution and use of appropriate personal protective equipment.
3. Situational awareness. Avoid low-lying areas where lahars or pyroclastic flows have occurred because of the risk of repeat episodes. Avoid basements or depressions where toxic gases may have accumulated unless air quality has been tested.
4. Be alert for repeat eruptions. The volcano may erupt multiple times.
5. Monitor ash and tephra accumulation on buildings in the medical facility. Tephra causes the most injuries

through building collapse. If ash clearing is undertaken, make sure that appropriate personal protective equipment is worn and that the conditions are safe enough to allow removal of the ash. If there is any concern about the risk of building collapse, consider evacuating the facility or building.

6. Monitor air quality and provide appropriate public health warnings. Those at risk for chronic obstructive pulmonary disease and asthma exacerbations may benefit from staying indoors, if it is safe to do so, while TSP concentrations are high.

MEDICAL TREATMENT OF CASUALTIES

Casualties during a volcanic eruption can be complex and require sophisticated and intensive multisystem trauma care. Detailing of all the medical treatments potentially required is beyond the scope of this chapter. The important factor to consider is the mechanism of volcanic-related injury in anticipating patient care needs. The broad categories of injuries seen are burns, crush injuries, head trauma, inhalation injuries, toxic exposure to gases, blunt force trauma, and amputations. For further information and recommendations please refer to the basics of disaster management of this book (Part 1), the accidental disaster section (chapter 57), and the following chapters: accidental versus intentional event (Chapter 57) building and bridge collapse (Chapters 169 and 170), landslide (Chapter 81) and building fires (Chapter 156).

UNIQUE CONSIDERATIONS

1. Gas release from lake water turnover in the absence of visible volcanic activity.
2. Dormant or suspected dormant volcano reactivation.

PITFALLS

1. Failure to assess whether your medical facility is at risk from volcanic eruption and failure to incorporate this eventuality into the hospital disaster plan.
2. Lack of consideration for a volcano's historic eruptive pattern when preparing a disaster plan.
3. Failure of your medical facility to procure adequate and appropriate supplies to deal with a volcanic eruption. Personal protective equipment should include heat-resistant coveralls, hard hats, and NIOSH-recommended respirators.
4. Failure to appreciate the risk for volcanic-related injuries in the absence of visible volcanic activity. Examples include mudslides, lahars, and volcanic gas release.
5. Failure to consider the need to evacuate a hospital posteruption and to determine whether the receiving facility is in a safe zone that will not be endangered by future or repeated eruptions.

CASE PRESENTATION

The eruption of the Galeras Volcano in Colombia in 1993 provides a better understanding of the need for adequate personal protective equipment and a more clear understanding of the injury spectrum that may be suffered during a volcanic eruption. Six volcanologists and three tourists were killed when the volcano erupted without warning. Autopsies showed that individuals closest to the eruption site within the caldera were torn apart by the force of the eruption. Those farther away from the eruption suffered burns from ejecta, fractures, concussions, and other head injuries from bombardment with ejecta. Analysis of the tragedy suggested that hard hats would provide some protection from head injuries during escape. Heat-resistant and water-repellent coveralls could limit the risk of burns and clothing ignition.¹¹

Famine

Laura Macnow and Hilarie Cranmer

DESCRIPTION OF EVENT

Famine is the most extreme form of lack of access to enough food and is often the result of natural or man-made disasters. Famine has been defined as “a condition of populations in which a substantial increase in deaths is associated with inadequate food consumption.”¹ Natural disasters such as drought, floods, crop infestations, and livestock diseases that limit a population’s food production are often popularly thought of as the events precipitating famine; however, insufficient access to food is now more commonly the result of war, civil strife, and economic collapse. Famine is usually caused by an exacerbation of preexisting conditions of poverty, debt, underemployment, and high malnutrition prevalence in a population, so that when added burdens arise, widespread starvation can occur rapidly.²

Famine is a complex emergency often involving massive population displacements between and within countries, and as such, complicates the ability of agencies to coordinate relief efforts and provide ongoing surveillance of the emergency.

The usual consequences of mass starvation during famine are increased malnutrition and mortality.³ Manifestations of starvation depend on the individual’s previous nutritional status, age, and severity of food deprivation.⁴ Malnutrition is the objective physical or laboratory findings of physical deterioration as a result of inadequate nutrient intake and encompasses a range of conditions, including acute malnutrition (characterized by wasting), chronic malnutrition (characterized by stunting or nutritional edema), and micronutrient deficiencies.⁵

To assess the prevalence of moderate-to-severe malnutrition in a population, it is a commonly accepted practice to do anthropometric surveys in a random sample of children younger than 5 years using the weight-for-height (WFH) index^{2,5}; these data are a reliable indicator of malnutrition in the wider population. Because weight is more sensitive to sudden changes in food availability,² the WFH index is used instead of height-for-age (which measures stunting). Mean upper arm circumference (MUAC) can also be measured to screen for acute malnutrition. The presence of edema, however, may confound these indices, and clinical judg-

ment must be used in their evaluation. Additionally, anthropometric data may be skewed by concurrent mortality rates. Anthropometric data are commonly interpreted using *z* scores (or standard deviation [SD] scores) where:

$$z \text{ score (or SD score)} = \frac{\text{Observed Value} - \text{Median Value of the Reference Population}}{\text{Standard Deviation Value of Reference Population}}$$

The WHO Global Database on Child Growth and Malnutrition⁶ uses a *z*-score cut-off point of less than -2 SD to classify low weight-for-age, low height-for-age, and low weight-for-height as moderate and severe undernutrition, and less than -3 SD to define severe undernutrition.⁶ If more than 8% of the children samples have a *z* score of less than -2 , a nutritional emergency exists. An excess of even 1% of children with *z* scores of less than -3 indicates a need for immediate action.²

Famines are often assessed and reported in terms of cases, rates, or degrees of malnutrition, or the number of deaths from malnutrition and its complications. Crude mortality rates (CMRs) can be useful for evaluating the severity of a disaster, using 1 death/10,000 population/day as the cut-off for an emergency.²

Although the most direct and obvious results of famine are severe malnutrition and death, the immediate cause of death in affected individuals is usually a communicable disease, most commonly measles, diarrheal illness, acute respiratory infections (ARIs), and malaria. Displaced populations and refugees almost always experience higher CMRs compared with nondisplaced populations, and this is likely due to increased risk of communicable disease associated with crowded, often unsanitary camps. Malnutrition predisposes individuals to certain micronutrient deficiencies, notably vitamin A deficiency; communicable diseases such as measles and diarrhea further deplete vitamin A stores and can cause worsening immune compromise and xerophthalmia, corneal xerosis, and ulceration and scarring, and can eventually lead to blindness.² Other important micronutrient deficiencies include vitamin C, niacin, iron, iodine, and thiamine deficiency.

PREINCIDENT ACTIONS

- Advance detection and monitoring of economic, social, and environmental factors that influence the development of food shortages and famine. Early warning systems may rely on community involvement. Local people can collect data on what they see as signs of growing food insecurity; for example, an increase in the number of animals sold in local markets may indicate that families need cash to buy food because their crops have failed.⁷ This information is used in conjunction with satellite imaging and meteorologic data to create the whole picture of drought and its effects.
- Support of socially responsible community development, including education about preserving the huge local ranges of hardy crop types and encouraging food production of a wide variety of crops, bred to be hardy and grown together in a robust mixed-crop pattern. This will help communities recover quickly in the event of natural disasters.⁷ Mono-cropping can increase vulnerability in times of natural or economic disasters, as can deforestation, desertification, and poor agricultural practices.²
- Coordination of relief agencies.
- Development of standard case management protocols.
- Establishment of reserves of essential supplies (medical and nutritional).
- Development of environmental management plans.

POSTINCIDENT ACTIONS

- Media and worldwide notification.
- Perform field assessment: determine total refugee or displaced population, determine age-sex breakdown and average family/household size, identify at-risk groups (children <5 years old, pregnant and lactating women, elderly, disabled/wounded persons). This information is needed to estimate quantities of relief supplies and for effective surveillance of mortality/morbidity rates.
- Initiate health and nutrition surveillance systems.
- Assess prior health/nutritional status, and determine prevalence of acute malnutrition and micronutrient deficiencies in children younger than 5 years old (this serves as a proxy for malnutrition in the general population).
- Calculate crude, age-, sex-, and cause-specific mortality rates and morbidity rates of diseases.
- Assess local community resources, and determine important health beliefs and traditions.
- Evaluate environmental conditions, such as water sources, sanitation arrangements, local disease vectors and epidemiology, and availability of materials for shelter and fuel.
- Evaluate resources such as food supplies and distribution systems, and assess logistics for food transport and storage.
- Ensure ongoing surveillance of communities' health and nutritional status and evaluate the effectiveness of the intervention and quality of care delivered.²

MEDICAL TREATMENT OF CASUALTIES

Medical treatment of victims of famine must include preventive as well as curative measures. Regardless of immunization status, all children up to age 16 should be immunized against measles. If vaccine supplies are limited, higher-risk children (up to age 5) should be immunized preferentially. One should never withhold immunization because of fever, ARI, diarrhea, HIV, or malnutrition. Vitamin A treatment should be instituted concomitantly. All children with clinical measles should receive 200,000 IU oral vitamin A (half-dose for children <12 months); children with complicated measles should receive a second dose on day 2. Individuals with eye symptoms of vitamin A deficiency should receive 200,000 IU oral vitamin A on day 1, day 2, and then again 1 to 4 weeks later (half-dose for children <12 months).

Diarrheal illness in malnourished populations is generally caused by the same pathogens that cause diarrhea in developing countries: *Escherichia coli*, *Shigella*, and *Salmonella*. Oral rehydration therapy (ORT) is a mainstay in the treatment of diarrhea, and chemotherapy should not be used for routine treatment of uncomplicated, watery diarrhea unless cholera, *Shigella*, *Giardia*, or amoebic dysentery is suspected. Preventive measures are of extreme importance in control of diarrheal illness and include providing adequate quantities of clean water, good sanitation, personal hygiene education, and promotion of breast-feeding of infants.^{2,5}

Nutritional interventions can be categorized as general ration distribution to the affected population, blanket supplementary feeding to all members of an identified risk group, targeted dry (take-home) supplementary feeding centers for the moderately malnourished, and therapeutic feeding centers for the severely malnourished. General rations must supply at least 2100 kcal/person/day, of which 17% of calories are in the form of fats and 12% of calories are derived from protein.⁵ Food should ideally be distributed in a community setting (avoiding risk of communicable disease associated with mass feeding centers), and adequate fuel and cooking utensils should be available. Supplemental feeding programs should be provided to acutely undernourished children younger than 5 years old, pregnant and lactating women, elderly individuals, and chronically ill individuals. The disadvantage of dry (take-home) supplemental feedings is that sharing of the ration among family members is likely. Therapeutic feeding programs (TFPs) are reserved for severely malnourished children (z score of less than -3 , clinical edema); feedings are provided in on-site, resource-intensive centers. Children should receive 150 kcal and 3 g of protein for each kilogram of body weight in four to six feedings per day.² Nasogastric feedings may be needed. Close monitoring is essential, and weight gain should be targeted to 10 g/1 kg of body weight/day. TFPs have serious limitations, and there have been suggestions that community-based therapeutic care is likely to be more successful. TFPs are resource-intensive and require skilled staff and imported therapeutic products; international standards require one care

provider for every 10 patients, with a maximum of 100 patients per center.⁸ Criticisms of TFPs include that they take months to become operational, have low coverage, are extremely expensive, undermine local health infrastructure, disempower communities, and promote the congregation of people around them, increasing risk of communicable diseases.⁸ Admitted children usually depend on the presence of their mothers to care for them around the clock, taking the mothers away from their community and decreasing their ability to look after their other children. Community-based therapeutic care, on the other hand, may be as successful overall as TFPs at decreasing overall mortality, while being more cost-effective and less disruptive to communities and families. A ready-to-use therapeutic food (RUTF) made from peanuts, dried skimmed milk, sugar, and a specially formulated mineral/vitamin mix can be distributed in a paste form, which keeps it from spoiling for several months, and is equally nutritious as TFP feedings. Proponents of community-based therapeutic care suggest that, when used to complement TFPs, overall death rates from starvation can be reduced while providing socioeconomic and educational benefits for the families of the malnourished.⁸

UNIQUE CONSIDERATIONS

The demographic groups that are most at risk during famine are young children and women, and it is important that establishment of Maternal and Child Health (MCH) care be given high priority to provide care for pregnant and lactating women and children younger than 2 years of age. Services should include health

CASE PRESENTATION

You have volunteered to work in a refugee camp in Rwanda. Your first patient is a 5-year-old with a cough and a rash. Physical examination reveals a severely malnourished child with a nonproductive cough. The rash is diffuse and has been present for at least 3 days. The child also has a fever and diarrhea.

education as well as routine monitoring, immunization, nutritional rehabilitation, micronutrient supplementation, and curative care. Breast-feeding should be encouraged for children, minimally up to age 6 months, and preferably up to 2 years. Local female health workers should be trained to provide culturally appropriate education and care. Ideally, one MCH clinic per 5000 population should be set up.²

PITFALLS

- Failure to recognize early warning signs of famine
- Failure to mobilize resources and coordinate relief agencies
- Neglect of preventive programs (e.g., immunizations, ORT, hygiene education), and failure to prevent communicable diseases
- Failure to preferentially target vulnerable populations
- Lack of variety in basic relief rations (risk of micronutrient deficiencies)
- Failure to recognize importance of cultural practices, beliefs, and taboos, and failure to involve the refugee community and its leaders in relief work

Landslides*

Mark E. Keim

DESCRIPTION OF EVENT

The term *landslide* includes a wide range of ground movement, such as rock falls, deep failure of slopes, and shallow debris flows. This chapter uses landslide terminology as presented by Varnes¹ and Cruden and Varnes.² As used, the term *landslide* will include all types of gravity-induced mass movements, ranging from rock falls through slides/slumps, avalanches, and flows, and it includes both subaerial and submarine mass movements triggered mainly by precipitation (including snowmelt), seismic activity, and volcanic eruptions. For simplification, the term *debris flow* will include mud flows, debris torrents, and lahars (volcanic debris flows).

Debris flows are fast-moving landslides that occur in a wide range of environments. A debris flow is a rapidly moving mass of water and material that is mainly composed of sand, gravel, and cobbles, but typically includes trees, cars, small buildings, and other anthropogenic material. A debris flow typically has the consistency of wet concrete and moves at speeds in excess of 16 meters per second (35 miles per hour).³

Although gravity acting on an over-steepened slope is the primary reason for a landslide, there are other contributing factors⁴:

- Erosion by rivers, glaciers, or ocean waves creates over-steepened slopes
- Rock and soil slopes are weakened through saturation by snowmelt or heavy rains
- Earthquakes create stresses that make weak slopes fail
- Earthquakes of magnitude 4.0 and greater have been known to trigger landslides
- Volcanic eruptions produce loose ash deposits, heavy rain, and debris flows
- Excess weight from accumulation of rain or snow, stockpiling of rock or ore, waste piles, or manmade structures may stress weak slopes to failure and other structures

*The material in this chapter reflects solely the views of the author. It does not necessarily reflect the policies or recommendations of the Centers for Disease Control and Prevention or the U.S. Department of Health and Human Services.

The world's largest landslides are prehistoric. Their remains are displayed as significant morphologic features on the Earth's surface. Most very large landslides have been triggered by earthquakes or volcanic eruptions.⁵

The world's largest historic landslide is the 1980 Mount St. Helens rock slide-debris avalanche in the Cascade Range of southwestern Washington State, which was triggered by a catastrophic volcanic eruption.⁶ This 24-km-long, 2.8-km³ landslide buried about 60 km² of the valley of the North Fork Toutle River under a cover of hummocky-surfaced, poorly sorted debris, ranging in size from clay to blocks of volcanic rocks with individual volumes as large as several thousand cubic meters.⁵

Landslides occur in every state and U.S. territory. The Appalachian Mountains, the Rocky Mountains, and the Pacific Coastal Ranges as well as some parts of Alaska and Hawaii have severe landslide problems. Landslides cost an estimated \$1 billion to \$3 billion per year in the United States alone. During 1990-1999, landslides were second only to hurricanes as the leading cause of death resulting from environmental disasters in the hazard-prone Pacific basin (4 times more than earthquakes and 30 times more than volcanoes).⁷

Landslides and debris flows triggered by earthquakes accounted for most of the fatalities and serious injuries in several recent earthquakes, including those in Peru (1970), Tajikistan (1989), the Philippines (1990), and Colombia (1994).⁸ In 1985, a lahar from Nevado del Ruiz volcano traveled over 30 miles and killed at least 23,000 people.⁹ In 1999, rainstorms induced thousands of landslides along the coast of northern Venezuela and resulted in a death toll estimated at 19,000 to 30,000 people and total damage estimated at \$1.9 billion^{3,10} (Fig. 81-1).

Landslides impact public health by causing injuries and severe property destruction. Landslide mortality is largely related to trauma and asphyxiation. Landslide morbidity is largely associated with traumatic injuries and a disruption of water, sanitation, shelter, and the locally grown food supply of the affected population¹¹ (Fig. 81-2).

Landslides triggered during the 1994 Northridge earthquake resulted in an outbreak of 203 cases of coccidioidomycosis when arthrospores were spread in dust clouds.¹² Debris flows associated with massive

FIGURE 81-1. Large debris flow channel caused during 1999 Venezuela landslides.

floods in northern Venezuela on Dec. 16 and 17, 1999 destroyed part of the port facilities in LaGuaira. The port facilities contained customs warehouses known to store hazardous materials, including corrosives, organic solvents, oxidants, compressed gases, heavy metals, and explosives. These chemicals were inundated by the debris flow, which came dangerously close to causing an explosion and toxic exposure with the potential to affect 80,000 nearby residents as well as closing that nation's largest airport and second largest seaport^{13,14} (Fig. 81-3).

Pre-Incident Actions

Landslides usually strike without warning. Therefore, pre-incident actions in prevention, preparedness, and mitigation are by far the most effective means of protecting life and property. Although the physical cause of many landslides cannot be removed, geologic investiga-

FIGURE 81-2. Makeshift living conditions of homeless family after 2002 landslides in Chuuk, Micronesia.

FIGURE 81-3. Venezuelan port warehouses storing hazardous materials were inundated by debris flow in 1999.

tions, good engineering practices, and effective enforcement of land-use management regulations can reduce landslide hazards.⁴ Two mitigation strategies can be implemented to protect property: (1) large structural flood control measures and (2) avoidance of the affected area. Land-use regulations can be used to reduce hazards by limiting the type or amount of development in high risk areas. In high-risk zones where development and reconstruction are inevitable, steps such as orienting buildings and streets parallel to the down-slope direction of debris flow will minimize the width of the building exposed and allow streets to serve as overflow channels.³ Monitoring, warning, and evacuation are non-structural approaches to hazard mitigation that reduce potential loss of life. Early warning systems based on weather forecasts and rainfall information can substantially improve emergency managers' responses to warn and evacuate threatened communities. Areas such as Hong Kong, San Francisco, and Denver use warning systems such as sirens and radio bulletins to alert residents of potentially threatening conditions.³ The public, first responders, emergency managers, and decision-makers should be educated regarding hazard awareness, as well as emergency preparedness, mitigation, and response measures.¹⁵ Box 81-1 list areas that are generally more prone to landslide hazards;^{3,16} Box 81-2 lists what to do if a home is suspected as being at risk for landslide danger.¹⁶ Box 81-3 lists features that may be noticed prior to major landsliding.¹⁶

BOX 81-1 AREAS GENERALLY MORE PRONE TO LANDSLIDE HAZARDS

On existing old landslides
On existing alluvial fans
On or at the base of slopes
In or at the base of minor drainage hollows
At the base or top of an old fill slope
At the base or top of a steep cut slope
Developed hillsides

BOX 81-2 WHAT TO DO IF A HOME IS SUSPECTED AS BEING AT RISK FOR LANDSLIDE DANGER

Get a ground assessment of your property.
Minimize home hazards:

- Plant ground cover on slopes and build retaining walls.
- In mudflow areas, build channels or deflection walls to direct the flow around buildings.
- Remember: If you build walls to divert debris flow and the flow lands on a neighbor's property, you may be liable for damages.

Learn to recognize the landslide warning signs. (See Box 81-3.)

Make evacuation plans.

Develop an emergency communication plan in case family members get separated.

Purchase flood insurance policies from the National Flood Insurance Program.

Post-Incident Actions

Landslides are associated with high rates of traumatic injury and mortality. If there is an imminent risk of landslides, individuals should stay alert and awake. Many debris-flow fatalities occur when people are sleeping. They should also listen to an NOAA Weather Radio or portable, battery-powered radio or television for warnings of intense rainfall. They should be especially alert when driving. Embankments along roadsides are particularly susceptible to landslides.¹⁷ During a landslide, persons at risk should take immediate steps to get out of the down-slope path of the flow or, if unable to evacuate, to protect themselves inside of a building. If escape is not possible, individuals should attempt to curl up into a ball and protect their head.¹⁷ Box 81-4 lists recommendations for actions to be considered after a landslide has occurred.¹⁷

Whenever possible, search-and-rescue operations should be performed by properly trained and adequately equipped professional rescuers. First-arriving incident commanders need to establish safety zones immediately. Soil engineers should be called and an emergency warning system, such as a siren blowing steadily for 30 seconds, immediately established. In the safety briefing of the Incident Action Plan, the incident

BOX 81-3 LANDSLIDE WARNING SIGNS

Springs, seeps, or saturated ground in areas that have not typically been wet before
New cracks or unusual bulges in the ground, street pavements, or sidewalks (especially at the base of a slope)
Soil moving away from foundations
Ancillary structures such as decks and patios tilting and/or moving relative to the main house
Tilting or cracking of concrete floors, tile, brick, or foundations
Broken water lines and other underground utilities
Leaning telephone poles, trees, retaining walls, or fences
Offset fence lines
Sunken or down-dropped road beds
Rapid increase in creek water levels
Sudden decrease in creek water levels although rain is still falling or has just recently stopped
Sticking doors and windows as well as visible open spaces indicating jambs and frames out of plumb for the first time
Faint rumbling sound that increases in volume as the landslide nears

BOX 81-4 ACTIONS TO BE CONSIDERED AFTER A LANDSLIDE

Avoid the landslide area as much as possible. There may be a danger of additional slides.
Check for injured or trapped persons near the slide area. Survival is more likely to occur near the slide periphery.
Provide first aid to injured persons and activate emergency medical services if necessary.
Report the event to your local fire, police, or public works department.
Inform and assist affected neighbors, especially those who may require special assistance such as infants, the elderly, or persons with disabilities.
Listen to a battery-operated radio or television for the latest emergency information.
Watch for flooding, which may occur after a landslide or debris flow.
Look for and report broken utility lines to appropriate authorities.
Check the building foundation, chimney, and surrounding land for damage.
Replant damaged ground as soon as possible since erosion caused by loss of ground cover can lead to flash flooding.
Seek the advice of a geotechnical expert for evaluating landslide hazards or designing corrective techniques to reduce landslide risk.
Support the local government in efforts to develop and enforce land-use and building ordinances that regulate construction in areas susceptible to landslides and debris flows.

commander should stress that evacuation and “all-clear” signals are not for discussion and must be obeyed immediately.

The organized literature for such rescues is minimal. In the absence of an engineer assessment, general guidelines for safety zones have been recommended as follows¹⁵:

Cold Zone

1. 100 feet from the outside edge of each side of the debris flow in situations involving stream order 1 situations (“stream order” is the geological classification of drainages; the number increases as the size and number of drainages increase)
2. 1000 feet from the sides and base of debris flows that are occurring on slopes that are 26 degrees or greater and involve areas with stream orders 2–4; and
3. 500 feet from the sides and base of flows in stream order 5 and above, which occur at the mouth of large canyons and have largely ceased flowing. All of these recommendations are based on weather reports of diminishing or ceasing rainfall. If rain continues, all distances should be increased.

Warm Zone

The warm zone is the area inside the distances mentioned for the cold zone, up to the edge of the flow. Safety gear should be worn by all personnel in that zone.

Hot Zone

The hot zone is the area on the debris field. All personnel on the field should have complete safety gear. All personnel in the warm and hot zones should be logged in and out of the areas.

With respect to personal safety equipment for rescuers, foot and leg protection is mandatory. Personal flotation devices should be worn if there is danger of further flows. Helmets and harnesses should be worn on steep slopes. A harness—at least a tubular webbing “hasty” harness—must be worn, even on reasonably flat terrain, in the event the rescuer becomes trapped. Additional equipment might include: work gloves; a small backpack or load-bearing rig for water bottles, or a “camel-back” irrigation system; small folding shovels; face masks; and goggles. All rescuers should be tethered from dry ground, if possible.

Small inflatable rafts assist rescuers in crossing soft mud and serve as a stable work platform. An air-filled hose—either laced back and forth through a roof ladder and then filled with air to make a field-expedient raft, or simply pulled out onto the mud as a handhold—is extremely useful. Helpful technical and USAR-type gear includes: ropes, “A” frames and confined-space tripods, plywood and shoring materials, and rescue “hardware,” such as carabiners and pulleys.

Chances of survival in a debris flow or mudslide are best on the edges and decrease toward the center. Most survivors are found in a zone that makes up about a quarter of the flow width, immediately along its edges. As a result, most rescues can be conducted using simple techniques from dry ground.

If a victim is mired higher than his or her waist, shore-based thrown lines are likely not going to work because there is simply too much suction on the victim. The rescuers will need to go out and extricate the victim by breaking the suction. The two best techniques involve air and water. A 1-inch fire hose with a metal “root wand”

affixed to the end can be shoved along the edge of the victim’s body. When the water is turned on, it creates a “slurry” next to the victim and releases the suction. Air has also been suggested, which involves using an SCBA bottle and a rigid hose that can be shoved down in the mud. Air charged into the mud creates large air bubbles that also help break the suction. It may become necessary to build an “island” around the victim so that a vertical pull can be attempted, using either a ladder “A” frame or a tripod. Combined with air and water, such techniques may free victims trapped all the way to their necks. Rescuers should also remain vigilant of the possibility of exposure to hazardous materials and should plan appropriately for response to hazardous materials exposures including decontamination of rescuers at the scene.

Medical Treatment of Casualties

The treatment of landslide casualties is the same as that for other causes of traumatic injury. In the case of mass casualties, an incident management system should be established and a system for triage of casualty care should be in place. After extended entrapments, extricated victims may have medical complications ranging from hypothermia, impaired airway, and compartment syndrome.

UNIQUE CONSIDERATIONS AND PITFALLS

The single most important issue regarding landslides is the priority of pre-incident prevention and mitigation efforts. Landslide morbidity and mortality is high and many of these deaths and injuries are preventable given the appropriate level of pre-incident intervention. In

CASE PRESENTATION

A desperate search for survivors is under way on a remote Pacific island after a typhoon triggered landslides that wiped out entire families. A typhoon struck the small Pacific nation 4 days ago. An official from the national Disaster Office told news agencies that there were 31 confirmed deaths. About 100 people are reported to have been injured and over 2000 are now homeless. Many of the deaths known were on one island. “Whole families are just left with one or two people,” he said. “It is a very bad time. There is a lot of suffering and a lot of pain.” But he said there could be worse to come. “We are still searching,” he said. “We are expecting many more. We have not been able to reach the outer islands yet.” Survivors are in dire need of food, water, and medical supplies. No outside help has reached them. Many of the seriously injured are unable to receive the medical treatment they need. The U.S. Joint Typhoon Warning Center says seas of about 18 feet with winds gusting to 90 mph are expected to continue through tomorrow. Rescuers are unable to transport heavy equipment to the affected islands. There are no local urban search-and-rescue teams in existence.

most cases, emergency response is often much too little and much too late to make a significant impact. The major pitfall of emergency management related to landslides is an over-reliance upon response compared with the overwhelming cost-effectiveness of prevention and mitigation. Another pitfall is to underestimate the public health needs of those populations displaced by the disaster.¹¹ In addition to an obvious lack of food security, shelter, and adequate sanitations, these populations are more prone to incur additional injuries, disease, and lingering mental illness (see Fig. 81-2).

Avalanche

Jason A. Tracy

DESCRIPTION OF EVENT

Deaths caused by avalanches are on the rise as more recreationalists are undertaking “extreme” outdoor sporting activities. Climbers, backcountry skiers, out-of-bounds skiers, and snowmobilers comprise a majority of these fatalities.¹ As many as 80% of these casualties are due to asphyxiation after snow burial²⁻⁴; time to extrication is the critical factor to survival. There is a 92% chance of survival in open areas if victims are found within 15 minutes; however, these odds decrease to 30% after 35 minutes.^{3,5} This statistic differs dramatically among building-confined avalanche victims, for whom there is only a 31% chance of survival if extricated within 190 minutes.⁵ Although rare, avalanches triggered by topographic or meteorologic conditions can be devastating to ill-prepared building inhabitants or to those traveling on exposed roadways.⁶

Professional rescue teams, compared with recreationalists, can improve survival of these victims, since time to extrication can be dramatically improved to within the “golden 15 minutes.” Depth of burial is also a critical survival factor; approximately 50% of individuals who are completely buried (head and chest under snow) will likely die, whereas only 4% of those who are partially buried will succumb to death.⁶ No avalanche victim buried to depths greater than 7 feet has ever survived in the United States.⁴

Asphyxiation from burial or from sudden burial-site airway obstruction causes the majority of avalanche deaths. However, it is clear from autopsy studies that blunt trauma also plays a significant role, not only as a cause of death, but as a critical consideration during rescue efforts.^{4,7} Injuries most commonly sustained by avalanche victims include craniofacial trauma with a high likelihood of closed head injuries,⁷ and chest and abdominal trauma.⁸ Trauma is reportedly the cause of death in up to 13% of all avalanche disaster cases.⁹

Creating an air space in the entombment site has been postulated as the reason that 7% of all victims survive for as long as 130 minutes postburial.⁵ As long as icing of the air space (“ice lensing”) does not occur, carbon dioxide diffusion can commence and delay asphyxiation.^{4,10} Appropriate survival training and readily available rescue equipment can reduce the time to rescue and prolong the oxygen supply.

Although hypothermia may prevent hypoxic damage,⁶ it can also cause vascular instability and death when core body temperatures fall below the 32°C hypothermic threshold.¹¹ In hypothermic-inducing conditions, body temperatures will fall predictably by approximately 3°C per hour. Complete burial limits the time up to which hypothermia avoidance is possible—90 minutes. Beyond the 90-minute cut-off, significant hypothermia in these conditions will occur.⁶

PREINCIDENT ACTIONS

Avalanche avoidance through appropriate training is the mainstay of prevention. Local weather conditions should be verified before any backcountry traveling. Training for at-risk individuals includes condition analysis as well as proper safety and rescue equipment usage. Individuals in an avalanche area should carry a snow shovel, which is used not only for rescue purposes, but also for building “snow pits” to analyze conditions. Long probes (ranging from 10 to 12 feet in length when extended) and/or personal avalanche beacons, both of which are useful for finding buried victims, are also requisite recreationalist trekking gear. Personal avalanche beacons have become the most widely used personal rescue devices worldwide. When buried, these devices emit a signal that can be received by active rescuers.¹² Newer survival equipment includes the artificial air pocket device (AvaLung), the ABS-Avalanche Airbag System, and the Avalanche Ball. Each of these devices provides a unique way of preventing death.⁴ As previously discussed, professional rescue teams improve avalanche victim survival through their ability to rapidly locate and extricate a buried victim. Regardless of extrication team training, it is critical that potential burial-site air pockets are preserved during extrication because any loss of this space will lead to rapid death.

POSTINCIDENT ACTIONS

Rapid location and extrication of buried victims are the key to survival. The last known location of a victim should be marked before launching the search and rescue effort. Subsequent topologic scanning for body

parts or debris and probing or rescue-beacon searching should immediately ensue. If a limited number of rescuers are in an isolated location, all immediate efforts should be focused on victim location. If they are close to a phone or if there is rescuer surplus, then a makeshift contact team can be organized and sent quickly to notify a professional rescue team. Once victims are extricated, medical treatment should occur immediately.¹²

MEDICAL TREATMENT OF CASUALTIES

Initial management of all avalanche victims should focus on the ABCs (airway, breathing, and circulation) of resuscitation. Immediate interment-site airway protection is critical; airway obstruction or respiratory arrest must be managed immediately using standard advanced cardiac life support (ACLS) guidelines. Due to potential cardiac instability, gentle handling of all hypothermic patients is mandatory.¹³ Core temperature and electrocardiogram monitoring should commence as soon as qualified personnel are available. Core temperature monitoring is best achieved via esophageal or rectal measurement, although the less-reliable eptympanic method is an acceptable alternative.^{13,14}

Prehospital assessment and treatment of hypothermia will likely be required for victims with prolonged burial (greater than 35 minutes). Assessment of hypothermia using the Swiss Society of Mountain Medicine guidelines can be performed by those with limited medical training and is based on the patient's mental status and presence or absence of shivering. In a patient who is alert and shivering, the core temperature is presumably between 32° to 35°C. Drowsiness and the absence of shivering are causes for concern, since this combination is symptomatic of a very low core body temperature (potentially as low as 28°C). If the temperature is less than this, the patient is likely to be unconscious and/or not breathing.^{6,14,15}

Rapid triage of multiple victims is determined on-scene, with cessation of resuscitative efforts applied to appropriate patients. Death determination on-scene limits futile use of resources and limits risk to rescue teams during patient extrication. Burial time, presence or absence of a burial-site air pocket, and core body temperature are all used as death determination factors. All patients with a burial time of less than 35 minutes and/or a core body temperature greater than 32°C should undergo ACLS treatment with rapid hospital transfer. Death pronouncement can occur in asystolic patients with no evidence of an air pocket or presence of obvious airway obstruction, with a burial time greater than 35 minutes, and/or with a body temperature of less than 32°C. If there is any evidence of an air pocket, hospital transport should occur regardless of burial time. The receiving facility should have cardiopulmonary bypass capabilities, since this method of active internal rewarming has had the best success.^{6,14,15}

Treatment of hypothermia should commence as soon as extrication occurs; the type of treatment will depend on available equipment and training level of on-site rescuers. Passive rewarming occurs through the removal of

wet clothes; shielding from the wind; and application of blankets, aluminum foils, or bivouac bags. Initial warming procedures should be performed on all hypothermic patients and is commonly the only treatment required for patients who can shiver.¹³ Active external rewarming occurs with heat packs applied to the trunk. Warm, sweet drinks should be provided to those who are conscious.^{6,14,15} ACLS recommendations limit active external warming applications to the trunk area only, for fear of “afterdrop” hypothermia. Afterdrop hypothermia, caused by warming of the extremities, can lead to recirculation of cold peripheral blood to the central circulation system, culminating in a substantial decline in core body temperature.¹³ Active internal rewarming in the field is best achieved through the use of warm, humidified oxygen. This can be achieved through either application of a mask or through endotracheal intubation.^{6,14,15} Hospital treatment of severe hypothermia victims (less than 30°C by ACLS guidelines) should be more aggressive and includes warm intravenous fluids and warm lavage of the peritoneum, pleural cavity, and gastric mucosa with cardiopulmonary bypass being the ultimate goal. Internal rewarming should continue until the core temperature reaches 35°C or there is return of spontaneous circulation.¹³

Severely hypothermic patients with confirmed ventricular fibrillation should not receive any intravenous medications but should receive a maximum of three attempts at defibrillation. Intravenous medications and defibrillation are ineffective at this temperature. Once the core temperature reaches 30°C, normal ACLS protocols should be followed.¹³ Serum potassium levels should be carefully monitored after avalanche burial because hyperkalemia is expected.¹³ All resuscitation efforts should cease for patients with substantially prolonged burial times (greater than 35 minutes) and high serum potassium levels (greater than 12 mmol/L).

Although hypoxia and hypothermia usually prevail as initial treatment priorities, attention to other life threats should not be overlooked. Traumatic injuries should be assessed as previously discussed. In victims with obvious traumatic injuries, transport to a trauma center should occur per local protocols. In-hospital evaluation of these patients includes complete trauma and medical requirement assessments.

UNIQUE CONSIDERATIONS

Hypothermic patients with prolonged burial in an oxygen-available tomb are potentially salvageable with active internal rewarming. Otherwise, resuscitative efforts among severely hypothermic patients or among patients with airway obstructions and burial times of greater than 35 minutes should cease.

PITFALLS

- Inadequate avalanche training of backcountry explorers
- Improper rescue techniques
- Failure to preserve a victim's air pocket

CASE PRESENTATION

Fourteen high school students, two mountain guides, and one parent were backcountry skiing in British Columbia's Glacier National Park during the winter of 2003. The skiing conditions were perfect with 2 feet of fresh powder on the 550-yard-wide trail.

The leaders, both avalanche-certified instructors, confirmed conditions for the day as being "moderate—natural avalanches are unlikely, but human triggers are possible." However, the area above their route was deemed to be at "considerable" avalanche risk.

While traveling, the group used the skills taught in their avalanche awareness and rescue courses—all paired skiers traveled 30 to 50 feet apart, and they routinely recited their rescue procedures. Each skier carried a shovel and a probe and wore an avalanche beacon.

At 11:45 AM, an 850-yard-wide avalanche came from above and buried most of the skiers. One of the freed members called for help on his satellite phone, and within 40 minutes, 10 rescuers were on-scene. Within 120 minutes, all members of the group were recovered, but seven of the students ultimately died.¹⁶

- Inappropriate triage of avalanche victims
- Inappropriate treatment of hypothermic patients

chapter 83

Introduction to Nuclear/Radiologic Disasters

Dale M. Molé

A familiarity with the medical aspects of nuclear or radiologic incidents is essential for any clinician in the 21st century. In addition to an increase in the number of nuclear power reactors around the world, the once unthinkable use of nuclear or radiologic devices against innocent non-combatants by terrorist groups or rogue nations may become reality in our lifetime. Underscoring this concern is the rampant proliferation of nuclear weapons technology within the Third World, the likelihood of stolen or black market tactical nuclear weapons from the former Soviet Union,¹ and the diversion of ubiquitous industrial and medical radioactive sources for nefarious uses.²

In the age of global terrorism, few things generate as much fear in the general public as radiation and its potential to produce painful death, malignant disease, or genetic mutations. Since radiation is undetectable by our normal senses, when used, its psychological effectiveness to achieve sinister goals is enhanced. Public perceptions, or in most cases misperceptions, regarding the risk of even low-dose radiation exposure makes the use of radioactive materials a very effective terror weapon.

Few in the general public realize that we live in a world surrounded by natural radiation sources. Cosmic rays from outer space; radioactive minerals on Earth; and some radioactivity in food, water, and air provide the majority of radiation exposure we receive. Additional exposure may be the result of medical procedures (e.g., radiographs, nuclear medicine studies). Even the human body contains natural radioactive materials, such as carbon-14, potassium-40, and polonium-210.³ With the exception of radon, found in excessive amounts in poorly ventilated dwellings in some parts of the United States, this low level of radiation has not been demonstrated to have any adverse clinical effects.

Radiation Physics

Radiation consists of either particles or electromagnetic waves, both of which deposit energy when interacting with matter. Radiation of sufficient energy to displace electrons from atoms, creating an ion and a free electron, is called *ionizing radiation*. *Particulate ionizing radiation* is made up of any atomic or subatomic particles, but

the ones of clinical interest are alpha particles, beta particles, and neutrons. X-rays and gamma rays are types of *electromagnetic radiation* energetic enough to produce ionization. Less energetic forms of electromagnetic radiation (radiant heat, light, lasers, radio, microwaves) expend energy mainly in the form of heat when interacting with matter, but they do not produce ions; hence, these are classified as *nonionizing radiation*.

Matter consists of atoms. All atoms have a small central nucleus composed of protons (positive charge) and neutrons (no charge) that are surrounded by orbiting clouds of electrons (negative charge). The atomic number, unique for each element and descriptive of its particular physical and chemical characteristics, is equivalent to the number of protons in the nucleus (e.g., since hydrogen has one proton, its atomic number is 1). The atomic mass is essentially equivalent to the number of protons plus the number of neutrons (e.g., ordinary carbon has six protons [atomic number 6], but it has an atomic mass number of 12 (six protons plus six neutrons).) Since ordinary carbon-12 is electrically neutral, it has six orbital electrons. Atoms of the same element (the same number of protons) having different atomic mass (different numbers of neutrons) are called isotopes. The isotopes of hydrogen include hydrogen-2, or deuterium, with one proton and one neutron and hydrogen-3, or tritium, with one proton and two neutrons.

The forces between various components of the nucleus determine the stability of an atom. Neutrons appear to play an important role in binding protons together, with the ratio of protons to neutrons determining the stability of an atom. Too many or too few neutrons in the nucleus cause the atom to be unstable, which then decays or emits particles and/or energy to become more stable.

Alpha radiation consists of a helium nucleus (two protons and two neutrons). This relatively massive particle is only able to travel a short distance in air (1-2 cm) and is stopped by a sheet of paper or the top layer of skin. However, if inhaled or ingested, it can produce large exposures to internal organs.

Beta radiation is an electron emitted from an unstable nucleus. Beta particles penetrate deeper into tissue than

alpha particles, but usually not beyond the few top layers of skin. They are completely absorbed by thin layers of glass, plastic, cloth, or metal foils. Beta particles of high energy can cause skin burns and are hazardous if ingested or inhaled.

Neutron radiation is produced when a neutron is emitted from the unstable nucleus of an atom, usually during nuclear fission in an atomic bomb or nuclear reactor. Being electrically neutral, neutrons are very penetrating and cause secondary beta and gamma radiation to be emitted when interacting with matter.

Gamma rays and *x-rays* are ionizing forms of electromagnetic radiation. Both are very penetrating and capable of delivering significant radiation doses to internal organs without ingestion or inhalation. Identical except for place of origin, gamma rays are emitted from an unstable nucleus, whereas x-rays originate from the outer electron shells of the atom.

The amount of ionizing radiation deposited in tissue or matter is called the *absorbed dose*, conventionally expressed in units of *radiation absorbed dose (rad)*. The International System of Units for absorbed radiation is the gray (Gy). One gray is equal to 1 joule per kilogram and is equivalent to 100 rads.

The biologic effect produced by each type of ionizing radiation depends on the mass, electrical charge, and energy of the radiation. Hence, the same absorbed dose of one type of ionizing radiation can result in more or less biologic damage than the same absorbed dose of another type. This is because the *linear energy transfer*, or LET—the amount of energy deposited in a unit of track length—is different for different types of radiation. One gray of alpha radiation will result in more damage to cells than 1 gray of beta radiation. To standardize the tissue damage produced by the different types of radiation, we use a measure of equivalent biologic effects produced or equivalent dose. The absorbed dose multiplied by a quality factor produces an equivalent dose. The quality factor for most x-rays, gamma rays, and beta particles is 1, so the absorbed dose and equivalent dose are essentially equal. Alpha particles have a quality factor of 20, and neutrons have quality factors between 5 and 20, depending on their individual energies. Expressed in conventional units, rads multiplied by the quality factor for that particular type of radiation equals *radiation equivalent man*, or *rem*. The international unit is the sievert (Sv). Since gamma radiation has a quality factor of one, 1 Gy (100 rad) of gamma radiation equals 1 Sv (100 rem).

Important factors in reducing radiation exposure are time, distance, and shielding. The absorbed dose is directly proportional to the length of time an individual is exposed and inversely proportional to the square of the distance from the radioactive source. Doubling the distance decreases the absorbed dose by a factor of four. The use of lead, concrete, or other shielding material significantly reduces or eliminates exposure.

Radioactivity decreases or decays with time. The *half-life* of a particular radioisotope is the length of time required for one-half of the radioactive material to decay or in most cases become nonradioactive. Some radioisotopes have half-lives of hours or days; others have half-lives of years or centuries. The decay rate can have an

important effect on medical management decisions regarding decontamination and/or treatment.

Biologic Effects

Ionizing radiation interacts with living cells by producing charged water molecules (i.e., free hydroxyl radicals) or by direct ionization of deoxyribonucleic acid. Clinical symptoms (acute radiation syndrome) occur if enough cells are damaged and die, or if the killed cells are essential for human survival. Rapidly dividing cells, such as bone marrow cells or the intestinal mucosa, are the most sensitive to radiation, whereas slowly dividing cells (e.g., central nervous system) are the most radio-resistant. Nonlethal radiation doses may cause some cells to undergo malignant transformation, leading to radiation-induced cancers years or decades after exposure.⁴

Nuclear or Radiologic Scenarios

History is replete with accidents involving radioactive materials. Fortunately, most involved exposure to only a few people. An exception was the Chernobyl incident in 1986 when reactor unit number four exploded, exposing the reactor core and dispersing radioactive material over a wide area. One hundred thirty-four people developed acute radiation syndrome, with 28 deaths directly related to radiation exposure. A dramatic increase in thyroid cancers among those who were either very young or in utero at the time of exposure has been noted.⁵

Occasionally, individuals without criminal intent can create radiologic hazards for themselves and the community. Such was the case of David Hahn, the “radioactive Boy Scout,” who attempted to build a breeder reactor in his backyard shed and ended up causing an expensive Environmental Protection Agency cleanup as well as terrifying his neighbors.

Terrorist groups such as Aum Shinri Kyo and Al-Qaeda, as well as state sponsors of terrorism, have tried to acquire radiologic/nuclear material and technology. The father of the Pakistani atomic bomb, A.Q. Khan, peddled nuclear weapon expertise to many rogue nations and terror organizations.⁷

In addition to Third World countries or terror groups trying to develop a nuclear weapons program beginning with uranium ore,⁸ an expensive and technologically intensive undertaking, there are other more likely nuclear or radiologic scenarios:

- Using radioactive materials to fabricate a radiation emission device (RED), or the detonation of a radiologic dispersion device (RDD) (i.e., “dirty bomb”)⁹
- Sabotage of nuclear facilities (e.g., nuclear power plants) with the subsequent release of large amounts of radioactivity¹⁰
- The detonation of an improvised nuclear device made from fissile material acquired by theft or purchased¹¹
- The detonation of an intact nuclear weapon acquired by theft or on the black market¹²

An RED irradiates passersby with high levels of radiation. Such a device is highly radioactive and poses a significant threat to those who place it. It therefore requires

some degree of sophistication to safely construct and deploy. A device using “induced criticality” could expose those nearby to lethal doses of neutron radiation and gamma rays in just moments.¹³

RDDs are often referred to as weapons of mass *disruption* since their psychologic and economic effects far outweigh the physical damage to life or property.¹⁴ The so-called dirty bomb consists of radioactive material surrounding or mixed in a conventional explosive. Those injured by blast effects from the explosion are contaminated by the radioactive material, as are the rescue workers.

The accidental contamination of the village of Goiânia, Brazil, in 1987 from an orphaned cancer radiotherapy source provides an insight to the consequences of an RDD. Junkyard workers broke open the lead shielding surrounding a medical radioactive source and exposed the 20-g cesium-137 chloride capsule. Soon afterward, 13 people became ill and sought medical care. Four people died. By the time authorities discovered what had happened, 249 people were affected by radiation and thousands more rushed to emergency departments fearing contamination. Economic damage as a result of clean-up ran into the millions of dollars—6000 tons of clothing, furniture, soil, and other materials had to be packed into steel drums and buried in an abandoned quarry.¹⁵

A nuclear reactor accident (e.g., Chernobyl) or sabotage remains an ongoing concern. In August 2003, 19 individuals were arrested for plotting to destroy a nuclear power plant on the shore of Lake Ontario, Canada. The method of attack used on Sept. 11, 2001, raised concerns that terrorists could use a commercial airliner as a guided missile against a nuclear power plant. A study produced for the Nuclear Energy Institute using the Boeing 767-400 as the attacking aircraft suggests that the reactor containment building, as well as irradiated fuel storage facilities, would survive a direct impact.¹⁶

A nuclear weapon detonation is the ultimate terrorist nightmare. The destructive effects from a nuclear explosion include widespread blast effects, burns from the initial flash and burning debris, and ionizing radiation from the fission process initially, followed by radioactive fallout. It has been estimated that a 10-kiloton weapon detonated at Grand Central Station in Manhattan would kill 500,000 people immediately, injure hundreds of thousands more, force the evacuation of all of Manhattan, and result in direct economic damage of well over \$1 trillion.

Terrorists may achieve a nuclear detonation by obtaining highly enriched uranium (HEU) and constructing a crude atomic bomb (improvised nuclear device [IND]). Many experts believe that a technologically sophisticated terrorist group could construct a nuclear weapon from HEU without state support. A plutonium bomb is much more difficult to construct and probably exceeds the abilities of substate organizations. Given the cost and complexity of a nuclear materials enrichment program, making a bomb from uranium ore is not currently feasible for a substate organization. Of concern, however, is the 130 research nuclear reactors around the world using HEU in the reactor core, many with minimal security and vulnerable to theft.

Nuclear fission is the process underlying the explosive power of an atomic bomb. When atoms of a fissile material (e.g., uranium-235 [U-235] or plutonium-239 [Pu-239]) absorb a neutron, they split or fission into two atoms of roughly equal mass, producing enormous amounts of energy, as well as additional neutrons that cause other atoms to fission. If enough fissile material is present (i.e., *critical mass*), a *chain reaction* will progress at a geometric rate, resulting in the liberation of tremendous quantities of energy in the form of heat, light, and radiation. The critical mass required for a self-sustaining chain reaction is a function of the shape, density, and type of fissile material. By surrounding the bomb core with a neutron reflector or tamper, the amount of material required to reach critical mass is significantly reduced. The critical mass for a bare sphere of U-235 is 56 kg, but with a thick tamper, this is reduced to about 15 kg. For Pu-239, critical mass is 11 kg and 5 kg, respectively.

Since the critical mass of a particular fissile material decreases as the density increases by an inverse square relationship, an implosion device requires much less material than one using a gun-assembly method.

Fission weapons require the “assembly” of a supercritical mass from a subcritical mass to occur in a very short period; otherwise, the weapon is blown apart before significant amounts of material have undergone fission, significantly lowering the yield. There are two classical assembly methods—gun and implosion (Fig. 83-1). Gun assembly is useful only for U-235 and involves firing a subcritical projectile of U-235 into a subcritical target of U-235 to create a supercritical mass. This is the easiest type of atomic bomb to make and did not even require testing before operational use over Hiroshima, Japan.¹⁷

An implosion device uses high explosives to create an inwardly directed shock wave that compresses a sphere of fissile material, increasing density to supercritical levels. Although very efficient, it requires much more sophisticated technology since the explosive “lenses” must detonate at exactly the same instant to produce a nuclear explosion. Also, a neutron generator emits a burst of neutrons to initiate the chain reaction at the point of maximum compression.¹⁸

Russia has many tactical nuclear weapons that are more widely dispersed and not as well guarded as strategic weapons. With the dissolution of the Soviet Union, there is uncertainty regarding the whereabouts of every weapon. It is not known whether any were sold on the black market, and if so, whether they remain fully functional.

HISTORICAL PERSPECTIVE

X-rays were first discovered in 1895 by Wilhelm Roentgen while experimenting with cathode ray tubes and were used in medical diagnosis only a few months later. The following year, Henri Becquerel, while conducting some experiments with uranium salts, discovered radioactivity.¹⁹ The danger of this mysterious new force was not fully appreciated. Initially, radiation was viewed as healthy, perhaps because of the small

FIGURE 83-1. Principles of gun-assembly (A) and implosion-type (B) nuclear devices.

amounts of radium and radon detected in waters in the health spas of Europe. Despite some evidence of the harmful effects of excessive radiation, such as the deep skin burns to those scientific pioneers who handled unsealed radioactive sources, radioactive material was added to everything from toothpaste to drinking water in an effort to provide a healthful, stimulating effect. Shoe salesmen used portable x-ray machines to check shoe fit. Radium was painted on tonsils and adenoids to reduce the size of lymphoid tissue. Radium was also used together with surgery to provide the “Curie therapy” for cancer patients before the development of effective chemotherapy.

With the discovery of nuclear fission by Otto Hahn, Lise Meitner, and O.R. Frisch in 1939 came the realization that this process could be used to make a bomb.²⁰ On Dec. 2, 1942, Enrico Fermi succeeded in creating the world’s first self-sustaining nuclear chain reaction under the squash courts at the University of Chicago. During the World War II, both Germany²¹ and Japan²² pursued atomic bomb development. The world changed forever on July 16, 1945, with the detonation of the atomic bomb in the New Mexico desert.²³

The following month, World War II ended with the use of atomic weapons on Hiroshima and Nagasaki, Japan. The pictures of the devastation in Japan helped shape public perception regarding the dangers of radiation. This was further enhanced by decades of science fiction movies and anti-nuclear literature. Movie images, from giant ants and humans to reactor cores melting through the Earth or melting flesh from bones, convinced many

in the general public that any amount of radiation is an immediate threat to life.

CURRENT PRACTICE

External irradiation is the exposure of the entire body or just a part of it to an external source of penetrating radiation. Unless exposed to high-intensity neutron radiation, a patient is not radioactive from external irradiation and no special protective measures are required of medical personnel.

Acute radiation syndrome (ARS) is the primary threat to life after exposure to major doses of radiation.²⁴ The diagnosis of ARS is based on a history of exposure and clinical findings (Table 83-1). ARS occurs when the entire body is exposed to a large dose of penetrating external radiation over a short period. There are three classic acute radiation syndromes.

Bone marrow, or hematopoietic, syndrome usually occurs with doses higher than 2 Sv (200 rem), depending on the premorbid state of health. Destruction or depression of the bone marrow produces a pancytopenia, resulting in increased susceptibility to infection and clotting abnormalities. As long as the bone marrow is not completely destroyed, granulocyte stimulating factors may enhance regeneration.

Gastrointestinal syndrome occurs with doses greater than 6 Sv (600 rem). Cell death and sloughing of the intestinal mucosa result initially in nausea, vomiting, and diarrhea. Since gastrointestinal symptoms coincide with

TABLE 83-1 ACUTE RADIATION SYNDROME

1 Gray (Gy) = 100 rads 1 centiGray (cGy) = 1 rad

WHOLE BODY RADIATION FROM EXTERNAL RADIATION OR INTERNAL ABSORPTION

Phase of syndrome	Feature	Subclinical range			Sublethal range			Lethal range	
		0 - 100 rad or cGy	100-200 rad 1-2 Gy	200-600 rad 2-6 Gy	600-800 rad 6-8 Gy	800-3000 rad 8-30 Gy	>3000 rad >30 Gy		
Prodromal phase	Nausea, vomiting	None	5%-50% 3-6 hr	50%-100% 2-4 hr	75%-100% 1-2 hr	90%-100% <1 hr	100% Minutes		
	Time of onset	None	<24 hr	<24 hr	<48 hr	<48 hr	N/A		
	Duration	Unaffected	Minimally decreased	<1000 at 24 hr	<500 at 24 hr	Decreases within hours	Decreases within hours		
	Lymphocyte count	Unaffected	Minimally decreased	<1000 at 24 hr	<500 at 24 hr	Decreases within hours	Decreases within hours		
CNS function		No impairment	No impairment	Cognitive impairment for 6-20 hr	Cognitive impairment for >24 hr	Rapid incapacitation, often after a lucid period of up to several hours			
	Absence of symptoms	>2 wks	7-15 days	0-7 days	0-2 days	None			
Latent phase (subclinical) Acute radiation illness or "manifest illness" phase	Signs and symptoms	None	Moderate leukopenia	Severe leukopenia, purpura, hemorrhage	Diarrhea, fever, electrolyte disturbance	Convulsions, ataxia, tremor, lethargy			
	Time of onset	None	>2 wks	2 days to 2 wks	1-3 days	1-48 hr			
	Critical period	None		4-6 wks: Most potential for effective medical intervention	2-14 days				
Organ system		None	Hematopoietic and respiratory (mucosal) systems	Hematopoietic and respiratory (mucosal) systems	GI tract Mucosal systems	CNS			
	% Duration	0	<5% 45-60 days	90% 60-90 days	100% 90+ days	100% Weeks to months	100% Days to weeks		
Mortality		None	Minimal	Low with aggressive therapy	High	Very high, significant neurologic symptoms indicate lethal dose

hematologic abnormalities, dehydration, electrolyte imbalances, and sepsis are part of the natural disease course. Severe bloody diarrhea is an ominous sign.

Cardiovascular (CV)/central nervous system (CNS) syndrome occurs with doses exceeding 20 Sv (2000 rem). The almost immediate nausea, vomiting, ataxia, and convulsions are the result of diffuse microvascular leaks in the central nervous system, causing edema and increased intracranial pressure. Cardiovascular collapse from a transient post-irradiation vasodilation has been observed.²⁵

ARS progresses through the following four clinical phases:

- *The prodromal phase* occurs within hours of exposure and may last for up to 2 days. Symptoms are a function of the total radiation absorbed dose and include anorexia, nausea, vomiting, diarrhea, fatigue, fever, respiratory distress, and agitation. Treatment should be symptomatic.
- *The latent phase* is a transitional period in which the patient is asymptomatic. This may last as long as 3 weeks, but is much shorter with higher radiation exposures.
- *The illness phase* produces overt clinical manifestations, including infection as a result of leukopenia, bleeding from thrombocytopenia, diarrhea, electrolyte imbalances, altered mental status, and shock.
- *The death or recovery phase* often occurs over weeks or months.

The clinical phases of ARS are related to cell reproduction, with the fastest-dividing cells affected earliest. The time of onset after exposure of general signs and symptoms related to the hematopoietic and gastrointestinal systems are good markers for prognosis. After exposure, a shorter time until symptom onset is associated with a poorer prognosis.

A more specific indicator is the absolute lymphocyte count (ALC). A 50% drop in lymphocytes at 24 hours postexposure is indicative of significant radiation injury.²⁶ At 48 hours postexposure, if the ALC is greater than 1200, the patient likely received a nonlethal dose. An ALC between 300 and 1200 indicates significant exposure and the need for hospitalization. If the ALC is less than 300, the patient is critically ill and should be considered for colony-stimulating factors. The ALC may be an unreliable indicator in a patient with combined injuries.

Cutaneous radiation syndrome (CRS) is the constellation of symptoms resulting from acute exposure to beta radiation or x-rays. This can occur when radioactive isotopes contaminate the patient's clothes or skin. Although similar in appearance to thermal burns, radiation burns may take several days to appear. Dermal changes can help estimate the dose of radiation received, so it is important to observe for signs of erythema, pain, blister formation, and necrosis. Sequelae from CRS include vascular insufficiency developing months or years after exposure and causing necrosis or ulceration of previously healed tissue, and sometimes requiring hyperbaric oxygen therapy, plastic surgery, or amputation. Because of radiation's effect on dividing cells, if a radiation patient requires emergency surgery, it

should be done within the first 24 to 48 hours after the radiation injury; otherwise, the surgery should be delayed for 3 months.

Radioactive contamination occurs if radioactive materials are deposited internally, externally, or both. Patients can be radioactive and require decontamination when radioisotopes are inhaled, ingested, or deposited in wounds. *Incorporation* occurs if radioactive materials are taken up by cells and incorporated into tissues or organs.

Effective treatment of internal contamination requires knowledge of the type and chemical form of the radioisotope. The goal is to hasten elimination and prevent incorporation. This is accomplished by reducing absorption (with Prussian blue in the case of cesium), by using dilution techniques (forcing fluids with tritium), chelation (plutonium), or through the use of blocking agents (potassium iodide for radioactive iodine).

External contamination is not usually a medical emergency. Simply removing clothing will eliminate 90% of the contamination. Water and detergent effectively remove skin contamination. Uncontaminated wounds should be covered before decontamination. Contaminated wounds should be treated conventionally with pressurized normal saline irrigation. Residual radioactivity often comes off with dressing changes, in exudates, or with the eschar. If the wound remains contaminated with long-lived radioisotopes, wound excision should be considered. All contaminated clothing and materials should be placed in labeled plastic bags for proper disposal.

Successfully treating radioactive-contaminated injured people requires teamwork and practice. In addition to the usual emergency medicine personnel, the hospital health physicist or radiation safety officer is essential, both for assistance in conducting surveys of the patient with radiation detection equipment and in providing additional advice regarding decontamination. Emergency department patient decontamination and treatment exercises should occur at least annually to ensure proper decontamination technique, reinforce appropriate treatment priorities, and provide familiarity with radiation detection equipment and personal dosimeters.

It is likely that patients will present with mixed injuries (i.e., trauma combined with significant radiation exposure or contamination). Evaluate, resuscitate, and stabilize the patient before completing decontamination.

Triage decisions based on radiation exposure can be difficult when there are large numbers of casualties since the individual exposure is unknown. Early onset of ARS symptoms portends a poor outcome. The Armed Forces Radiobiology Research Institute has a Biodosimetry Assessment Tool (BAT) available for download at its Web site.

Surgeons operating on irradiated patients should consider them to be immunocompromised. Impaired wound healing, as well as fluid balance, electrolyte, and clotting abnormalities, should be expected. The earlier the patient is operated on after exposure, the better. If operations are performed early, surgical wounds should be in the healing phase when the immune system is at its nadir. Because of the high potential for sepsis, wound

debridement must be meticulous.²⁷ Prophylactic antibiotics should be considered for any patient with combined injuries of radiation exposure, burns, and classical trauma, and should be continued until the absolute neutrophil count rises above 500 and the patient is afebrile for at least 24 hours. The use of hematopoietic growth factors shortens the duration of neutropenia and should be started as soon as significant radiation exposure is identified.

PITFALLS

- Failure to treat life-threatening injuries or stabilize a patient because of concern regarding radioactive contamination on clothing or skin
- Failure to plan, train, and exercise the emergency management of radiologic events
- Lack of personal dosimetry equipment for medical workers
- Poor decontamination skills
- Failure to set and monitor radiation boundaries to prevent the spread of contamination throughout the hospital
- Failure to provide timely and appropriate risk communication regarding the hazards of radiation exposure

Ionizing Radiation Incident

Carrie Barton

DESCRIPTION OF EVENT

Exposure to significant levels of radiation is a rare occurrence but an everyday possibility. It can occur through occupational exposure at a medical facility or among persons processing nuclear materials or waste. Other sources include a nuclear power plant reactor core accident, a nuclear weapon detonation, a dirty bomb, or radioactive material placed accidentally or intentionally in an area exposing the public. It is important to understand the different types of radiation to understand the ways it affects the body.

Ionizing radiation includes alpha and beta particles, x-rays and gamma rays, and neutrons. Alpha particles are composed of two protons and two neutrons, are relatively large, and are easily stopped; colliding with matter causes them to lose their energy. A single piece of paper has enough density to stop them, as does the epidermis of the skin. Because they give up their energy over a very short distance, they have the most potential to cause damage, but because they are stopped easily before reaching the dermis, they are not a significant source of injury unless exposure is through broken skin, inhalation, or ingestion.^{1,2} Examples of alpha emitters are uranium, plutonium, americium (found in smoke detectors), and radon (a naturally occurring gas and the major source of natural radiation exposure).³

Beta radiation is composed of electron-like particles. They are much smaller, will travel about 1 meter through air, and can penetrate 1 to 2 cm into human tissue. They are stopped by higher-density material, such as a few millimeters of aluminum.^{1,2} Beta particles can cause severe local damage to the dermal tissue as well as areas of bony prominence, such as the wrist and hands; these particles also can cause bone necrosis. Morbidity from beta radiation skin injury is proportional to the body surface area affected, similar to thermal burns. Examples of beta emitters are nuclear fallout, tritium (used in emergency lighting, gauges, and nuclear weapons), and radiostrontium (produced in nuclear reactors).⁴

X-rays and gamma rays are, like sunlight, a form of electromagnetic radiation composed of photons, which have no mass or electrical charge. They are generated during

a fission reaction but are primarily encountered in medical use.

Both gamma radiation and x-rays travel several meters and are not stopped by human tissue. They require 5 cm of lead to be stopped.⁵ They result in whole body irradiation and are associated with acute radiation syndrome. Sources of gamma radiation include radiocesium, which is a by-product in nuclear fuel and is often used as a radiation source for medical treatments. Radiocesium is considered likely to be used in a “dirty bomb” due to its abundant use as a source.²

Neutrons are released during nuclear fission, such as in a criticality device, a nuclear reactor, or a nuclear detonation. They are very penetrating and pass through the body, where they collide with other atomic nuclei, causing them to become unstable and therefore radioactive, giving off alpha and beta particles and gamma rays. Although gamma irradiation alone does not render a person or object radioactive, a survivor of a neutron exposure would be rendered only minimally radioactive and would not present a great enough threat to prevent appropriate healthcare intervention.⁶

PREINCIDENT ACTIONS

Local hazardous materials (HazMat) teams should have the ability to detect radiation. Hospitals should also have access to real-time detection equipment, such as Geiger counters, in the event patients present with a reported exposure. Remember that most detectors do not detect alpha radiation. If the equipment is not kept in the emergency department, arrangements should be made beforehand to have 24-hour access to devices used elsewhere in the hospital. The hospital's radiation safety officer should be on call in a hospital's disaster plan for any known radiation exposure or for any intentional explosion until a “dirty bomb” scenario is ruled out. Planning to be able to decontaminate mass numbers of patients is similar to chemical decontamination; however, emergency intervention should be done before decontamination when indicated.⁶

POSTINCIDENT ACTIONS

There are four types of radiation exposure: (1) irradiation, (2) external contamination, (3) internal contamination, and (4) incorporation. In the event of a “dirty bomb” or detonation, patients may have both trauma injuries and radiation exposure; don’t forget to use standard trauma assessment and intervention.⁷ Radiologic injury is always of secondary importance to traumatic injury.

Irradiated patients pose no hazard to healthcare workers or other patients. Patients suspected of any type of contamination should be treated with contact and respiratory precautions and examined with radiation detection equipment. This should ideally be managed by the radiation safety officer. For patients with a stable condition who are awaiting decontamination of particulate matter (e.g., from a “dirty bomb” or possible fallout exposure), it is advised to take swabs of the ears and nares before decontamination for later testing to help confirm the exposure.

Healthcare providers should take respiratory precautions when treating a person externally contaminated with radioactive dust. Patients should avoid making airborne any particulate dust to prevent inhalation. This is especially important during removal of clothing. There must be no eating or drinking in the contamination area, and all patients and healthcare workers must be decontaminated and screened with detection equipment before entering the clean area. If necessary, the emergency room can be divided into a clean area and a dirty area. If so, plastic and/or sheets should be taped in place on the floor and on frequently used door handles etc. to prevent long-term contamination of the facility.

Clothing should be removed and saved for further testing to determine presence, type, and quantity of exposure and for evidence, if indicated. Patients should be washed with soap and water before entry into the hospital when possible. Plastic bags for clothing and temporary garments for patients (e.g., paper scrubs, sheets) should be available. Runoff water from decontamination must be collected with the same priority used with chemical contaminants.⁴

Healthcare providers should only use instruments to remove radioactive shrapnel because touching the material could result in severe local damage to their hands. All material removed during contamination should be saved and stored behind shielding or away from persons. If a patient has radioactive shrapnel that cannot be immediately removed and he or she requires immediate care for another life-threatening illness, lead shields may be placed over the affected area and patient care initiated before full decontamination.

Internal contamination occurs after swallowing or inhaling radioactive material and allows radiation to contact the gastrointestinal endothelial lining and respiratory parenchyma. Although alpha radiation is relatively benign when shielded by the epidermis, because it gives up its energy over a very short distance, when unshielded, alpha particles cause severe damage. Radioactive shrapnel can cause deep tissue radiation damage and prolonged exposure to radiation. The decision to

remove radioactive shrapnel must balance long-term risk against aggressive surgical morbidity.

Radioactive material may be incorporated into the body after internal contamination from inhaled or swallowed radioactive particulate matter. If ingested or inhaled, it has the potential to be absorbed and deposited in vital organs, or absorbed into macrophages and deposited in lymph nodes. This incorporated radioactive material can damage organ tissue over time. If this is not accompanied by more serious injuries, it is usually concerning as a cause of increased long-term cancer rates and not acute illness. Many sources of radiation are more concerning for their heavy metal components and toxicity than for their radiation effects.

Radiation causes two clinical syndromes: cutaneous radiation syndrome (caused by local tissue damage, usually due to alpha or, more likely, beta radiation) and acute radiation syndrome (ARS) (caused by whole body radiation, usually due to gamma radiation). Both of these have delayed presentations and are characterized by four stages: the prodrome, a latent asymptomatic stage, the manifest illness stage, and finally death or a period of recovery. The rapidity of progression through these stages is directly related to the severity of the exposure. The presence of burns without a known thermal or chemical exposure or the presence of immune suppression without a cause (especially associated with acute onset of general alopecia) should prompt consideration of an occult radiation exposure.

Cutaneous radiation syndrome is caused by localized damage to the basilar layer of the dermis, which leads to blistering. The vascular tissue is often destroyed, causing delayed necrosis. During the prodrome, which occurs hours after the exposure,² persons may notice redness or itching of the affected area. During the latent phase, there are no symptoms, and the affected skin appears normal. This phase may last minutes to weeks, depending on the severity of the exposure.² The manifest illness phase is characterized by local hair loss, blistering, and necrosis as the dermal tissue dies without adequate vascular supply. There may be underlying bone necrosis as well. Hair loss is expected to occur about 17 to 21 days after exposure.² There may be dry desquamation (peeling of the skin) or wet desquamation (blisters and bullae). Desquamation may occur within hours or up to 2 to 4 weeks after exposure. Necrosis can develop in days to months.

ARS is caused by whole body radiation and affects stem cells with high mitotic rates first (particularly the hematopoietic cells of the bone marrow, the endothelial microvilli of the small intestine, spermatogenesis, and hair follicles), leading to many of the clinical features.³ Lymphocytes are the most radiosensitive cell in the body and are used to estimate the dose of radiation received.^{1,7} Both the acute and cutaneous radiation syndromes may simultaneously be manifest.

The prodromal phase is characterized by gastrointestinal symptoms—nausea, vomiting, and diarrhea. Onset of ARS can be minutes to weeks after exposure, can last for minutes to days, and can be episodic. Onset within 2 hours indicates a life-threatening exposure, although

other causes of nausea and vomiting should be considered. Persons may appear healthy during the latent period, which may last 2 to 3 weeks, but after extremely high radiation doses, this phase may be minimal. The manifest illness includes up to three syndromes and lasts days to months. Fatal infectious complications usually occur during the initial 2 to 3 months. Full recovery will require weeks and potentially up to 2 years.

The three types of manifest illness in ARS are (1) bone marrow, (2) gastrointestinal, and (3) cardiovascular/central nervous syndrome. The signs and symptoms are based on the amount of damage done, with different organ systems being variably sensitive. Bone marrow is the most sensitive, and medically significant doses will cause marrow suppression only. Higher doses will cause damage to the gastrointestinal lining as well, and very high doses result in all three constellations of signs and symptoms. Bone marrow symptoms are caused by the pancytopenia that follows irradiation and is marked by severe anemia and immunosuppression. Neutrophil counts drop after 2 to 4 days, but thrombocytopenia can take 2 to 4 weeks to be seen.⁸ There may be a misleading transient initial period of thrombocytosis after exposure. If fatal, death usually occurs within a few months and usually due to infection and hemorrhage.¹

Radiation exposures severe enough to cause gastrointestinal damage are usually fatal, and death may occur within 2 weeks. Damage to the intestinal villi leads to endothelial sloughing, diarrhea, hemorrhage, malabsorption, and opportunistic infections as bacteria transit the intestinal lining concomitant with immune suppression. Death is due to dehydration, infection, and/or electrolyte imbalances. Very severe exposures can cause nervousness, confusion, severe nausea and vomiting, convulsions, and coma. Death due to cardiovascular/central nervous system damage occurs within 3 days.

MEDICAL TREATMENT OF CASUALTIES

Decontaminate patients if indicated. Remember that irradiated patients are not radioactive and do not require decontamination. Decontamination can be postponed in patients with trauma or burn injuries or medical disorders requiring emergent intervention. Collect swabs from patients with a stable condition before decontamination. In a mass casualty situation, remember to transfer patients with a stable condition early so that resources will remain for new patients and those whose condition is not stable for transfer. Mortality increases dramatically when surgeries are performed more than 48 hours after whole body irradiation injury. It is important that all surgeries be performed during this window, or delayed up to 3 months. For patients with internal contamination and incorporation, bodily fluids may contain traces of radioactive isotopes.

In a mass casualty scenario, analgesia and antiemetics may be the only appropriate treatment for patients with fatal exposures or major trauma. Patients with absolute lymphocyte counts less than 1000/mm³ 12 to 24 hours after exposure will eventually require reverse isolation

and will likely not survive. For patients whose radiation exposure is amenable to treatment, several interventions are appropriate. Trauma injuries should be addressed rapidly, and radiation skin injury may initially be treated similar to thermal burns. Prophylactic antibiotics are controversial but should be considered. Bone marrow stimulation may be helpful. Pulmonary contamination may require pulmonary lavage, but this should be discussed with an expert in treatment of radiation injuries before implementation and is not an emergency. Shrapnel and other foreign bodies may require debridement, but destructive surgery for removal is not indicated. Depleted uranium fragments have been left in numerous persons who have had close monitoring without complications.⁹

Patients whose condition is stable and who are without symptoms should have baseline laboratory samples drawn, including blood, urea, nitrogen; creatinine; complete blood count; and urinalysis. They may then be discharged home with arrangements made to have their 24- to 48-hour postexposure lymphocyte count checked and are to be instructed to seek immediate care for any symptoms of acute radiation sickness or cutaneous radiation syndrome.

Although patients presenting with radiation pose little risk to healthcare workers, pregnant healthcare workers should not participate in their treatment, and other healthcare workers should rotate out often to minimize the exposure to any contaminated individual. Ideally, providers will receive dosimeters from their radiation safety officer to ensure no provider gets an exposure above occupational safety guidelines. Because radiation exposure is such a rare occurrence, management should include prompt consult of the Radiation Emergency Assistance Center/Training Site (REAC/TS).¹⁰

PITFALLS

- Make sure the radiation detection equipment has working batteries!
- Any noise from the detection equipment will alarm patients; do not turn the equipment's sound on unless headphones are used.
- Make sure a baseline radiation level is checked remote from those potentially contaminated to prevent a false elevation determination.
- Scanning too quickly will fail to detect radiation, so go slow.
- Geiger counters do not detect alpha radiation.

Nuclear Detonation*

William E. Dickerson

DESCRIPTION OF EVENT

The detonation of a nuclear device is, perhaps, the most ominous of terrorist scenarios. Although unlikely, the consequence of such an event must be considered as part of a robust disaster preparedness program. If a terrorist organization detonates a nuclear device equivalent to 10 kilotons (KT) of trinitrotoluene (TNT) in a truck parked in a large city, one can expect a series of catastrophic events. There would be immediate casualties due to the blast, heat, and radiation from the bomb. Because this would most likely be a surface burst, radioactive fallout would also be produced, which would travel for several miles, depending on the size of the particles and weather conditions.¹ The Hiroshima nuclear detonation in August 1945 was equivalent to approximately 15 KT of TNT and was an air burst, which produced minimal fallout. Approximately 100,000 people died within 4 months in the city with a population of about 310,000. The result of such a blast today would cause enormous casualties and structural destruction and result in an area of contamination that may require a prolonged quarantine.

PREINCIDENT ACTIONS

If there is warning of a potential nuclear detonation, the population can be instructed to evacuate or find shelter, but forewarning is unlikely. Every medical center should include in its emergency preparedness program a radiation disaster plan, which identifies personnel assignments and duties for a radiation decontamination and management team. Since teamwork is essential, training and exercises are necessary. Every team must have a medical or health physicist familiar with the detection and management of radiation hazards, and subject matter experts should be identified who can guide the treatment of radiation casualties. Reference materials such as those in the References section of this chapter should be available.

POSTINCIDENT ACTIONS

After a radiologic disaster, local responders and facilities will be overwhelmed. The infrastructure will be dam-

*All material in this chapter is in the public domain, with the exception of any borrowed figures or tables.

aged, and there will be chaos. Most likely, the city mayor will request assistance from the state, and the state governor will request federal aid. A federal emergency will be declared, and the National Response Plan and/or Federal Radiation Emergency Response Plan will be activated. However, as in all disasters, the local communities will have to rely on their own resources for the first several hours. (See Chapter 61, Nuclear Disaster Management.)

Initially, it may not be apparent that the blast or bomb was a nuclear device. However, the extensive area of complete destruction stretching within approximately a 1-km radius from ground zero; the blast winds, which would be felt kilometers away from ground zero; and the probable appearance of a mushroom cloud will indicate that there was a nuclear detonation. The distribution of energy from a nuclear detonation is approximately 50% blast, 35% thermal radiation, 4% initial ionizing radiation (first minute), 10% residual nuclear radiation (fallout), and 1% electromagnetic pulse (EMP).² The percentage of casualties from each modality is not clear. Nuclear weapons with a yield of 10 KT or less have a higher percentage of radiation casualties than do nuclear weapons with a yield of more than 10 KT. Thermal radiation is the primary cause of injury from weapons larger than 10 KT because the thermal envelope extends well beyond the radiation contours.² The approximate range for casualties from a 10-KT weapon is as follows³:

- 590 meters for 50% mortality from blast effects
- 1800 meters for 50% mortality from thermal burns
- 790 meters for 4-Gy initial nuclear radiation (approximately 50% lethality)
- 9600 meters for 4-Gy fallout in first hour after the blast

Any combination of blast, burn, and radiation injury will cause synergistic effects worse than only one type of injury.

First responders will need to evaluate the areas near victims for high levels of radioactivity. It is recommended that first responders use a radiation dose of 0.1 Sv per hour as a “turn-around” dose. However, for life-saving purposes, a dose of 0.5 Sv or more may be received if the situation warrants it and the responder is aware of the potential health effects.³

State response will include National Guard and Civil Support Team involvement. Federal response will include early actions by the Department of Energy to identify the extent of surface and atmospheric radiation and actions by the Department of Defense, the National Disaster Medical System, the Strategic National Stockpile, and other federal agencies to provide emergency and long-term assistance. (See Section Two, Governmental Resources.)

Radiation Protection Guidance

1. Time, distance, and shielding.

- Time: Limit the time exposed to radioactive material.
- Distance: The radiation dose received from a source decreases as the inverse square of the distance from the source increases.
- Shielding: The more material (especially earth, water, concrete, or metal) between a radiation source and a victim, the less dose to a victim. Therefore, one of the best places to take shelter from initial radiation and fallout is in an underground basement away from any windows.

2. **Do not look at a nuclear fireball, even from a distance:** Flash-blindness and retinal burns may occur up to 20 km from the source during the daytime and up to 50 km at night.²

3. **The 7/10 rule:** For every sevenfold increase in time after a nuclear detonation, the dose rate of early fallout decreases by a factor of approximately 10.⁴ For example, if the radiation dose 1 hour after a detonation is taken as a reference, then the radiation dose at 7 hours would be 0.1 of the dose rate at 1 hour. The radiation dose at 49 hours would be $0.1 \times 0.1 = 0.01$, and the radiation dose rate at 343 hours ($7 \times 7 \times 7$, or about 14 days after a detonation) would be $0.1 \times 0.1 \times 0.1$ or 1/1000th of the radiation level at 1 hour. Therefore, maintaining shelter for 14 days would significantly reduce the radiation exposure from fallout.

4. **Take shelter or evacuate:** Due to radioactive fallout, the government may initially advise people to take shelter if they are within a specific radial distance, such as 30 miles, from the hypocenter. Later, after radiation plume data are available, the government may direct some population areas to take shelter and others to evacuate based on the predicted downwind path of the plume.

5. **Should potassium iodide be taken to block the uptake of radioactive iodine?** In general, the answer is no. The fission products that make up fallout include more than 300 different isotopes of 36 elements. Radioactive iodine is no more of a problem than other radioactive isotopes unless the radioactive iodine is inhaled or ingested. In this case, it will concentrate in the thyroid gland.⁴ The best measure to take is to avoid inhaling radioactive fallout or ingesting crops or milk contaminated with radioactive iodine. The food supply should be monitored for radioactive contamination. In a situation such as a nuclear reactor accident where large amounts of radioactive iodine might have been released, potassium iodide would more likely be beneficial.

MEDICAL TREATMENT OF CASUALTIES

The area in the vicinity of ground zero will be completely devastated with no survivors. Continuing out in a radius from ground zero, the percentage of immediate survivors will increase. First responders will be overloaded, and most ambulatory victims will need to walk to the nearest medical facility. Medical facilities closest to ground zero may not be functional, and local medical facilities that are functional will be overloaded beyond their surge capacity. (See Chapter 28, Surge Capacity.) Victims with blast and thermal injuries may initially outnumber victims with only radiation injury due to the latent nature of manifest radiation injury. (See Chapter 83, Introduction to Nuclear/Radiologic Disasters.)

Local medical facilities should:

- Activate their disaster plan.
- Secure their medical center to control patient flow and avoid having contaminated patients contaminate the facility.

The following radiation safety precautions should be taken:

- Follow the guidance of the facility's radiation safety officer.
- Wear personal protective equipment (PPE), such as surgical face masks, caps, gowns, double gloves, and shoe covers, with dosimeters if performing triage or decontamination procedures. (See Chapter 36, Personal Protective Equipment.)
- Perform triage and decontamination outside the medical facility if possible.

First triage and treat life-threatening injuries, then decontaminate. Be aware that the risk of radiation injury to care providers treating those exposed is exceedingly low. In fact, there are no known instances in which nurses, physicians, or other medical professionals have become ill due to their involvement in caring for someone injured in a radiation accident. (See Chapter 43, Triage, and Chapter 70, Radiation Decontamination.)

Blast Injury

Important differences exist between the blast effects from a nuclear weapon and the effects due to a conventional high-explosive bomb. With a nuclear weapon, the combination of high peak overpressure, high wind (or dynamic) pressure, and longer duration of the positive (compression) phase of the blast wave results in "mass distortion" of buildings similar to that produced by earthquakes and hurricanes. An ordinary explosion will usually damage only part of a large structure, but the blast from a nuclear weapon can surround and destroy whole buildings.⁴ (See Chapter 141, Introduction to Explosions and Blasts.)

Burn Injury

Thermal injury may initially be difficult to differentiate from skin injury due to radiation. One difference is that thermal injury occurs early, and radiation skin injury may

not appear for several days. The combination of thermal burns and irradiation significantly increases mortality.⁵ Thermal injury may also cause eye injury. Two types of eye injury are temporary blindness, which occurs if a person indirectly sees the flash of a nuclear fireball, and permanent blindness, which occurs from looking directly at a fireball and results in retinal damage.⁶ (See Chapter 155, Introduction to Fires and Burns.)

Acute Radiation Injury

Radiation injury may occur alone or in combination with blast and/or thermal burn injuries. Combined injuries result in a significantly worse prognosis than radiation injury alone. For the diagnosis and treatment of acute radiation injury, the following principles should be used (see Chapter 84, Ionizing Radiation Incident):

- Treat life-threatening injuries (e.g., airway, breathing, circulation) first.
- Decontaminate. The removal of clothes may remove up to 90% of external contamination.
- Anticipate combined injuries (e.g., radiation plus blast and/or thermal).
- Close open wounds within 48 hours of the event for best results.
- Base early dose estimates on symptoms and changes in lymphocyte counts. The Biodosimetry Assessment Tool (BAT) is a computer program that assists with dose estimates and is available free at the Armed Forces Radiobiology Research Institute (AFRRI) Web site (www.afri.usubs.mil).⁷

Acute Radiation Syndrome

Acute radiation syndrome (ARS) may require early use of hematopoietic colony stimulating factors such as filgrastim (Table 85-1). ARS may occur miles from an incident due to radioactive fallout (Fig. 85-1). There will probably

be no major role for the use of potassium iodide, Prussian blue, or diethylenetriamine pentaacetic acid (DTPA) after a nuclear detonation. See chapters 83 and 84 for a more thorough discussion of ARS.

Delayed Radiation Effects (2 to 4 Weeks After Event)

Due to the delayed onset of the hematopoietic subsyndrome of ARS, some patients may do well for 2 to 4 weeks before developing manifest symptoms with neutropenia and infections. If these patients could be identified the first few days after the event, they could be assigned to distant, even out-of-state, facilities for treatment of their impending symptoms.

Psychologic Injury

Long-term follow-up care will be necessary to identify late effects from radiation injury and trauma and to assist with posttraumatic stress symptoms. (See Chapter 8, Psychological Impact of Disaster.)

UNIQUE CONSIDERATIONS

The following should be considered when treating patients as a result of a radiologic event:

- Hospital surge capacity for all services will be exceeded. It will be best for many victims with minimal injury to go home, shower, change clothes, and take shelter.
- For acute radiation injuries, first check airway, breathing, and circulation, and then perform radiation decontamination.
- Decontaminate and triage outside a medical facility if possible to avoid contaminating the medical facility.
- Mass deaths will exceed immediate storage and burial capacity.

TABLE 85-1 TREATMENT GUIDELINES FOR RADIATION EXPOSURE*

NATURE OF INCIDENT	PROPOSED RADIATION DOSE FOR CYTOKINES: FILGRASTIM (G-CSF) OR SARGRAMOSTIM (GM-CSF)	PROPOSED RADIATION DOSE FOR ANTIBIOTICS†	PROPOSED RADIATION DOSE FOR STEM CELL TRANSPLANTATION
<100 casualties, healthy, no other injuries	3-10 Gy	2-10 Gy	7-10 Gy for allogeneic 4-10 Gy if autograft stored or syngeneic donor available
<100 casualties, but multiple injuries or burns Mass casualties, >100 casualties, healthy, no other injuries	2-6 Gy 3-7 Gy	2-6 Gy 2-7 Gy	Not applicable 7-10 Gy for allogeneic 4-10 Gy if autograft stored or syngeneic donor available
Mass casualties, >100 casualties, multiple injuries or burns	2-6 Gy	2-6 Gy	Not applicable

*This table summarizes the consensus guidelines of the Strategic National Stockpile Radiation Working Group. (Adapted from Waselenko J, MacVittie TJ, Blakely WF, et al. Medical management of the acute radiation syndrome: recommendations of the Strategic National Stockpile Radiation Working Group. *Ann Intern Med.* 2004;140[12]:1037-51, W-64-W-67.)

†Prophylactic antibiotics should be administered to neutropenic patients who have received the whole-body or significant partial-body dose listed in the table. Prophylactic antibiotics in general include a fluoroquinolone, acyclovir (if the patient is seropositive for herpes simplex virus or has a medical history of this virus), and fluconazole.

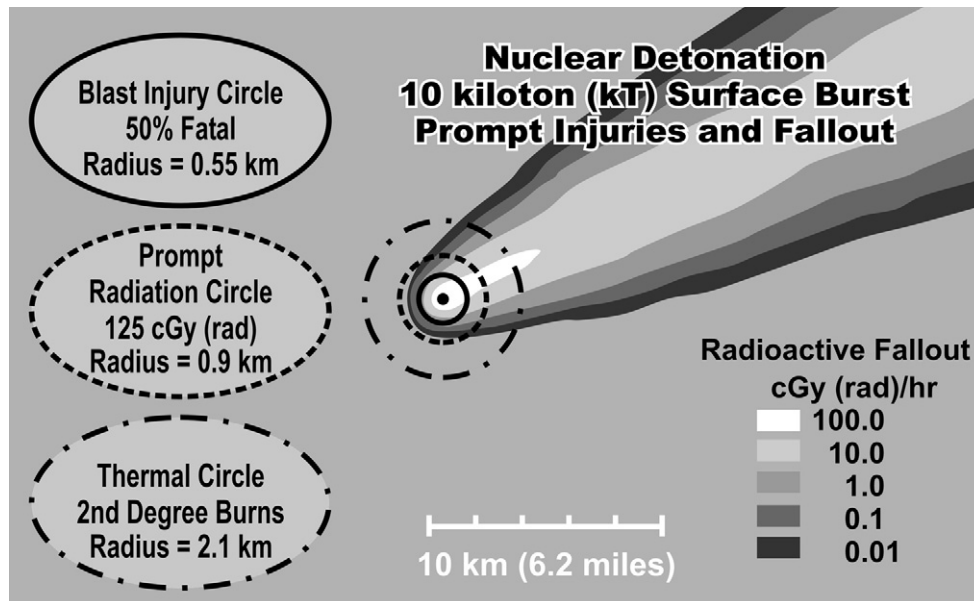

FIGURE 85-1. A 10-KT nuclear detonation, surface burst, hazard prediction assessment capability (HPAC) plot⁸ with wind 10 mph from the southeast. The plot shows both prompt effects and fallout 4 hours after detonation. Prompt effects include blast injury fatal in 50% of victims out to a radius of 0.55 km, radiation injury of 125 cGy (rad) out to a 0.9-km radius, and second-degree burns out to a 2.1-km radius. Fallout shows a 100 cGy/hour area out to about 5 km downwind and much larger distance coverages for 10 cGy/hour and less.⁸

PITFALLS

In the event of a nuclear detonation, there will be damage to the community infrastructure with limited communications and limited services. Failure to secure the medical center will result in radiation contamination throughout the facility. Health professionals may fail to anticipate the manifest illness phase of pure radiation casualties.

Management

In a mass casualty situation, this patient is expectant. He received a dose, which by itself would be lethal to about 50% of the population. His second-degree burns will have a synergistic effect on his morbidity. Survival

might be possible if all medical resources are available (e.g., the patient might require several weeks of care in an intensive care unit). In a mass casualty situation, triage may require that his treatment include only comfort measures. In that case, the patient would develop progressive symptoms of ARS and succumb within a few days.

CASE PRESENTATION

A 40-year-old white male is seen in the emergency department several hours after a nuclear detonation by a terrorist organization. The patient was working approximately three-fourths of a mile from a nuclear blast. He started vomiting 3 hours after the event. His lymphocyte count dropped from a level of 1000/mm³ 12 hours after the event to a level of 500/mm³ 24 hours after the event. According to the Biodosimetry Assessment Tool (BAT), he was exposed to approximately 4 Gy of radiation. The patient also has second-degree thermal burns over 60% of his body.

Radiation Accident—Isolated Exposure

Jeanette A. Linder and Lawrence S. Linder

DESCRIPTION OF EVENT

Intentional radiation exposure is an integral part of medical care, industrial monitoring, calibration, signage, nuclear reactors, sterilization of agricultural products, and x-ray screening of luggage and cargo. Accidental exposure from radioactive sources and x-ray-producing machines can easily occur with minor variations in practice, loss of custody of radioactive sources, or equipment malfunction. Although accidents are infrequent, rapid recognition of an exposure and intervention can prevent significant, and sometimes fatal, outcomes. Conversely, the risk to the healthcare worker is minimal, provided that simple precautions are taken.

Ionizing radiation is capable of creating ions. These ions then cause cell damage to varying degrees, depending on the total dose, the portion and proportion of body exposed, the duration of exposure, and comorbidities.

Radiation exposure is commonly divided into two broad categories: external irradiation and contamination. Exposures from an external source are described in this chapter. Both internal and external contamination are described in Chapter 87. This chapter focuses on the simplest form of radiation accident: isolated external exposures to a single person over a finite period.

Sealed radioactive sources and radiation generators (diagnostic and therapeutic x-ray machines) can cause external radiation without contamination. X-ray machines do not deposit lasting radioactivity in a person. Radioactive sources, on the other hand, are sometimes implanted into patients, permanently or temporarily. High-activity sources are also used in industry for imaging. Sources can be sealed within metal or unsealed in liquid or powder form. Unsealed or damaged sources can transfer radioactivity (i.e., contaminate) and are discussed in Chapter 87.

The most commonly encountered forms of radiation are:

- *Alpha*: Topical, absorbed/shielded by clothing or paper
- *Beta*: Barely penetrate only a few millimeters
- *Gamma*: Go all the way through, deeply penetrate
- *Neutrons*: Nastiest and nuclear, deeply penetrate and cause more damage than gamma

Sealed sources containing iridium-192, cesium-137, and cobalt-60 are commonly used in industry and medicine. These beta and gamma emitters are the primary cause of isolated exposure without contamination.¹ Alpha and neutron emissions usually occur in nuclear reactions, such as nuclear power plant accidents and nuclear detonations and are discussed in Chapters 85 and 88.

PREINCIDENT ACTIONS

Preparation for a rare event involves ensuring rapid access to infrequently used references and an early warning system. Any facility using radioactive materials or x-ray equipment must have a detailed plan to minimize exposure and respond to unintentional exposure. Exposure limits are defined by Occupational Safety and Health Administration guidelines, which vary for the general public, radiation workers, and disaster recovery workers.^{2,3} Incorporating the radiation safety plans of nearby industrial facilities, including mines, nuclear facilities, municipal landfills, metal works, and radiation therapy accelerators, may help prepare for the most likely accidents.

Basic precautions, such as shielding, minimal handling, and maintaining exposure at a maximal distance and minimal time, provide primary prevention of radiation accidents. An orphan source is one not under the custody of an authorized radiation safety officer (RSO). To help prevent orphan sources, all radioactive sources, sealed and unsealed, should be registered, clearly labeled, inventoried, and stored in a locked facility that is clearly marked as radioactive storage with access limited to authorized personnel. Orphan sources are addressed in Chapter 87.

Hospitals must post radiation detectors at strategic locations around diagnostic and therapeutic radiation use areas.² They must clearly signal removal of a source or failure to turn off a radiation generator. Hospitals may also consider placing detectors at hospital entrances. Alarm levels are suggested in the National Council on Radiation Protection and Measurements (NCRP) *Report No. 138—Management of Terrorist Events Involving*

Radioactive Material.³ The benefits and consequences of immediate detection and possible disproportionate emotional reactions should be considered when choosing a threshold for alarms or whether to post monitors at all. Be sure to discuss alarm levels with an RSO and a method of rapidly communicating the alarm (audible versus electronic message to a remote authority, on-site or off-site).

Simple forms are available for documentation of signs, symptoms, and details of exposure (isotope or beam generator, direct contact or exposure to a beam, time of exposure, distance, whole versus partial body, single incident, intermittent exposure, or ongoing exposure with contamination). These forms are available online and in multiple texts.^{4,5}

A communication plan for radiation accidents should describe reporting to your RSO and a radiation specialist. If your hospital does not have specialists who can treat radiation injury, you can call the Radiation Emergency Assistance Center/Training Site in Oak Ridge, Tenn. (REAC/TS at [865] 576-1005) or the Medical Radiobiology Advisory Team (MRAT at [301] 295-0316 daytime; [301] 295-0530 after hours) at the Armed Forces Radiobiology Research Institute (AFRRI) for advice. Local and federal authorities may also need to be notified. If there is a significant exposure, either large dose or multiple victims, REAC/TS (for civilian incidents) and/or MRAT (for military incidents) should be notified.

References on basic care of radiation accidents, both hard copies and electronic, are available. Computers can have clearly labeled Web site shortcuts in a separate corner of the desktop for rapid access. The Biodosimetry Assessment Tool (BAT) is detailed later in this chapter and is one of the most useful resources. Other resources include: AFRRI: www.afrii.usuhs.mil, accessed October 11, 2005. A PDF file of Medical Management of Radiological Casualties: Handbook, 2nd edition, can be downloaded at: www.afrii.usuhs.mil/www/outreach/pdf/2e_dmmrhandbook.pdf.

- U.S. Centers for Disease Control and Prevention (CDC): www.bt.cdc.gov/radiation.
- U.S. Food and Drug Administration (FDA): www.fda.gov/cder/drugprepare/default.htm#Radiation.
- REAC/TS: www.orau.gov/reacts.
- American College of Radiology (ACR): http://www.acr.org/s_acr/sec.asp?CID=3127&DID=18846. This site contains preapproved patient education handouts and the ACR's disaster preparedness publication, Disaster Preparedness for Radiology Professionals.

Basic medical fact sheets and patient handouts are available on the CDC Web site. Patient education should address the following:

1. Short- and long-term health risks of radiation exposure: physical and psychological
2. Signs and symptoms requiring medical intervention, especially subacute to chronic
3. References to Web sites and other literature for further support

4. Ways to prevent further exposure
5. Referral to a radiation specialist

Basic equipment for detection and management of radiation accidents includes a variety of radiation detectors. Preparedness plans should be reviewed and tested periodically, and supplies should be inventoried.

POSTINCIDENT ACTIONS

The most common accidental single exposures occur with previously identified sources and beam generators.^{1,6} Most medical and nuclear reactor facilities can immediately identify the radioactive source(s) (usually iridium-192, cobalt-60, cesium-137) or a generated beam and an approximate dose. Details about the isotope and form of exposure (topical, inhaled, ingested, or absorbed through skin) will focus medical care on the critical organ for that particular isotope and exposed body site. Irradiation by a completely removed isotope, such as a sealed source, or a machine-generated beam over a finite period is much simpler and is the focus of this chapter.

Recognition of a radiation accident may be elusive. The signs and symptoms of radiation sickness are similar to many common syndromes, including thermal burns, gastroenteritis, vague malaise, nausea, and vomiting.¹ Burns without previous thermal or solar exposure, nausea, vomiting, epilation, and/or bone marrow suppression, especially in clusters of patients, may be due to unidentified radiation exposure. The history and physical should address therapeutic, diagnostic, and occupational sources of radiation, particularly in close proximity to nuclear reactors, scientific laboratories, particle accelerators, or other facilities with high radiation exposure.

Unrecognized exposure to radiation is uncommon, but can be deduced from signs and symptoms over time.⁶ Whole-body radiation exposure causes predictable and proportional declines in blood counts, increasing constitutional symptoms, and other factors.⁷ Once a radiation accident has been confirmed, you should follow your emergency department's (ED's) communication protocol and notify at least the RSO and a radiation specialist.

MEDICAL TREATMENT OF CASUALTIES

Initial emergency care is the same for both the nonradiation and radiation casualty. Airway, breathing, and circulation are always the first priority.³ Radiologic exposure does not cause immediate loss of consciousness; you should assess other toxic exposures or trauma in the immediately unconscious patient. Once the patient's condition is stabilized, the most important distinction for initial medical management is contamination versus irradiation. Irradiated patients have no detectable radioactivity and pose no risk to providers.⁶

The history and accompanying documentation usually quickly identify the source, machine or isotope; form of isotope (sealed or unsealed); body distance and position from the source; and approximate dose. One must

determine whether the exposure was whole body, local, or both. Small portions of the body can tolerate much larger exposures than the whole body. Sequelae of whole-body irradiation can quickly escalate without immediate intervention, whereas partial-body exposures can often be observed and treated days to weeks after the exposure, when local symptoms occur, if necessary.^{1,8,9}

Localized Exposure

Acute treatment of uncontaminated local exposures is similar to that of thermal burns or other trauma.^{9,10} Trauma of the irradiated area must be avoided. The time course to development of erythema, epilation (hair loss), desquamation, and blistering requires days to weeks. These signs usually result in predictable cutaneous changes, which vary depending on the dose and distribution of exposure. Consequences of exposure and the time delay until those consequences become clinically apparent will vary with the volume of tissue exposed and the dose absorbed.⁸ Epilation occurs in 2 to 3 weeks at doses greater than approximately 3 Gy.⁹ The threshold for erythema being visible on day 1 is 10 Gy; the erythema rapidly dissipates at relatively low doses, then recurs days to weeks later. Twenty Gy local irradiation causes moist desquamation and possibly ulceration in about 2 weeks. Delayed or lack of healing of ulceration is caused by 25 Gy and greater. Higher doses shorten the time in which these changes develop. Local radiation tissue injury can be treated in a manner similar to thermal burns, but manipulation of erythematous tissue should only be undertaken with severe trepidation. Ulcerated areas will gradually expand to include surrounding erythematous regions as the tissue injury is expressed over time. Follow-up care should be transferred to a radiation specialist.^{8,10,11}

Patients with signs of local exposure may also have lesser degrees of whole-body exposure. Other injuries will hinder recovery from whole-body exposure. All patients should be monitored for acute radiation sickness or some other phase of radiation exposure, as noted later in the chapter. In patients with concomitant total body exposure, closure of wounds should be done either within 36 to 48 hours before bone marrow suppression or several weeks to months later once the marrow has recovered.¹⁰⁻¹²

Whole-Body or Large Partial-Body Exposure

Radiation exposure of ~1 Gy or more to large portions of the body causes predictable syndromes. The time to emesis (first vomiting after exposure [TE]), lymphocyte depletion kinetics, and chromosome aberrations are dose-dependent over time.^{7,9,11} A sophisticated but user-friendly software program, BAT, is a free download from the AFRRRI Web site (www.afrrri.usuhs.mil) and is based on these indicators.^{11,13} Signs and symptoms and validated data can be systematically recorded in the program at varying intervals. The program will calculate estimated doses based on input data and physical parameters.

Initial symptoms of acute radiation sickness can occur within minutes to days after whole-body exposure. Affected systems increase with increasing dose in the following order: hematopoietic, gastrointestinal, cardiovascular, then central nervous system.^{7,9,10} Each syndrome has four phases: (1) prodromal, (2) latent, (3) manifest illness, and (4) recovery or death. The prodromal phase is predictive of the severity of subsequent phases. Prodromal symptoms include nausea, vomiting, diarrhea, fatigue, weakness, headache, parotid pain, and erythema. The time between exposure and the first episode of emesis (time to emesis, or TE) often correlates with general ranges of total body dose. A TE of less than 4 hours may indicate a significant whole-body dose of 3.5 Gy or more. Without appropriate medical treatment, a whole-body dose of approximately 3.5 Gy is generally considered lethal to 50% of patients within 60 days ($LD_{50/60}$). The $LD_{50/60}$ may nearly double to 6 to 7 Gy with aggressive intervention.^{10,11} Without medical care, this 6- to 7-Gy dose would allow few survivors. A TE of less than 1 hour possibly indicates a lethal exposure even with intensive medical care; palliative care is recommended if the supralethal dosage is confirmed by clinical evaluation. Healthy adults with a TE of more than 4 hours, which implies a dose of less than 1 to 2 Gy whole body, will probably survive without medical care, unless additional medical factors complicate the issue. If there are mass casualties, patients without concomitant injuries who have a TE of more than 4 hours can be triaged to delayed evaluation in 24 to 72 hours, but reevaluation is mandatory.¹⁴

The speed at which lymphocyte counts decrease is directly proportional to the whole-body dose. An absolute lymphocyte count (ALC) decline of 50% or more within 24 hours indicates at least a moderate whole-body dose. If the victim has other injuries, then ALC is a less reliable predictor.^{7,10,13}

Physical Examination

Initial physical examination should focus on vital signs (fever, hypotension, orthostasis), skin manifestations (erythema, blistering, onycholysis, edema, desquamation, petechiae), central nervous system deficits (motor, sensory, ataxia, mental status, cognition), and abdominal signs (pain or tenderness).¹⁰

Laboratory Studies

A complete blood count with differential and platelet count should be drawn immediately and at least three times per day for several days in anyone with prodromal symptoms. Blood samples for cytogenetic studies should be drawn around 24 hours after exposure. Verify in which tube to collect blood (currently 10 mL in a lithium-heparin collection tube), proper labeling, and storage temperature with MRAT or your RSO.¹¹

Treatment

Treatment is stratified by the estimated total body dose in addition to treatment of known injuries or infections.

Estimated dose, probability of survival, and treatment are based on signs, symptoms, and approximate blood counts in Table 86-1 or by the results of serial data input into the BAT program.^{1,13,15}

The Strategic National Stockpile Radiation Working Group (SNS) has consolidated the seminal literature on radiation injury. It recommends treatment of neutropenic or anticipated neutropenic patients with: (1) broad-spectrum prophylaxis using a fluoroquinolone with streptococcal coverage or augmented with penicillin or amoxicillin; (2) acyclovir; and (3) fluconazole. Known sites of infection should be managed according to established guidelines. Underlying foci of current or new infection are likely to be due to loss of integrity of the integument or gastrointestinal tract. Add anaerobic coverage when there is known bowel injury.¹⁰

The SNS recommends supportive care with cytokines (G-CSF, Peg-G-CSF, GM-CSF), prophylactic and therapeutic antibiotics, leukoreduced/irradiated transfusions, antiemetics, antidiarrheals, opiates, parenteral fluids, and

nutrition.¹⁰ In patients with concomitant total-body exposure, closure of wounds should be done either within 36 to 48 hours before bone marrow suppression or months later when the marrow has recovered.¹⁰⁻¹² Treatment should be transferred to a radiation specialist or should continue under the guidance of REAC/TS, MRAT, or other response teams. Long-term care should be transferred to a specialist in radiation injury. When chronic, nonhealing wounds are present as late effects of exposure to radiation, consideration of hyperbaric oxygen therapy should be made before and after attempts at flaps or skin grafts, and consultation from a specialist in hyperbaric medicine should be sought as part of a multispecialty approach to wound healing.^{16,17}

UNIQUE CONSIDERATIONS

All radiation accident victims carry some risk of an induced malignancy.³ This is usually far less than

TABLE 86-1 RESPONSE CATEGORIES

RESPONSE CATEGORY	WBE	PROBABILITY OF SURVIVAL*	CLINICAL SIGNS†	ALC‡	ANC§	TREATMENT
1	~0.4 to 1.4 Sv	~100% without treatment	None or minimal	0.5-2	>2	Follow-up as outpatient

§ANC, Absolute neutrophil count in units of 10⁹/L.

Nausea and vomiting can be quite severe after large doses to the abdomen or moderate whole body doses.¹² The most effective antiemetics are 5HT₃ antagonists.¹⁵

anticipated and only slightly greater than the preincident risk, since radiation is a relatively weak carcinogen.³ Risk is related to quality and dose of radiation, affected organs, age at the time of exposure, and other risk factors.³ Education about the usual small increase in risk may diminish stress significantly. General educational materials can initially allay fears, and subsequent consultation with a radiation specialist can better define risks and proper surveillance.

Loss of fertility is common with irradiation of the gonads. This may be temporary or permanent, depending on dose, depth of penetration, age, and maturation of the patient.³ Doses to the testes of 0.15 Gy are likely to cause temporary sterility, but 3.5 Gy or more will cause permanent sterility. Ovarian doses for permanent sterility range from 2.5 to 6 Gy.³ There has been some recovery of fertility even in major radiation accidents, such as Chernobyl recovery workers.¹⁸

Fetal doses should be estimated separately from whole-body and local doses to a pregnant woman. In some cases, the fetus receives a lower whole-body dose than the mother due to natural shielding of the baby by surrounding structures. Very low doses of only 0.1 to 1 Gy can be very harmful to the fetus depending on the stage of gestation. Exposure to ionizing radiation before implantation usually results in undetectable death of the fetus or failure to implant. Exposure during organogenesis (weeks ~3 to 7) may cause malformations. Later exposure during weeks 8 to 25 causes decreasing IQ with increasing dose. There is a small increased risk of childhood cancers and leukemias.³

Patients, family members, co-workers, recovery workers, and even healthcare providers often require some psychological intervention. The emotional trauma and possible stigma of radiation exposure can be intense and outlast the physical manifestations. Acute stress reactions of insomnia, impaired concentration, and social withdrawal should be anticipated. If the radiation accident is associated with an act of terrorism, then psychological effects will increase. Patients should be followed-up long term for signs of posttraumatic stress disorder. Groups at particularly high risk are children, mothers of young children, pregnant women, emergency personnel, recovery and cleanup workers, and those with a history of mental illness. Education and early intervention can prevent much of this psychological stress.^{9,19}

PITFALLS

Failure to prepare a response plan and learn basic radiation medicine can lead to excessive morbidity and mortality or failure to recognize an accidental or intentional radiation incident by terrorists. There are multiple educational resources and a sample emergency plan on the Web sites listed in this chapter.²⁰ REAC/TS and AFRRRI provide physician training online and at various courses, remote and on-site, at varying levels of intensity for first responders, ED personnel, and radiation specialists. Detailed references are provided by multiple government agencies and other organizations, including the CDC, AFRRRI, and ACR. If communications systems are not

CASE PRESENTATION

An airport security worker habitually reaches into a luggage x-ray machine in an attempt to reduce the time passengers wait in line. On a particularly busy night, he was asked to work a double shift to help with an unusually high number of passengers. During his 16-hour shift, he rested his left hand on the bags inside the screening machine so he would be ready to immediately pull them out. His hand was actually behind the lead curtains, resting on the bags as the fluoroscopy unit was being used.

The security worker noticed some faint redness of his left middle and ring fingertips that evening. This had resolved by morning. Fifteen days later he noticed erythema and epilation of all four fingers of the left hand and intact hair on his thumb. In a few days, blisters had formed on the ends of the middle and ring fingers. The security worker was seen in the ED near the airport for painful blistering. The triage nurse identified him as a radiation worker. The patient denied any history of thermal or caustic injury, so the ED physician considered radiation exposure. After speaking to the hospital's RSO and radiation oncologist, the ED physician confirmed his suspicions that luggage screening x-ray machines do generate enough radiation to cause burns if used improperly for many hours.

Over the next few days, the patient's fingers developed dry desquamation and hyperpigmentation. The blisters healed over a 3-week period while the patient was using topical creams. Four months later, the tip of his left middle finger became fibrotic and contracted. The hair grew back on all of the fingers except the middle and fourth distal fingers.

REAC/TS and the National Institute for Occupational Safety and Health investigated the accident. They confirmed that radiation worker training and monitoring were insufficient. Training sessions and radiation badges (lapel and left ring finger) were instituted.

operational, several resources, such as the latest edition of the *Medical Management of Radiological Casualties: Handbook* and the Biodosimetry Assessment Tool (BAT), can be stored on a portable memory device. Basic facts sheets on medical management and documentation of radiation emergencies are on the CDC Web site (www.bt.cdc.gov/radiation). The latest drug recommendations and approvals will be noted on the U.S. Food and Drug Administration Web site (www.fda.gov/cder/drug-prepare/default.htm#Radiation).

Radiation Accident—Dispersed Exposure

Jeanette A. Linder and Lawrence S. Linder

DESCRIPTION OF EVENT

Dispersed ionizing radiation accidents are caused by unsealed or damaged radiation sources. Contamination can be external or internal (by injection, ingestion, inhalation, or absorption through intact skin or wounds). The most common dispersed exposures have been medical and industrial accidents.¹ Less commonly, orphan sources, those no longer in the custody of a radiation safety officer (RSO), were knowingly or unwittingly transported and/or altered by unauthorized persons. Coupling an orphan source with a conventional explosive will create a dirty bomb. Fortunately, the small amounts of radioactivity dispersed by a dirty bomb or from spraying radioactive powders or liquid would be unlikely to cause significant illness beyond psychological terror.² Radiation dispersal devices and other intentional dispersion are addressed in Chapter 87. The most dangerous and feared dispersed exposure is due to nuclear explosion, and this is addressed in Chapter 85.

Beta, gamma, and minimal neutron exposure are most prevalent in industry and medicine, whereas alpha and neutron emitters usually occur in nuclear reactions, such as those in nuclear power plants or nuclear detonations. Medical or industrial sources are the ones most likely to be dispersed, either accidentally or intentionally, in a dirty bomb.¹ These sources are usually sealed in metal. In decreasing frequency, accidents can involve iridium-192, cobalt-60, and cesium-137, which emit penetrating gamma and minimal beta radiation.¹ Iodine-125 and palladium-103 seeds are weak gamma and beta emitters. They are commonly used in radiation oncology for permanent implantation of the prostate gland and other organs and usually pose little to no risk. Many unsealed sources are used in scientific laboratories and nuclear medicine testing and treatment, including tritium-3, iodine-131, iodine-125, strontium-90, and technetium-99m. The chemical and radiation characteristics of each isotope will determine which organs are affected. The effective time of exposure without intervention depends on the body's incorporation and/or excretion of that substance or the vehicle on which the isotope is carried. Incorporation of an isotope into tissues may be temporary or permanent and depends on the chemical nature,

size of the particles, phase state (liquid versus solid), and route of entry. For example, radium can be permanently incorporated into bone matrix, whereas iodine is taken up into the thyroid. Others may eventually be excreted in the urine or feces without intervention. Table 87-1 provides basic facts for the most commonly encountered isotopes in accidents.³⁻⁶ The RSO and agencies such as the Radiation Emergency Assistance Center/Training Site (REAC/TS) in Oak Ridge, TN (865-576-1005), will provide detailed information on detection, dose estimation, decontamination, and consequence prevention and management.

PREINCIDENT ACTIONS

As in Chapter 86, preparation for a rare event involves ensuring rapid access to infrequently used references and an early warning system. In the case of contamination with dispersed radioactive materials, patients may know they were contaminated during medical or industrial accidents. For the rare case of accidental or intentional contamination that has yet to be identified, mounted radiation monitors at strategic entrances to the hospital may detect undeclared or unrecognized radioactivity. Alarm levels are suggested in the National Council on Radiation Protection and Measurements (NCRP) report number 138.⁷ The benefits of immediate detection and consequences of possible disproportionate emotional reactions should be considered when choosing a threshold for alarming or deciding whether to post monitors at all. This will require a well-thought-out floor plan, response, and notification of appropriate authorities, including the local RSO and radiation specialists. Sample emergency plans are available on various Web sites and in radiation texts.⁸ Hospital and clinic emergency preparedness exercises should include a radiation-exposed patient or scenario to ensure familiarity with and provide practice of the radiation response, containment, and treatment procedures by the emergency department and other hospital staff members.

First responders to any detonation should always survey for radioactivity on arrival.⁷ First responders at the accident site may receive significant doses; however,

TABLE 87-1 DECONTAMINATION OF COMMON ELEMENTS IN INDUSTRIAL AND MEDICAL ACCIDENTS*

ELEMENT	EMISSIONS	CRITICAL ORGAN	EFFECTIVE T _{1/2} †	DECONTAMINATION
Cesium-137	Beta, gamma	Total body	70 days	Prussian blue (Radiogardase) 3 g po 3 times per day (adults and adolescents); 1 g po 3 times/day (2-12 years old); consider lavage and purgatives
Cobalt-60	Beta, gamma	Total body	10 days	Lavage, purgatives, penicillamine
Iodine-125, iodine-131	Beta, gamma	Thyroid	Iodine-125, 42 days; iodine-131, 8 days	Potassium iodide: 0-1 month, 16 mg/day; >1 month to 3 years, 32 mg/day; >3 to 12 years and < 70 kg, 65 mg/day; adults or ≥70 kg, 130 mg/day; consider lavage
Iridium-192	Beta, gamma	Lung	74 days	Lavage for large quantities
Technetium-99m	Gamma	Total body	5 hours	Potassium perchlorate to reduce thyroid dose
Tritium-3	Beta	Total body	12 days	Forced fluids
Uranium-235 and uranium-238	Alpha	Kidney,‡ bone, liver, lung	Can be permanent if in bone	Bicarbonate to alkalinize the urine

*See Chapter 86 for a description of possible elements and types of radioactivity.

†Effective t_{1/2} combines radioactive and chemical properties and rates of elimination without decontamination efforts.

‡The kidney is most vulnerable to large amounts of uranium due to the chemical properties of this heavy metal. Uranium can ultimately be deposited in bone. po, Per os; qd, once per day.

with proper real-time monitoring, limited time, and maximal distance, exposures can be acceptable. When following simple procedures, providers receive very little exposure even while caring for large numbers of contaminated victims. It is reassuring that no U.S. health-care worker who has adhered to simple precautions has become contaminated from handling a contaminated patient.⁹ Habitual use of gowns, double gloves, masks, and hair and shoe covers and remaining within the contaminated zone until cleared for exit by the RSO will keep exposures well within limits in nearly all scenarios.¹⁰ Any site the patient has visited prior to decontamination must be considered radioactive and, therefore, a hot zone. An adjacent transitional or warm zone is for step-off as protective clothing and gear are removed. Radioactive materials deposited on clothing and skin can be quickly decontaminated up to 90% simply by removing clothing and washing gently with soap and water. Personnel are then monitored to ensure minimal to no residual activity before they step into the cold zone.^{5,6}

A floor plan should be detailed in an accident-preparedness plan. Only essential equipment and necessary furniture should be in the hot zone. Supplies and personnel are brought in only as needed. A defined pathway from the entry point/ambulance reception to the treatment area should be covered in plastic and roped off with radioactive warning signs. Traffic through the

emergency department must be tightly monitored to minimize spread of contamination. A detailed security plan restricting admittance to authorized personnel and patients should be clearly defined before any incident occurs.¹¹ If the radioactive contaminant may be airborne, air handlers and ventilation should be isolated, if possible.

Background radiation levels for various hospital locations should be documented well in advance of an accident.¹² Plans must map the locations and use of beta-gamma detectors and alpha detectors. Plans should also address personal dosimeters of varying types (defined by the RSO), a large supply of sealable plastic containers, various sizes of plastic bags, radiation warning signs, ropes, plastic for covering the floor, gowns, gloves, tape, and current references on management of contaminated patients.^{7,11} The Web sites, agencies, and literature mentioned in Chapter 86 are essential.

Protective clothing and gear in the hospital setting is nearly the same as for universal precautions. The exception is double gloving. If time allows, tape the first pair of gloves to gown sleeves so they are not removed when the top pair is frequently removed. All other seams and transitions, pants legs and shoe covers, can be taped. Detailed instructions on donning and removing protective clothing and gear are available from the Centers for Disease Control and Prevention (CDC).¹³ Lead aprons are not recommended. The weight of the aprons may

cause overheating, accelerate fatigue, and slow down providers, with little to no benefit.

Details of whom to notify, education of providers and patients, and other details of the disaster plan are summarized in Chapter 86 and detailed in multiple other references.^{5-9,11}

POSTINCIDENT ACTIONS

Initial emergency care is the same for both nonradiation and radiation casualties. Airway, breathing, and circulation are always the first priorities. In other words, patients with life-threatening conditions are treated first and decontaminated second. Stable patients can be decontaminated first.⁶ Radiologic exposure does not cause immediate loss of consciousness; assess other toxic exposures or trauma in the immediately unconscious patient. One exception is that there may be transient incapacitation after extremely high doses to the head or whole body.¹⁴ Once stabilized, the most important distinction for initial medical management is contamination (radioactive material present on or within the body) versus irradiation (previous exposure without any radioactive material deposited on or within the body).

The history and accompanying documentation usually quickly identify the source, machine or isotope, form of isotope (sealed or unsealed), body distance and position from the source, and approximate dose. One must determine whether the exposure was whole body or local. Sequelae of whole body irradiation can quickly escalate without immediate intervention, whereas partial body exposures can often be observed and treated days to weeks later when or if signs and symptoms develop.^{1,11,15}

First responders should complete an identification tag specifying the usual triage information plus radiation-specific details. Information for internal contamination should include the radionuclide, route of contamination, nasal counts, wound counts, whole body counts, bioassay samples already collected, and treatment initiated. Data for external exposure to penetrating radiation should include the location and position of patient with respect to the source, exact time and duration of exposure, whether a dosimeter was used and where it was located, who has the dosimeter and its current location, type of symptoms, time to onset of symptoms, and treatment at the site of the accident/assessment/facility.⁵

Ambulatory patients should be decontaminated, if possible, before transport to the hospital, especially at a facility with its own decontamination process. A radiation dispersal device may contaminate as many as 1000 victims,² most of whom will be ambulatory. The few who are not ambulatory most likely have significant blast injuries. Ambulatory patients should remove clothing in a manner that minimizes further contamination, taking care not to contact undergarments and skin with the external surfaces of the garments being removed. Removing clothing and washing gently with soap and water will remove significant amounts of surface contamination. Splashing into eyes, mouth, nose, and open wounds must be avoided to minimize internal contami-

nation. Cover all wounds to prevent further contamination and limit contamination of clean areas by the wound. Washing should be repeated until the radioactivity is less than twice that of the background activity, until it is unwise to continue due to medical conditions or impending skin abrasion, or until further measures fail to decrease activity significantly. Wastewater and any shiny or metallic particles should be retained and identified as radioactive contaminate. Abrasions and shaving should be avoided. Hair can be clipped, if necessary. All clothing and hair should be sealed in a labeled bag for assessment by the RSO.^{5,6} When decontamination efforts fail to reduce any radioactivity, suspect internal contamination with a gamma-emitter.⁵

Patients requiring transport by stretcher, if stable, should have clothing cut off.⁶ The patient should then be wrapped in cloth sheets, not plastic, to minimize the spread of radioactive material and minimize hyperthermia.^{6, 13} First responders should notify the hospital before arrival that a contaminated patient is on the way. They should also provide additional medical information including the following:

1. Other injuries and medical conditions besides radioactive exposure/contamination;
2. Whether toxic or corrosive chemicals are involved in addition to the radionuclides;
3. Whether the compounds are soluble or insoluble and the size of the particles;
4. Measurements from the site of the accident that will help determine dose;
5. What decontamination efforts have already been attempted, and whether they were successful;
6. Verification that clothing removed at the site has been saved to allow identification of isotope and dose estimation;
7. Which excreta, swipes, and samples have been collected, time of collection, current location, when analyses will be completed and by whom; and
8. Any previous radiation therapy or accidental exposure.^{5,6,7,9}

Co-morbidities may affect the clearance, absorption, or tolerance of decontamination measures (e.g., renal disease may affect the tolerance of chelators).⁵ Once stable, either first responders or hospital providers should swab nasal cavities and collect multiple samples of excreta and blood. All metal fragments should be removed with forceps and monitored. If these are contaminated debris or particles from a damaged source, your RSO will direct you to seal high-activity sources in lead containers or at least 6 feet from personnel.²

MEDICAL TREATMENT OF CASUALTIES

As stated above, initial emergency care is the same for both the nonradiation and the radiation casualty. Once airway, breathing, and circulation are stable, radiation surveys and decontamination can be considered. First, one must identify that a radiation accident has occurred. Occupational and therapeutic exposures may be easily

identified after a brief history is taken or a discussion with supervisors or treating physicians is undertaken. More elusive to diagnosis are accidental exposures to unsealed or damaged orphan sources in the community at landfills or construction sites or in malfunctioning equipment. One should include radiation exposure in the differential diagnosis of unexplained bone marrow suppression; skin burns or desquamation with no history of thermal injury; and clusters of people with unexplained nausea, vomiting, and decreasing blood counts currently or several days to weeks earlier.¹ Radiation detectors mounted at hospital entries might identify significant contamination.

External or internal contamination will determine the initial intervention. There also may be a combination of external penetrating radiation with concomitant contamination. Prodromal symptoms and serial peripheral blood counts should predict the overall total body dose, including external components not necessarily identified at the time of presentation.

Once the patient is stable, surface surveys and nasal swabs with a moist cotton-tipped applicator or filter paper swab can be obtained by gently rotating the swabs over accessible surfaces. This should not be done by the patient, who might contaminate the swab with material already on hands and clothing.⁵ Nasal swab counts represent approximately 5% of lung activity.²

Medical intervention should be orderly and should include the following:

1. Triage and medical stabilization;
2. External decontamination: remove clothing, wash skin, irrigate wounds (collect bandages and attempt to collect drainage), clip and collect hair if stubborn to shampooing;
3. Documentation of prodromal symptoms or whole body exposure: nausea, time to emesis, diarrhea, transient incapacitation, hypotension (the presence of all indicates very high dose), parotid pain, erythema;
4. Documentation of signs and symptoms of local exposure (erythema, dry and moist desquamation);
5. Initial complete blood count with differential and platelet count immediately and every 4 to 6 hours for at least 24 to 48 hours;
6. Collection of all excreta for at least 48 hours;
7. Collection of blood at 24 hours for cytogenetics;
8. Nasal swabs; and
9. Internal decontamination (see Table 87-1).

LOCALIZED EXTERNAL CONTAMINATION

Removing clothing and gently washing with soap and water will remove significant amounts of external contamination. When the skin is unbroken and levels fall below twice background levels, decontamination can stop. Even with broken skin and other injuries, there are no immediate consequences of localized exposure.

Patients with localized external contamination may have also had significant external radiation and may manifest acute radiation syndrome (ARS). Only those casual-

ties who were in intimate contact with the source before its dissemination are likely to exhibit this level of injury. Evaluation and treatment of ARS are the same as described in Chapter 86. Radiation specialists and agencies (REAC/TS for civilian events and/or the Medical Radiobiology Advisory Team, MRAT, for military events) should be contacted upon confirmation of a dispersed exposure.

INTERNAL CONTAMINATION

Initial evaluation and treatment are the same as for the externally irradiated patient with respect to ARS. Once a patient's condition is stabilized, measures to reduce internal contamination and incorporation (binding radioactive material into tissues or bone) can proceed. The route of entry and particular isotope will determine decontamination methods. Currently recommended interventions and drugs for each isotope can be found on numerous Web sites, such as those maintained by the CDC and the U.S. Food and Drug Administration (FDA). The four main mechanisms of internal decontamination are as follows: (1) reducing uptake; (2) isotopic dilution or use of blocking agents; (3) mobilizing agents; and (4) chelation.⁵ See Table 87-1 for specific interventions.

Reducing Uptake

Nasopharyngeal, bronchoalveolar, and gastric lavage (within 1 to 2 hours of ingestion), emetics, purgatives, and enemas may significantly reduce contamination.^{2,5-7} Prussian blue, recently approved by the FDA as Radiogardase, prevents absorption of cesium-134 and cesium-137 and promotes excretion in stool.³

Blocking Agents

Blocking uptake of the radioactive material, also called *isotopic dilution*, can decrease uptake into stable metabolic pools, such as bone, where uptake becomes permanent. For instance, potassium iodide will block radioactive iodine if given before or within 4 to 6 hours of exposure. Potassium iodide will not block any other isotopes, although patients and families may request it.^{4,5,16} It has no medical value except for the emergency treatment of radioiodine exposure. See Table 87-1 for doses of potassium iodide.

Mobilizing Agents

Mobilizing agents accelerate excretion in feces or urine. Forced fluids will reduce uptake and increase the excretion of tritium-3 in the urine. Alkalinizing the urine with bicarbonate can increase excretion of uranium.^{5,7}

Chelation

Americium-241, plutonium-238-239, and curium can be chelated with pentetate calcium trisodium and pentetate zinc trisodium; these older agents were recently approved by the FDA for this use. Care must be exerted

because these agents also bind endogenous metals in the body, (i.e., zinc, magnesium, and manganese), and plasma levels should be monitored. Depletion of these trace metals can interfere with necessary cellular mitotic processes. Mineral and vitamin supplements may be indicated. In animal studies, chelates with uranium and neptunium were less stable than chelates of americium, plutonium, and curium, in vivo, resulting in deposition of uranium and neptunium in tissues including bone, and thus they are *not* expected to be effective for uranium or neptunium.¹⁷⁻²¹ Ethylenediamine tetraacetic acid can also be used, on the recommendation of REAC/TS or a radiation specialist. Chelated salts are then excreted by glomerular filtration in the urine.^{5,7}

Collect blood, urine, feces, wound exudates, and dressings at least three times per day for at least 48 hours. Initial excreta may underestimate exposure before transit through the intestines. Any initial orifices with activity above background should be swiped periodically. Be

careful not to cause abrasions, which could cause further internal contamination. Collect blood for cytogenetics at around 24 hours. Your RSO and radiation specialists will help identify those patients who require subsequent surveys. Patients who are not hospitalized must be given containers and instructed to collect all excreta. Each sample must be labeled with the time and date for proper dosimetry assessment. All contaminated instruments, specimens, clothing, and equipment should be saved in separate containers and labeled with patient name, time, and date. These samples will contribute to identifying isotopes and approximate dose. Radioactive tissue should NOT be removed as a means of decontamination unless under the guidance of a trained radiologic physician. Extreme measures, such as amputation, are rarely indicated except for unremovable embedded highly radioactive particulate contamination with long-lived sources. Destructive surgeries should only be performed after complete evaluation by, and on recommendation of, a radiation medicine specialist.^{5,7}

CASE PRESENTATION

A salvage worker finds an "EXIT" sign among the rubble of an office building. It is crushed and no longer glowing. During the 2-hour drive back to the landfill, the exit sign rests on the front seat of his truck, approximately 14 inches from his right hip. Upon arrival at the landfill, he notices the radioactive warning label on the back of the sign indicating that it contains tritium,³ H. The worker abandons the sign and rushes to the emergency department in a panic.

This worker is relieved to hear that tritium is a rapidly dispersed gas that was probably not even present at the time that he found the broken exit sign. He has no signs or symptoms of radiation exposure (i.e., no erythema of the closest body part, the right hip, and no prodromal symptoms or signs). Local HazMat authorities are dispatched to recover the sign, and after examination, they determine that it no longer contains radioactive material. Your RSO has verified only background levels of beta radiation on the patient. Urine specimens taken at the time of arrival and 1 hour later are negative for beta activity above background. The patient is reassured that even if there were tritium present in his urine, and therefore throughout his body, tritium is a pure beta emitter that is exhaled, and, if metabolized, excreted in the urine. It would be unlikely to cause any signs or symptoms.

You reassure the patient that he is fine. A full analysis by authorities to better define his exposure and risk of consequences is not indicated in this case because there was no true exposure. This worker is referred to his primary care physician for follow-up and psychological assessment. If a true radiologic exposure had been validated, then the RSO would have reported the incident to REAC/TS, and both local and perhaps federal authorities could have performed a full analysis and recommended treatment and follow-up of this patient. Regardless of the absence of radiation injury, this patient has likely suffered some emotional injury and needs psychological follow-up. This can be done with his primary care physician or with a radiation medicine specialist a day or so later for reassurance.

UNIQUE CONSIDERATIONS

The number of casualties involved in a radiation accident may range from one patient to thousands contaminated by a dirty bomb. The number of patients with significant exposure will usually be quite small. The only people exposed to very high activity contamination due to a dirty bomb are usually those involved in its production or delivery, i.e., the terrorists themselves. Triage may differ depending on the number of casualties and total whole body doses. The Strategic National Stockpile Radiation Working Group (SNS) has published guidelines for triage of fewer than or more than 100 casualties.⁹

Accidents involving pregnant women or young children are unique. Internal contamination of the pregnant woman can increase or decrease the relative fetal dose, depending on the element, route of exposure, and age of gestation. Internal contamination with elements excreted in the urine may increase the fetal dose because of the proximity to the bladder. Developing organs in the fetus or young child may have greatly increased uptake of particular elements, especially iodine. The threshold dose for giving potassium iodide is much lower for them (≥ 0.05 Gy expected dose) compared with adults 18 to 40 years old (≥ 0.1 Gy expected dose) and adults older than 40 years (5 Gy).⁴

All radiation accident victims carry some increased lifetime risk of an induced malignancy.⁷ This is usually far less than anticipated and only slightly above the preincident risk because radiation is a relatively weak carcinogen.⁷ Risk is related to quality and dose of radiation, affected organs, age at the time of exposure, and other risk factors.⁷ Education about the usual small increase in risk may diminish stress significantly. General educational materials can initially allay fears, and subsequent consultation with a radiation specialist can better define risks and proper surveillance.

Mortuary procedures and burial of contaminated corpses must be coordinated with an RSO. The NCRP and the Disaster Mortuary Operational Response Team

provide guidelines (see <http://www.dmort.org>) for handling deceased patients with radioactivity significantly above background levels.^{2,7} Most decedents can be decontaminated for conventional burial; however, cremation may be restricted. All corpses must be stored in the hot zone until decontaminated and released by an RSO.⁷

Finally, psychological stress can be intense and long-lasting in victims, relatives, coworkers, first responders, and providers.^{7,16} Counseling and educational handouts can allay many fears. The stigma of radiation exposure and posttraumatic stress disorder may require long-term psychological follow-up.^{5,16} Preparation of general and specific educational handouts in advance can provide quick reassurance. The CDC Web site has several excellent handouts on these topics. Local electronic storage is appropriate, as authoritative Internet sites will likely be overloaded during an incident. Your facility should prepare specific instructions in advance relative to the known industrial and medical radiologic hazards in your region.

PITFALLS

Rapid assessment and limited contamination will only be possible by providers who promptly recognize radiation accidents and appropriately institute a predetermined response plan. Failure to have detection equipment available and accessible can lead to delays in initial interventions. Failure to consider radiation scenarios in disaster exercises can lead to inadequate responses in the event of a true radiologic emergency.

Nuclear Power Plant Meltdown

William Porcaro

DESCRIPTION OF EVENT

Nuclear power plants that provide safe, clean energy to many areas of the globe have the potential to cause massive disasters, both through accidents and terrorist events. About 17% of the world's energy is generated by nuclear fission. Whereas only about 15% of U.S. power is nuclear generated, the French create about 75% of their energy by the nuclear route.¹ Figure 88-1 shows a schematic of a typical nuclear power plant. A catastrophic meltdown would pose many threats, ranging from various flavors of radiation escaping into the atmosphere to more conventional dangers such as steam and fire. Commercial U.S. nuclear reactors have been cited numerous times in the media as potential targets for terrorist attacks.

Risk for radiation leak and exposure may occur at many points. In the most drastic situation, a fire, coolant failure, control rod failure, or sabotage may allow a reactor to overheat and melt itself. As the reactor self-destructs, radioactive solids and gases may be released into the environment. Volatile radioactive isotopes may also be elaborated from the core, including those of iodine and the noble gases. Over 100 radioactive elements were elaborated into the atmosphere during the core fire caused by exploding gases in the number four reactor at Chernobyl. The vast majority of these isotopes decayed quite quickly. The most dangerous and longest-lasting isotopes are of iodine, strontium, and cesium, which possess half-lives of 8 days, 29 years, and 30 years respectively. Internalized strontium may lead to leukemia. Cesium, which traveled the farthest, may be linked with liver and spleen pathology.² Experience from nuclear incidents and nuclear medicine accidents has proved the long-term implications of such a release, most notably the increase in childhood thyroid cancer attributed to radioactive iodine.³

In addition to the health hazards posed by radioactive materials, nuclear power plants harbor many other potential hazards. The steam and high pressures that exist in the reactor coolant systems and heat exchangers in pressurized water reactors may cause severe thermal burns because either simple steam or radioactive steam may be evolved. Over the past 50 years, there have been

several instances of nuclear power plant disasters and near disasters. In 1952, the Chalk River nuclear reactor near Ottawa, Ontario, sustained a partial meltdown of the uranium fuel core after four control rods were accidentally removed. Millions of gallons of radioactive water accumulated inside the reactor, but no injuries occurred. In 1957, fire in a graphite-cooled reactor north of Liverpool, England, spewed radiation over the countryside. In 1976, near Greifswald, East Germany, the radioactive core of a reactor nearly melted down due to the failure of safety systems during a fire. At Three Mile Island, near Harrisburg, Pa, coolant loss allowed overheating and partial meltdown of the uranium core in one of two reactors, and some radioactive water and gases were released.

On April 26, 1986, the worst nuclear accident in history occurred at the Chernobyl power plant in Kiev, U.S.S.R. (now Ukraine). During a shutdown for routine maintenance, a test was performed to see whether enough energy could be maintained to operate emergency equipment and cooling pumps. As workers tried to compensate, they accidentally caused a power surge estimated at 100 times nominal power output. This surge caused part of the fuel rods to rupture and react with water, creating a steam and hydrogen gas explosion and a subsequent graphite fire that destroyed the core. The lack of a containment facility and thermal loft resulted in the release of tremendous amounts of radioactive material into the atmosphere. The failure of officials to acknowledge the incident to the general public resulted in the ingestion of contaminated foodstuffs during the days immediately after the meltdown. The estimated death toll was 31, but the total number of casualties is unknown.

In addition to nuclear power plants, many TRIGA nuclear reactors (a brand name that stands for Training Research Isotopes, General Atomics, the builder) used for research exist primarily in universities throughout the world. They are often located in densely populated urban areas with relatively minimal security. TRIGA reactors are considered "inherently safe." Their safety profile is based on the construction of their fuel rods, which force overheating fuel to limit the fission process and stop the nuclear reaction. Even when all of the control rods are simultaneously removed by

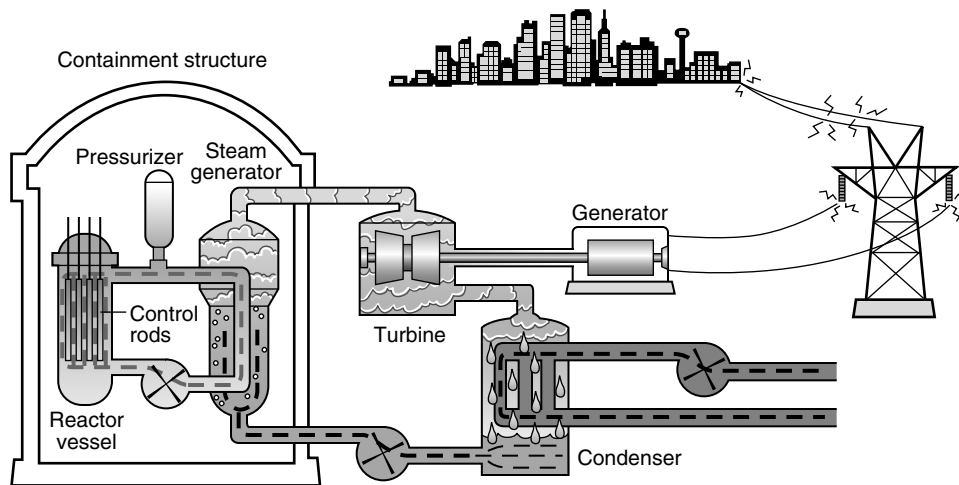

FIGURE 88-1. Anatomy of a pressurized water reactor. (From the U.S. Nuclear Regulatory Commission Web site. Available at: <http://www.nrc.gov/reading-rm/basic-ref/students/reactors.html>.)

accident or deliberate intent, the reactor cannot generate enough heat to cause a problem; it simply shuts down.⁴

← PREINCIDENT ACTIONS:

Hospitals that may receive victims after a nuclear power plant incident should have the capability to detect radioactivity, primarily through the use of Geiger counters. Large institutions should have a Radiologic Emergency Response Team that can be activated when needed. This group may be composed of emergency department providers, security personnel, radiation safety officers, maintenance personnel, and laboratory support. Staff should be fitted with appropriate anti-contamination clothing, including double gloving so that the outer pair can be removed when contaminated. Personnel should also be issued dosimeters to track their exposure. A radiation decontamination area should be prepared with plastic lining and plastic waste containers. Flooring should be covered and cordoned off. Special ventilation to isolate the area is desirable but not necessary because there is very low likelihood that radioactive material will become aerosolized.⁵

Evacuation plans are paramount to preparation for a nuclear power plant meltdown. All Nuclear Regulatory Commission-regulated power plants have community contingency plans as a requirement for licensure. In addition to local and state authorities, the Federal Emergency Management Agency (FEMA) plays a role in orchestrating these strategies. One of the special concerns surrounding nuclear power plant meltdowns involves radioactive iodine and exposure to the thyroid gland. Appropriate plans must be in place for the prophylaxis or treatment of persons who live in close proximity to nuclear power plants to decrease their risk of thyroid cancer if a release occurs, by providing prompt potassium iodide to compete with released radioactive iodine for binding sites in the

thyroid. Preparedness should be practiced through exercises involving power plants and area hospitals.

→ POSTINCIDENT ACTIONS

After a nuclear power plant incident has occurred, containment of radioactive contaminants in and around the facility continues to be a priority. The Chernobyl Exclusion Zone served as an evacuation area and continues to use natural and manmade boundaries to prevent migration of radionuclides and to control the illegal harvesting of contaminated foodstuffs. Evacuation of the at-risk population will lead to the need for sheltering and medical care of large numbers of evacuees and screening for necessary prophylaxis.

Numerous other details must be considered after a meltdown, including radioactive and hazardous waste removal, economic sustainability in the surrounding areas, and food supply/agriculture. Contaminated soil leads to contamination of plants and animals and their products, such as milk and beef.⁶

👤 MEDICAL TREATMENT OF CASUALTIES

Victims from a nuclear power plant meltdown or persons potentially exposed from the surrounding area must be evaluated for possible contamination. However, immediate medical attention must be paid to serious or life-threatening problems. At triage, a brief radiologic survey should be performed to determine exposure. Non-acutely ill victims should have clothing removed and sealed in plastic bags by staff wearing proper protective equipment. Wounds that may be contaminated should be cleansed, after thorough draping to avoid spread of radioactive material. Cleansing of intact skin must be performed in a manner that limits mechanical or chemical irritation to avoid deeper spread of the radioactive material.

Contaminated orifices may require special attention; for example, decontaminating the mouth may require aggressive brushing with toothpaste or gargling with 3% hydrogen peroxide.⁵ Irrigation solutions used to clean open contaminated wounds must be carefully retained and surveyed, so they can be disposed of properly.

Victims who are believed to have suffered radioactive contamination should have several basic laboratory studies. All specimens must be sealed in plastic and sent in properly labeled containers that specify name, date, time of sampling, area of samples, and size of sample areas. Complete blood count with stat differentials must be obtained to follow absolute lymphocyte counts, and this should be repeated approximately every 6 hours for 2 days to monitor for bone marrow suppression in any patient suspected to have suffered whole body irradiation. Urinalysis should also be performed on all victims of radiologic injury to ensure proper renal function, which is necessary to clear possible internal contamination. Externally contaminated patients should have swabs from wounds and all body orifices sent to be monitored for

radioactivity. In cases where internal contamination is suspected (i.e., inhalation, ingestion, or absorption), 4 days of 24-hour urine and feces should be sampled for detection of radionuclides excreted from the body.

Acute radiation syndrome may be seen in victims who were in close proximity to the reactor meltdown such as plant workers, first responder firemen and law enforcement officers, or EMS officials who were unable to use appropriate precautions. Signs and symptoms arise secondary to cellular deficiencies and the reactions of various cells, tissues, and organ systems to ionizing radiation.

In addition to radiologic injuries, traditional emergencies may present during a nuclear power plant incident. Steam is a real and present danger in all power plants. From a nuclear standpoint, radioactive steam may serve as a medium to rapidly spread nuclear fallout and allow it to penetrate the body through burns and inspiration. However, the dangers of injuries inflicted by nonradioactive steam should not be underestimated. Severe thermal skin burns as well as inhalational burns to the distal airway causing stridor and respiratory distress and failure should be anticipated. In August 2004, nonradioactive steam leaked from a nuclear power plant in Mihama, Japan, killing four workers and severely burning seven others.

As discussed in the unique considerations section, patients from areas of radioactive iodine fallout should be treated with potassium iodide within 4 hours of exposure.

CASE PRESENTATION

It's 6 PM on a Friday during a hectic emergency department shift. The medical control radio alarms, and you learn that there has been an incident at a nuclear power plant reactor in a neighboring state. Authorities have learned that an international terrorist group has had operatives in the plant for the past several years. This afternoon, these radicals were able to defeat the control rod safety features and plant cooling system to initiate a core meltdown. Simultaneously, others detonated a huge truck bomb to form a breach in the plant's concrete-containment system. It is now believed that a radioactive plume has escaped from the plant and is traveling toward the city.

The area surrounding the plant is currently being evacuated. Rescue efforts are under way at the plant and numerous victims are being airlifted to your facility. The department triage nurse also tells you that there are a number of people calling and presenting to the hospital concerned that they are contaminated with radiation.

You immediately initiate a disaster code within the hospital and begin looking for your hospital's plans on how to manage a mass radiologic disaster. You take the following initial steps: You notify the hospital's radiation safety officer on call, considering it is after hours and they have likely already left the facility. You meet with the nurses in your emergency department and start to discharge all stable walk-in patients in your waiting room after explaining what has happened, keeping only those patients who truly appear ill. You also ensure that the emergency department is being prepared to receive radiologically exposed and possibly contaminated patients. You check the batteries in the radiation-detection device kept in the emergency department, in case you need it before the radiation safety officer arrives. The remainder of this chapter discusses some of the unique considerations and possible pitfalls that may be associated with the simulated preceding case.

UNIQUE CONSIDERATIONS

Like all nuclear/radiologic events, the factors of time, distance, and shielding are crucial at determining human exposure and ultimately disease and outcome of a nuclear power plant meltdown. Simple actions such as rapid and orderly evacuation from contaminated areas, rapid and effective decontamination, and containment of hazardous waste can greatly reduce risk. As alluded to above, any time there is a leak of radioactive material into the environment, concerns about soil and plant/animal food sources come into play. Therefore, an adequate, noncontaminated food and water supply must be ensured.

The increased risk of thyroid cancer in children must be anticipated. Strong consideration must be given to the treatment of children and infants with potassium iodide when there is risk for inhalation of contaminated air or ingestion of contaminated food. Administered before or within 4 hours after intake of radioactive iodine, potassium iodide can block or reduce the accumulation of radioactive iodine in the thyroid, thereby reducing the risk of cancer.⁷

If a genuine nuclear power plant meltdown has occurred, concerns about public response during and after the incident will almost certainly arise. The public is often quite eager to obtain as much information as possible regarding the incident. When instructions are given, they must be clear and repeated, and the rationale for the warnings and instructions must be provided.⁸

Well-crafted and rehearsed strategies are the key to success during the genuine incident. Failure to appropriately set up decontamination areas and unsuccessful decontamination may lead to dispersing contaminated patients throughout the hospital, further exposing these patients as well as contaminating the staff caring for them. Studies suggest that evacuation time estimates are crucial for proper emergency response planning. Evacuation time estimates must consider many factors, ranging from traffic management to uncontrollable events such as weather, when projecting for an event.⁸ “Shelter in place” should always be considered.

Although treatment or prophylaxis with potassium iodide is relatively safe for children, there are some risks, including gastrointestinal effects or even hypersensitivity reactions. Additionally, thyroidal adverse effects may result from stable iodine administration, especially in iodine-deficient patients or in connection with thyroid disorders, such as autoimmune thyroiditis or Graves’ disease.⁷

chapter 89

Introduction to Chemical Disasters

David Marcozzi

This chapter serves as an overview and a broad outline toward managing victims of chemical releases, both accidental and intentional, including those related to terrorism. Although the specific agents that may be released vary immensely, the clinical approach to response is fairly uniform. When a chemical release occurs, rapid and effective response is dependent on thorough pre-event planning, appropriate medical treatment, and subsequent post-event analysis to allow for refinements in future response operations. These steps help to ensure rapid deployment of resources, accurate identification and treatment of victims, and protection of medical providers, the environment, and the scene for law enforcement.

Chemical exposures may come from environmental, industrial, warfare, or terrorism sources. Historically in the United States, the overwhelming majority of chemical-release incidents have been the result of industrial accidents, the effects of which may be in sharp contrast to those of intentional releases.

In the present world climate, the potential for chemical warfare and terrorism, the intent of which are to produce casualties, continues to change our planning, response, and overall perspective. *Chemical warfare* refers to the utilization of weapons using the toxic properties of certain chemicals to produce debilitating physiologic, psychological, and economic effects on their targets. Chemical terrorism is the use of chemical agents to further political or social objectives by intimidating or coercing any segment of a government or of a civilian population. The exact number of states and stateless groups that possess chemical agents is difficult to assess, but industrial chemicals are widely available throughout the world. This has been pointed out by the U.S. Central Intelligence Agency to Congress and its committees:

Although U.S. intelligence is increasing its emphasis and resources on many of these issues, there is continued and growing risk of surprise. We focus much of our intelligence collection and analysis on some ten states, but even concerning those states, there are important gaps in our knowledge. . . . Moreover, we have identified well over 50 states that are of concern as suppliers, conduits, or potential proliferants.¹

The threat of terrorists using chemical, biological, radiological, and nuclear (CBRN) materials appears to be ris-

ing—particularly since the 11 September attacks. Several of the 30 designated foreign terrorist organizations and other non-state actors worldwide have expressed interest in CBRN.²

A response to any hazardous material (HazMat) release, whether as a result of deployment from these new threats or from an accidental industrial release, must be well coordinated among HazMat teams, hospitals, fire, emergency medical services (EMS), Emergency Management and law enforcement personnel. Paramount to chemical releases is the mandate for quick and efficient deployment of resources to extricate, decontaminate, and treat the largest number of victims ensuring the greatest benefit to the greatest number of casualties. Simultaneously, there are fundamental principles to which any chemical exposure response must adhere to ensure the protection of healthcare workers, the environment, and the potential crime scene.

HISTORICAL PERSPECTIVE

No significant intentional mass-casualty chemical disaster has yet occurred on U.S. soil. The sad reality is that an event of that nature, related to an act of war, terrorism, or a major industrial sabotage, will likely occur in the future with the potential to affect hundreds or thousands of people. The distress caused by the use of such an agent or the accidental release of a toxic chemical would be psychologically traumatic for many more.

The first employment of chemical weapons in modern times was in World War I by the Germans at Ypres, Belgium, on April 15, 1915 (Box 89-1). That afternoon, German units released an estimated 150 tons of chlorine gas against Allied troops. Its use was followed on Dec. 19, 1915, by the use of phosgene, which like chlorine was denser than air but which had a greater predilection than did chlorine to produce death from pulmonary edema (see Chapter 93). Still later in the war, sulfur mustard (a liquid at ambient temperatures) was introduced. As a persistent agent, sulfur mustard remained in the environment for weeks and could act as a barrier to troop movements. Mustard was subsequently used extensively and with decisive results by Italy in Abyssinia (now Ethiopia) in 1935 (see Chapter 92). Nerve agents

are organophosphorus anticholinesterases and are the most potent chemical warfare agents. These agents were first developed in the 1930s by the German scientist Gerhard Schrader in conjunction with his research on insecticides. Nerve agents include the nonpersistent G-series agents and the V agents, which are environmentally persistent (see Chapter 91).

Chemical agents were not extensively used during World War II due to the fear of retaliation and because chemical weapons are of limited use in a mobile front in which their use would slow the advance of one's own troops. In addition, chemical warfare requires supply from railroads, which were available in the fixed fronts of World War I but which were not well suited to supply to the often rapidly mobile fronts of World War II. However, the fear that the German military might use such weapons led to the production of mustard agent bombs by the United States, to be used only if the Axis forces used chemical weapons first. Such weapons were shipped to Europe on a U.S. Liberty ship, the John Harvey, in 1943. Before the unloading of the vessel in Bari Harbor, Italy, it was struck by a direct hit during a Luftwaffe air raid and exploded, killing the entire crew and spreading its toxic mustard agent throughout the port and into the air, affecting hundreds of servicemen and civilians.³ The incident was kept secret for decades. Dozens of shiploads of such toxic chemicals, many of

them captured German weapons, were scuttled in waters off shore in the Norwegian Trench and the Baltic Sea, and many agents were brought back to the United States and scuttled in the Gulf of Mexico. The environmental impact has been poorly studied, but many instances of fishermen injured by such weapons in Europe have been reported.³ In 1974, the United States signed the Geneva Protocol of 1925, which bans the use of poisonous substances in war. At that time, the United States reserved the right to retaliate in kind if an enemy were to use any chemical agent against it; the power to order such retaliation resided with the president. On April 4, 1984, President Ronald Reagan called for an international ban on chemical weapons, and the United States currently has a no-use policy for any official chemical agents (the official U.S. military definition of chemical agents excludes riot-control agents, herbicides, and smoke-and-flame material from consideration as chemical agents; this distinction is not universally accepted internationally) and is in the process of dismantling its chemical-agent stockpiles. The United States has additionally renounced the use of herbicides and riot-control agents in war, except in retaliation.

In June 1994, a team of cultists from Aum Shinri Kyo sprayed vaporized sarin for 10 minutes at residential quarters in Matsumoto, Japan. Three judges staying at the residence were about to rule on a civil case over a

BOX 89-1 A HISTORY OF CHEMICAL WEAPONS

1899

An international peace conference held in The Hague leads to an agreement prohibiting the use of projectiles filled with poison gas.

1915

First large-scale use of chemical agents on the World War I battlefields near Ypres (Ieper), Belgium.

1918

By the end of World War I, the use of over 100,000 tons of toxic chemicals during the war had resulted in the deaths of 90,000 soldiers and had caused more than a million casualties.

1925

The Geneva Protocol is concluded. This treaty bans the use of both bacteriologic and chemical weapons but is not enough to stop countries from producing, stockpiling, or using chemical weapons thereafter.

1972

The countries of the world conclude the Biological and Toxin Weapons Convention in Geneva and commit themselves to continue negotiations on a treaty to ban chemical weapons as well.

1984-1989

Iraq uses chemical weapons against Iran and (in 1988) against its own Kurdish citizens in the town of Halabja.

1992

The negotiators in Geneva agree on the text of the Convention on the Prohibition of Development, Production, Stockpiling, and Use of Chemical Weapons and on Their Destruction (Chemical Weapons Convention).

1993

The Chemical Weapons Convention (CWC) is opened for signature at a January signing ceremony in Paris; 130 countries show support for the CWC and for international disarmament by signing the convention. In February 1993, a Preparatory Commission is set up in The Hague to prepare for the entry into force of the convention.

1995

In Japan, the Aum Shinri Kyo cult releases the chemical agent sarin in a terrorist attack on the Tokyo subway.

1997

The CWC enters into force for 87 original member countries. The organization created by the Convention to carry out the terms of the Convention, the Organisation for the Prohibition of Chemical Weapons (OPCW), opens its headquarters in The Hague.

2003

The CWC has grown into an international regime with 152 member countries (as of May 6, 2003), covering 90% of the world's population, 92% of the world's landmass, and 98% of its chemical industry. The OPCW has overseen the destruction of nearly 10% of the stockpiles of chemical weapons declared to it.

fraudulent land deal involving the cult. In this attack, 7 people were killed and 144 injured, many of them seriously.⁴

On March 20, 1995, in a more well-known incident, members of the Aum Shinri Kyo cult released the G-series nerve agent sarin in the Tokyo subway system during rush hour, killing 11 and injuring more than 5500 people.^{5,6} Secondary contamination occurred in more than 20% of healthcare workers at St. Luke's International Hospital, a facility near the release site. Eighty percent of patients arrived via means not involving their EMS system. This release served as the modern-day landmark event with regard to chemical warfare on civilians. The response to this incident has been extensively reviewed. In addition to the physical effects of the release that required immediate treatment, 60% of victims suffered from posttraumatic stress disorder, persisting in several cases for more than 6 months.

Chemical exposures on U.S. soil are predominantly industrially related accidental releases. HazMat transportation incidents are reported to the U.S. Department of Transportation. For the last 10 years, of the almost 156,500 incidents that occurred, 3218 injuries and 226 deaths were reported.⁷

In another data set, a total of 13,808 emergency events relating to hazardous substances were reported in 1999 and 2000 to the Hazardous Substances Emergency Events Surveillance System (HSEES), which collects information from approximately 15 states.⁸ These data deserve review and can help focus efforts with regard to pre-event planning for HazMat releases. Approximately 70% of the reported events occurred at fixed facilities, with 96% of all events involving only one substance. The nature of the agent was balanced, with a spill occurring in 54.0% of the releases, followed by 41.7% for air releases, 6.8% for fires, and 1.2% for explosions. Ammonia, sulfur dioxide, and sulfuric acid were the most frequently released substances. Fortunately, only 9.1% of all events resulted in victims. Of the events that did involve victims, 73.2% involved only one or two casualties. It should be noted that the HSEES reports do not cover hazardous materials events occurring due to petroleum products. Interpretation of the data from the HSEES and the Department of Transportation, whose morbidity and mortality are low, demonstrates a marked contrast to the potential results of a terrorism or warfare chemical release, where the intent is aimed at producing casualties—both physical and psychological.

CURRENT PRACTICE

Any chemical release has the potential to produce mass casualties. The safe and effective management of the scene, patients, and environment depends on prioritizing scene safety and staff protection for emergency responders and hospital personnel.

Pre-event planning and training are critical to maximize resources and to ensure that those most in need receive aid while preventing rescue and hospital workers from becoming patients themselves. Unfortunately, HazMat preparedness has largely been reactive instead of

preemptive. Although no community can prepare for every chemical emergency, the potential for mass casualties and secondary contamination can be mitigated with the help of a Hazard Vulnerability Analysis. Before an event, many issues need to be addressed (Box 89-2), all of which are important for a sufficient response to chemical disasters. These topics are addressed in this text and should be referred to accordingly. In attending to these various issues, a local emergency planning committee, hospital, private organization, or government agency should systematically address each concern in the local area and cover additional ones specific to its scope of practice, environment, level of risk, and capabilities.

Depending on the chemical or chemicals released, the mode of dissemination, the properties of each agent, various physical effects, and various degrees of symptoms and signs will result. Many key terms, acronyms, and principles relating to chemical properties are important to understand (Box 89-3).

Unlike bioterrorist incidents, an event of this nature is unlikely to be covert. Due to the presence of a foreign chemical in the environment, effects will likely be seen immediately—within minutes or hours. Within 90 minutes of an event, 50% to 80% of the acute casualties will likely arrive at the closest medical facilities (Figure 89-1).⁹

Depending on the type of chemical release, different interventions, antidotes, and treatments will be needed for the casualties. Decontamination of victims remains a primary medical response. The maneuvers of removal of clothing or the application of soap and water (or simply copious amounts of water) limit further absorption of a toxicant by the victim and serve to protect medical providers from secondary contamination. Decontamination by means of chemical compounds such as alkaline bleach solutions may cause more tissue damage, leading to further penetration of agent, and physical or mechanical decontamination should be preferred over decontamination using chemicals. Immediate medical care may need to be provided before full-body decontamination, but removal of all agent visible on body surfaces should never be delayed. Immediate local, or spot, decontamination of skin and wounds can make the difference between life and death, since many chemicals are absorbed quickly and since chemicals already in transit through the skin are no longer amenable to surface contamination. Spot decontamination should always

BOX 89-2 PRE-EVENT CONSIDERATIONS

- Hazard vulnerability analysis
- Personal protective equipment
- Decontamination capabilities
- HazMat training
- Public education
- Press cooperation
- Patient-surge capacity
- Additional mobilizable resources and personnel
- Coordinated response between all agencies
- Communications plan
- Evacuation and shelter-in-place plans

BOX 89-3 HAZMAT DEFINITIONS

- **Flash point:** The temperature at which a liquid will give off enough flammable vapor to burn. Because there are several flash-point test methods, and because flash points may vary for the same material depending on the method used, the test method must be indicated when the flash point is given.
- **Immediately dangerous to life and health (IDLH):** Any condition that may result in damage to health that cannot be repaired. IDLH situations include explosive and oxygen-deficient environments and the presence of class A poisons or substances that can be absorbed through the skin.
- **Lower explosive limit (LEL):** The lowest concentration (i.e., lowest percentage of the substance in air) that will produce a flash of fire when an ignition source (e.g., heat, arc, flame) is present.
- **Manifest form:** The form required by the EPA to track hazardous wastes.
- **Material safety data sheet (MSDS):** An informational sheet that is sent with hazardous materials. It lists chemical properties, emergency response procedures, reactivity data, control measures, safe handling procedures, and the manufacturer.
- **Permissible exposure limit (PEL):** The highest level of a substance to which a person can be exposed. This limit is set by the Occupational Safety and Health Administration (OSHA).
- **Short-term exposure limit (STEL):** An exposure limit that sets the maximum concentration that a worker can be exposed to during a 15-minute period.
- **Threshold limit value (TLV):** The airborne concentration of a material to which nearly all persons can be exposed day after day without adverse effects. The American Conference of Industrial Hygienists expresses TLVs in three ways:
 - **TLV-TWA:** The allowable time-weighted average concentration for a normal 8-hour workday.
 - **TLV-STEL:** The short-term exposure limit, or maximum concentration for a continuous 15-minute exposure period (maximum of four such periods a day, with at least 60 minutes between exposure periods and provided that the daily TLV-TWA is not exceeded).
 - **TLV-C:** The ceiling exposure limit or “the concentration that should not be exceeded during any part of the working exposure ... a 15-minute period except for those substances which may cause immediate irritation ...”
- **Time-weighted average (TWA):** A measurement to determine the average exposure of a worker to a substance over a typical 8-hour work shift. The actual exposure is then compared to OSHA standards or other professional guidelines.
- **Upper explosive limit (UEL) or upper flammable limit (UFL)** (pertaining to a vapor or gas): The highest concentration (i.e., highest percentage of the substance in air) that will produce a flash of fire when an ignition source (e.g., heat, arc, or flame) is present. At higher concentrations, the mixture is too “rich” to burn. See also lower explosive limit.
- **Vapor density:** The weight of a vapor or gas compared with the weight of an equal volume of air; an expression of the density of the vapor or gas. Materials lighter than air have vapor densities less than 1.0. Materials heavier than air have vapor densities greater than 1.0.
- **Vapor pressure:** The pressure (usually, a partial pressure acting as one component of the total pressure of the atmosphere) exerted by the vapor arising from a solid or liquid.
- **Volatility:** The tendency of a substance to evaporate (this property is directly correlated with speed of evaporation).

receive the same high priority as airway, breathing, circulation, and specific antidotal therapy and should therefore be included as one of the “ABCDDs” (airway, breathing, circulation, decontamination [spot], and drugs [specific antidotes]) of the immediate medical response

FIGURE 89-1. Predicted emergency department casualties.

to a chemical casualty (J.M. Madsen, personal communication, November 1, 2004). Casualties who are triaged as low priority may be escorted to a waiting area after decontamination to allow for appropriate treatment of those requiring emergent attention. Continued reevaluation of the victims is of the utmost importance because effects and routes of exposure may differ from patient to patient, thus affecting the time of onset of symptoms and signs. Initial recognition and a careful step-by-step approach to victims exposed to a chemical agent are paramount; this approach should use a logical progression from agent through agent in the environment to agent on and in the host and then follow through with an appreciation of toxicologic principles such as toxicokinetics (i.e., absorption, distribution, biotransformation, and elimination), toxicodynamics (i.e., mechanism of action), the continuum of exposure (from external dose through internal dose and biologic effective dose to early biologic effects, altered structure and function, and clinical intoxication), and clinical pearls such as the inverse relationship between the dose of most agents and their latent (clinically asymptomatic) periods.

This toxicologic approach is often not stressed in the education and training of healthcare providers but provides a vital framework for the clinical evaluation of

casualties exposed to chemicals. It can be summarized by means of one or more acronyms suitable for posting in ambulances and emergency departments and for memorization (see Table 89-1) and Table 89-2 [J.M. Madsen, personal communication, November 1, 2004]). Knowledge of specific symptoms and signs of each agent is of great importance, as this will determine further efforts and treatment. Accurate triage systems incorporating immediate, delayed, minimal, and expectant categories are required to allow the medical resources to effectively reach those in greatest need. Depending on their level of training, specialized teams may be inserted into the warm and hot zones to provide triage and medical stabilization before decontamination. After full-body decontamination, secondary triage may occur and subsequent medical management may be instituted.

As stated, based on patient presentations, specific treatments and antidotes may be instituted for each agent once confirmation or suspected agent recognition occurs. It is unlikely that toxicant identification will occur prior to casualties presenting to a healthcare provider or institution. Therefore, the ability of prehospital and hospital providers to recognize toxidromes associated with chemical agents is essential. This initial recognition can be lifesaving for the patients, their providers, and even for patients in an institution not involved in the event.

The U.S. Centers for Disease Control and Prevention divide chemical agents into 13 categories (Box 89-4). These categories are based either on chemical properties of the agent or on specific physiologic or psychological effects the agents induce in victims. Toxicologic effects will vary depending on the agent, means of dissemination, amount and concentration of the agent, length of time of exposure, environmental conditions, and the location or locations of release.

TABLE 89-1 ASBESTOS: ACRONYM FOR THE SYSTEMATIC APPROACH TO THE EVALUATION OF CHEMICAL CASUALTIES

Agent(s) State(s)	Type(s) and estimated dose Solid? Liquid? Gas? Vapor? Aerosol? Combinations?
Body site(s)	Where exposed/route(s) of entry? <i>[exposure/absorption]</i>

Time course	Onset? Latent period? Getting better/worse? Prognosis?
Other diagnoses	Instead of? <i>[differential diagnoses]</i> In addition to?
Synergism	Combined effects of multiple exposures or insults?

(From Madsen JM. Toxins as weapons of mass destruction: a comparison and contrast with biological-warfare and chemical-warfare agents. *Clin Lab Med.* 2001;21(3):593-605.)

After triage and treatment of casualties, issues must be addressed relating to environmental contamination, law enforcement, and critical-incident stress debriefing. The release of a toxic agent into the environment and subsequent rapid decontamination of victims may well result in the substance permeating the nearby infrastructure, soil, water table, or sewer systems. The U.S. Environmental Protection Agency (EPA), specialized private and federal teams, HazMat environmental response teams, and local and state public works must be involved in the clean-up of such an event. In a terrorism event, the location is also a crime scene. Although preservation of life is the primary concern, it should be understood by all parties that any and all debris, patients, and clothing are

TABLE 89-2 ALTERNATIVE ACRONYMS TO ASBESTOS FOR THE SYSTEMATIC APPROACH TO THE EVALUATION OF CHEMICAL CASUALTIES

TOXICANT

Toxicant/toxidrome	Agent: does it fit with a specific toxidrome?
Outside the body	Solid? Liquid? Gas? Vapor? Aerosol? Combinations?
Xing into the body	Where did agent cross into the body? <i>[exposure/absorption]</i>
Inside the body	Where did agent go inside the body? <i>[distribution]</i>
Chronology	<i>Past:</i> Duration of exposure? Onset? Latent period? <i>Present:</i> Getting better or worse? <i>Future:</i> Prognosis?
Additional diagnoses	Possible coexisting diagnoses?
Net effect of diagnoses	Interaction among all diagnoses; patient as a whole
Triage	Priority for treatment, decontamination, evacuation

POISON

Poison(s)	Type(s) and estimated dose
Outside the body	Solid? Liquid? Gas? Vapor? Aerosol? Combinations?
Into/inside the body	Where did it get into the body? <i>[exposure, absorption]</i> Where did it go inside the body? <i>[distribution]</i>
Sequence of events	Time course <i>[past, present, future]</i> Onset? Latent period? Getting better or worse? Prognosis?
Other diagnoses	Instead of? <i>[differential diagnoses]</i> In addition to?
Net effect of diagnoses	Interaction among all diagnoses; patient as a whole

BOX 89-4 CATEGORIES OF CHEMICAL AGENTS

- Biotoxins
- Blister agents/vesicants
- Blood agents
- Caustics (acids)
- Choking/lung/pulmonary agents
- Incapacitating agents
- Long-acting anticoagulants
- Metals
- Nerve agents
- Organic solvents
- Riot control agents/tear gas
- Toxic alcohols
- Emetic agents

(From U.S. Centers for Disease Control and Prevention. CDC Emergency Preparedness and Response Web site. Available at: <http://www.bt.cdc.gov/agent/agentlistchem-category.asp>.)

potential evidence and should be treated as carefully as possible to preserve maximum authenticity and validity. Finally, after the event, it is important to plan for involved parties to undergo stress debriefing. After an event of such magnitude, psychologists, psychiatrists, social work-

ers, and licensed professional counselors should be consulted to provide support to all involved personnel.

Whatever the type of chemical release—intentional or accidental—effective pre-event planning and preparation are paramount to ensuring that an optimal response will be delivered to the injured persons, that preservation of the crime scene will be maintained, and that protection of the environment will be considered.

PITFALLS

Chemical disasters pose unique issues to patients, health-care providers, and the environment. The involvement of a chemical toxicant adds another element to an already complicated paradigm. Mass-casualty incidents involving biologic or radiologic agents often lead to delayed effects in casualties; moreover, biologic and radiologic agents in contact with the skin usually do not pose a high risk of percutaneous absorption. In contrast, many chemical agents (especially, although not exclusively, as liquids) can begin penetrating the skin within seconds of contact and can relatively quickly build up to a lethal internal dose.

CASE PRESENTATION

At noon on any given Sunday, your professional football team takes the field. The crowds are out in force to support their favorite team. The security checks have not hampered the enthusiasm of the crowd, and as the game kicks off anticipation for a win is high. Near the end of the first half of the game, large explosions occur outside the stadium, outside the inner security perimeter. They are audible to all inside the stadium and are seemingly very close. In panic, the crowds begin to move away from the explosions. Their fairly orderly evacuation is met with terror as a previously staged secondary device explodes. With its detonation, a strong odor, which some compare to that of geraniums, becomes apparent. As the plume spreads, fans near the detonation who were not immediately killed begin to complain of chest pain and to cough severely. In addition to their respiratory complaints, the victims begin to complain of burning of their skin and intense eye pain.

The number of dead and of severely and partially injured patients totals, at best initial estimates, close to 1000. The scene at the stadium is described as chaotic, with evacuation degenerating into a mass exodus and with many trampled. Crowd control, decontamination, security, and triage are difficult to establish in the initial minutes; news crews, EMS personnel, police, and firemen continue to rush to the scene. As the news breaks minutes later, you realize your hospital is closest to the stadium, and you are the only physician on duty in the emergency department. You immediately do the following:

- Activate your facility's Multicasualty Incident (MCI) Emergency Preparedness Plan and notify your hospital administrator and Incident Command Center (ICC)[DM11] director.
- Notify personnel in your emergency department to start alerting people in the waiting room that if they have

minor medical problems, to leave and see their own physician, but if they are there for severe chest pain, shortness of breath, high fevers, or abdominal pain, they should stay and wait to be seen.

- Make contact with the trauma service and make sure they know of the impending surge of hospital patients.
- Notify your emergency department backup personnel to come in, as they will likely be needed.
- Activate your hospital HazMat response plan, and have your decontamination tent(s) brought out, erected, and prepared to receive contaminated patients responding on their own who did not wait for Fire/EMS to activate decontamination at the site.
- Make contact with your Hospital Incident Commander under Hospital Emergency Incident Command System (HEICS) to make sure the HEICS management system has been activated and is up and running.
- Prepare to receive patients for triage either to decontamination site or to the usual areas of your hospital uses during an MCI. Review triage procedures with the other members of the triage team from your emergency department.
- Consider a phone call to the local or regional Poison Control Center, advise them of what you have heard about the events at the stadium, and review what their recommendations are for the suspected agent(s).
- Meet with on-call security and make sure they understand the nature of the events and their need to have at least one or two members suit up in personal protective equipment to manage the potential of unruly contaminated patients.

The first patients begin to arrive.

Depending on the chemicals and their forms in the environment, clinical effects may be of short onset or may be delayed even though tissue damage may begin within seconds or minutes of exposure. Thus, lifesaving interventions for victims of biologic and radiologic agents are often those administered at the hospital level, whereas the lives of chemical casualties, even those who may not yet have developed clinical signs or symptoms, may be saved or lost well before transport to a hospital and in many cases even before the arrival of emergency medical responders. This critical difference between chemical agents in general and biologic or radiologic agents has crucial implications for preparation (including education and training) and response.

Because immediate intervention may be lifesaving, the general public should be educated about the importance of prompt removal (by physical or mechanical means such as adsorption followed by brushing, plucking, picking, or flushing with field-expedient materials) of the agent and about the importance of basic life-support measures (i.e., the ABCDDs). For example, it is possible that many victims of the October 2002 storming of the Moscow theater occupied by Chechnyan terrorists might have survived exposure to an opioid or anesthetic agent (see Chapters 97 and 100) had attention been given at the scene to basic airway management.

Emergency medical responders need to emphasize these urgently required interventions, and both emergency responders and hospital personnel need to see the overall picture by means of the use of an easily posted or memorized mnemonic device such as ASBESTOS, TOXICANT, or POISON (see Tables 89-4 and 89-5). Those involved in hospital stockpiling of antidotes need to realize that although administration of vaccines or antibiotics after biologic agent exposure may in many cases be delayed until patients arrive at a hospital, chemical agent antidotes need to be prepositioned for immediate use by emergency responders, who will not have time to wait for antidotes shipped from national stockpiles.

As stressed repeatedly throughout this chapter, chemical disasters, in contrast to other disasters, require advance planning for prompt local (spot) decontamination, for subsequent thorough (full-body) decontamination, for the capability to set up and perform mass decontamination in an efficient manner, and for a quick, logical, and systematic toxicologic review of the situation and the patient. A coordinated, preplanned strategy for immediate deployment of resources to accomplish these goals is mandatory. This approach may at times conflict with the prehospital tenet of “scene safety,” since it is certainly possible that victims will present to healthcare providers and to police and fire personnel prior to agent decontamination and identification. A remedy to this dilemma is additional advanced training—including the maintenance of a high index of suspicion for potential chemical exposures—for all public service and hospital personnel with regard to HazMat incidents. The current level of mass casualty weapon preparedness in the United States may not be acceptable for realistic, immediate hot and warm zone operations.

The philosophy of preparing “specialized teams” to respond may simply not be practical in chemical-release incidents, since the event and patients will not wait for deployment of these groups. Instead, casualties will walk, drive, or be driven to a healthcare facility, diverting the hazard from the prehospital providers to the hospital and increasing the potential for contamination at the hospital. The likelihood in a chemical scenario is that the responding teams will be treating those casualties who are the most critical (including immediate casualties) or who are expectant. Therefore, increased training and equipment (including ventilatory support and specific antidotes) is mandatory for emergency response personnel.

One problem with chemical response is that it occurs infrequently and disrupts the routine of daily patient care involving trauma and medical illness. A high index of suspicion, early recognition, the ability to assess the situation toxicologically and systematically, and agent-specific treatment are all essential and can make the difference between life and death for a casualty. This is perhaps our greatest vulnerability. Our comfort with everyday cases far surpasses our ability to care for, recognize, and treat victims from chemical exposures. This is a natural behavioral phenomenon but one that can no longer be tolerated. Additional education and training is necessary so that competence and confidence with HazMat agents increases (see Box 89-4).

Another concern is the ability to handle the surge of patients presenting to the medical system. Prehospital and fixed-facility plans should be implemented and regularly drilled so that a large influx of patients can be accommodated and cared for. These plans should include consideration of alternative care sites, appropriate diversion of patients to nonlocal hospitals that are already absorbing the majority of patients, and the ability to “treat and street” the worried well.

Any disaster scenario is fraught with difficulties. In almost all cases, communication will be one area of complication. Some of the issues that need to be addressed include the following: number and type of radios, frequency coordination, redundancy of equipment, backup power, the ability of a communication system to adapt to the additional resources entering the theater of operations, and the availability of specialized devices so that teams within the hot zone are able to communicate.

The approach to chemical exposures and disasters must be proactive rather than reactive. Comfort and confidence with everyday practices must include preparedness for all hazards. The great potential for healthcare workers to be injured and the necessity of rapid patient identification and treatment need to be recognized. Victims of chemical disasters depend on the ability of emergency responders and hospital personnel to think of the possibility of chemical exposure, to recognize and manage toxidromes and injuries, and to assess the overall scenario just as competently and confidently as they would manage cases of acute pharyngitis, for example. This degree of preparedness, competence, and confidence must remain the goal of planning, training, education, and response to the accidental or intentional release of chemicals in a mass-casualty setting.

Industrial Chemical Disasters*

Mark E. Keim

DESCRIPTION OF EVENT

Definition

An *industrial chemical disaster* is defined as the release or spill of a toxic chemical that results in an abrupt and serious disruption of the functioning of a society, causing widespread human, material, or environmental losses that exceed the ability of the affected society to cope using only its own resources.

The chemical release itself may be acute or chronic in duration. It can be overt or insidious in its onset. Although less dramatic than a major explosion, environmental contamination from the toxic residue of industrialization has resulted in health and environmental problems of immense proportions.¹

Industrial chemical disasters may occur as the result of fire, explosion,² and chemical releases or spills.³ Between 1993 and 2001, most major chemical releases or spills in the United States involved a single substance at fixed facilities.^{4,5} The substance was most frequently a volatile hydrocarbon compound followed by ammonia, sulfur dioxide, carbon monoxide, and nitric oxide, in that order.⁴ Employees were the most commonly reported victims.⁴ Toxic chemicals are more strongly associated with worker injury, whereas flammables are more strongly associated with property damage.⁶

Scope of the Problem

Incidents involving either slow or explosive release of chemicals are common and on the increase.⁷ Between 1988 and 1992, more than 34,000 chemical release events were reported in the United States alone.⁸ During 2001, a total of 8978 events were reported.⁴ A 1989 study showed that, on average, 1.6 hazardous substance emergency events occur per day in the United States, resulting in death, injury, or evacuation.⁹

*The material in this chapter solely reflects the views of the author. It does not necessarily reflect the policies or recommendations of the Centers for Disease Control and Prevention or the U.S. Department of Health and Human Services.

Chemical Release Events in Developing Countries

In many rapidly industrializing countries, less elaborate measures for the protection of the environment, human health, and safety have been an important item in economic negotiations, and these have often led to unfair international division of risks.^{1,10-12} This “comparative powerlessness of certain societies to control risk” has been described as sociopolitical amplification of risk.¹⁰

Between 1945 and 1991, India, Brazil, Mexico, and China led the world in the number of chemical releases resulting in greater than five fatalities.¹² The largest industrial chemical disaster in world history occurred in Bhopal, India, in 1984. The Bhopal disaster killed over 2500 persons and affected an additional 200,000 to 300,000.¹³

Poverty and Vulnerability to Chemical Disasters

In general, poverty is the single most important risk factor for vulnerability to disasters.¹⁴ In one study of over 15,000 industrial facilities located in some 2333 counties in the United States between 1994 and 2000, larger and more chemically intensive facilities tended to be located in counties with larger African American populations, and higher-risk facilities were more likely to be found in counties with sizable poor and/or minority populations that disproportionately bear the collateral environmental, property, and health risks.¹⁵

PREINCIDENT ACTIONS

Risk Management Strategies

Recently, the overall approach to emergencies and disasters has shifted from ad hoc postdisaster activities to a more systematic and comprehensive process of risk management that also emphasizes the importance of predisaster activities including prevention, mitigation, and preparedness.¹⁴ *Risk management* is the process of selecting and implementing prevention and control measures to achieve an acceptable level of that risk at an acceptable cost. In general, risk management is composed of four main elements: risk assessment,

countermeasure determination, cost-benefit analysis, and risk communication.

Emergency Preparedness

Elements of emergency preparedness typically include emergency planning, training and education, warning systems, specialized communication systems, surveillance activities, information databases and resource management systems, resource stocks, emergency exercises, population protection measures, and incident management systems.

Emergency Planning

During an emergency, time constraints place a premium on available plans, data, and record-keeping systems. Planning and preparedness are essential and carefully crafted procedures, and checklists can help; at the same time, prior training in how to respond during emergency situations will aid in handling the difficult circumstances involved.¹⁶ Disaster plans should also be developed for all special facilities, such as schools, hospitals, and nurs-

ing homes, which may be at risk for industrial chemical disasters.¹⁶⁻¹⁸

Information Databases and Resource Management Systems

There are several widely available software and Internet-based tools that have been widely used to rapidly access information regarding hazardous materials. Examples of these software programs include the following:

- TOMES Plus (CD-ROM database), Micromedex, Inc.
- Chemical Hazards Response Information System, U.S. Coast Guard
- TOXNET, National Library of Medicine, Special Information Services

A list of related information available on the Internet can also be found on the U.S. Centers for Disease Control and Prevention (CDC) Web site at <http://www.cdc.gov/exposurereport>.

Table 90-1 includes a list of other resources that planners and responders can use in the event of industrial chemical disasters.

TABLE 90-1 RESOURCES FOR INFORMATION RELATED TO INDUSTRIAL CHEMICAL RELEASES

INFORMATION RESOURCE	APPLICATION
Major Hazard Incident Data Service (MHIDAS)	A database of incidents involving hazardous materials that had an off-site impact or had the potential to have an off-site impact. MHIDAS features searchable codified and textual information on more than 11,000 incidents involving the transportation, storage, and processing of hazardous materials over the past 20 years.
Environmental Protection Agency (EPA) Toxic Release Inventory (TRI)	A publicly available EPA database that contains information on toxic chemical releases and other waste management activities reported annually by certain covered industry groups as well as federal facilities.
Chemical Transportation Emergency Center (CHEMTREC)	Provides its preregistered customers with a 24-hour emergency telephone number for shipments of hazardous materials or dangerous goods assistance in identifying the hazardous substance and precautionary measures. There is an annual fee for this service.
National Library of Medicine	Offers many electronic databases such as MEDLINE and TOXLINE, which provide literature references, and CHEMLINE and TOXLIT, which provide information from books and journals and information on other hazardous-materials databases.
National Institute of Occupational Safety and Health (NIOSH) Pocket Guide to Chemical Hazards 2000 Emergency Response Guidebook (ERG2000)	Offers key information and data on 198 chemicals or substance groupings that are commonly found in the workplace Developed jointly by Transport Canada, the U.S. Department of Transportation, and the Secretariat of Transport and Communications for use by first responders at the scene of a transportation incident involving dangerous goods. It is primarily meant to guide first responders in quickly identifying specific hazards and in protecting themselves and the general public.
National Response Center (NRC)	Provides 24-hour assistance and hazardous-materials information to people responding to major industrial accidents.
Agency for Toxic Substances and Disease Registry (ATSDR)	Provides 24-hour assistance to emergency responders who require assistance in managing hazardous-materials emergencies. Such assistance includes information on treatment protocols, laboratory support, and emergency consultation related to assessment and decontamination.
Hazardous Substances Emergency Events Surveillance (HSEES)	Established by ATSDR to collect and analyze information about releases of hazardous substances that need to be cleaned up or neutralized according to federal, state, or local law, as well as threatened releases that result in a public health action such as an evacuation.
National Pesticide Telecommunications Network (NPTN) CDC	Provides information for dealing with pesticide exposures to medical personnel and emergency responders. The Second National Report on Human Exposure to Environmental Chemicals provides an ongoing assessment of the exposure of the U.S. population to environmental chemicals using biomonitoring.
Toxic Exposure Surveillance System (TESS)	A comprehensive poisoning surveillance database compiled by the American Association of Poison Control Centers (AAPCC). The cumulative AAPCC database now contains 33.8 million human poison exposure cases. These data are used to identify hazards early, to focus prevention education, to guide clinical research, and to direct training.

Specialized Communication Systems

Coordination of activities of an on-site facility with those located off-site is essential in an emergency.¹⁹ National, regional, and local public health departments must be linked in a network of real-time communication with the medical response community, public safety, regional poison control centers, and regional laboratory capacities for integration of information management, passive and active surveillance systems, and epidemiologic investigation.²⁰⁻²³

Resource Stocks

A lack of hospital preparedness for chemical casualty care has been well documented in regions throughout the United States.²⁴⁻²⁹ In 1999, Congress charged the Department of Health and Human Services (HHS) and the CDC with establishing the National Pharmaceutical Stockpile (NPS). In March 2003, the NPS became the Strategic National Stockpile (SNS), managed jointly by the Department of Homeland Security (DHS) and HHS. The SNS is a national repository of antibiotics, chemical antidotes, antitoxins, life-support medications, intravenous-administration supplies, airway maintenance supplies, and medical/surgical items. The SNS supplements and resupplies state and local public health agencies within 12 hours of federal deployment. Local communities should therefore be prepared to operate on their own during the critical first 12 hours of a chemical disaster without assistance from the SNS. In addition, local communities should be prepared to receive, protect, and store the SNS, and develop distribution plans for ensuring its use in a timely fashion.

Training and Education

Caregivers should be familiar with basic principles of toxicology, trauma, burn care, mass-casualty management, occupational safety and health, and hazardous materials decontamination as well as incident management systems. Public health officials should also be aware of population protection measures, information resources, environmental health, environmental law, public warning systems, and risk communication.

Warning Systems

To mount a safe and timely evacuation in the event of an industrial chemical disaster, there must first be an effective system in place for warning the population at risk.^{1,16,17,22} The system must use redundant methods of communication, including direct contact. It must also address the needs of special populations such as persons with disabilities and extremes of age as well as those with language differences. Recent advances in the telecommunications arena allow for reverse 911 systems to be used as a new method of communicating hazards to local residents.

Exercises

Exercises are a common way of monitoring and evaluating parts of emergency preparedness programs. The purpose

of an exercise, and the aspect of emergency preparedness to be tested, must be carefully decided and fairly specific. Adequate predrill instruction and training are vital for success. Special attention should be given to the training of personnel to wear personal protective equipment at the decontamination and initial triage sites.¹⁸

POSTINCIDENT ACTIONS

Detection and Management of the Consequences of Industrial Chemical Disasters

The primary functions that must be performed at any toxic release remain fairly consistent. Box 90-1 contains a listing of these actions^{16,19,30}:

Assessment and Surveillance for Industrial Chemical Disasters

The primary role of rapid assessment after an industrial chemical disaster is to gain timely and accurate information suitable for directing efficacious action to minimize health impacts. Activities of a rapid assessment should focus on information objectives that can be undertaken consecutively and/or concurrently. Box 90-2 lists examples of such objectives.^{1,16,31}

Triage for Chemical Exposures

The clinical condition of exposure victims may be triaged according to four main categories as follows:

BOX 90-1 PRIMARY FUNCTIONS THAT MUST BE PERFORMED AT ANY TOXIC RELEASE

- Rapid assessment
- Scene control and establishment of a perimeter
- Product identification and information gathering
- Pre-entry examination and characterization of site
- Selection and donning of appropriate personal protective clothing and equipment
- Establishment of a decontamination area
- Entry planning and preparation of equipment and supplies
- Victim rescue from release area
- Containment of spill
- Neutralization of spill/release
- Decontamination of victims and responders
- Triage of injured
- Consultation with toxicologist/emergency department/Poison Control Center
- Medical care, including antidotes
- Transport of patients
- Post-entry evaluation of rescuers and equipment
- Delegation of final clean-up to responsible party
- Record-keeping and after-action reporting

BOX 90-2 INFORMATION OBJECTIVES FOR RAPID ASSESSMENT AFTER CHEMICAL DISASTERS

- Determine the types, size, and distribution of the release
- Identify the specific type(s) of chemicals and their by-products
- Characterize the hazardous release site
- Identify human exposure pathways
- Define the populations at risk
- Conduct a toxicologic evaluation and assessment
- Describe morbidity and mortality
- Identify appropriate treatment regimens
- Evaluate emergency medical care and health service capabilities
- Ensure provision of appropriate medical care
- Identify and evaluate environmental control strategies
- Evaluate evacuation and mass care strategies
- Develop criteria for defining comprehensive databases

(1) nonambulatory injured; (2) ambulatory injured; (3) ambulatory noninjured; and (4) dead or expectant.

Historically, nonambulatory injured victims of chemical exposures have made up a small percentage of event survivors. Although some of these victims may be transported to the hospital via bystanders, most will be treated and transported by first responders. These casualties should be decontaminated and transported immediately.

Ambulatory injured and ambulatory noninjured victims comprise the largest group (80% to 90% in most series).³² They will self-evacuate from the area of release and thus mitigate their exposure. Many will be transported to the closest hospital without decontamination via bystanders. Ambulatory injured casualties should be decontaminated immediately and then transported to the hospital. If these patients present to the hospital outside of the emergency medical system, they should be decontaminated immediately upon arrival to the hospital. Ambulatory noninjured victims should be triaged to a secondary location by non-ambulance transportation for registry, interview, and a secondary medical assessment by emergency medical personnel.

Decontamination

Decontamination is a process of removing or reducing the concentration of harmful substances. It should be performed whenever there is a likelihood of contamination or risk of secondary exposure.¹⁹ The most important factor in effective decontamination is the speed of removal of the agent.³³ Copious skin lavage with water or gentle cleansing with soap and water has proved to be beneficial for both liquid and solid substances. It may be difficult to determine whether a victim has been exposed to a chemical; responders and hospital personnel should assume that these victims are contaminated, since it takes too long to prove otherwise.

Population Protection Measures

Proper evacuation can save lives and decrease disruption of social networks.^{5,17} However, since mass evacuation may result in disrupted health or other critical services, it may by itself cause a disaster and therefore should not be entered into lightly in the absence of accurate predictive models for population exposure. Many modeling tools are available to assist in creating a database of industrial chemicals present at a local industrial site, rapidly estimating plume-dispersion patterns, and predicting the consequences of a technologic or natural hazard using real-time weather models. Examples of these tools include Computer-Aided Management of Emergency Operations (CAMEO)³⁴ and The Consequence Assessment Tools Set (CATS).³⁵ Once modeling has been completed for potential areas at risk, the decision can be made regarding the need for evacuation or shelter-in-place contingencies.¹⁷

Population protection measures may include population evacuation, sheltering in place, and individual protection measures. Sheltering in place may be necessary when sufficient time for evacuation is not available. Generally, providing individual protection measures in the way of protective gear is impractical and potentially dangerous to the general population.³⁶

The effectiveness of shelter-in-place strategies is time dependent and is not always applicable. Shelter-in-place strategies are employed when it is safer for a population to remain indoors as opposed to an outdoor evacuation. Indoor shelters may initially provide protection from atmospheric releases as compared to the outdoor environment during the early timing after a chemical release. However, 30 to 60 minutes after the plume dispersion has ceased, chemical levels indoors may actually then exceed outdoor concentrations. Recommendations for population protection measures should therefore be based on an accurate exposure modeling system and should not remain static over time. Box 90-3 is a list of recommendations for implementing effective population evacuations.^{3,5}

Risk Communication

The public will have obvious concerns about their exposure to fire, smoke, and hazardous materials.³⁷ Public health and medical personnel should anticipate this need for information and develop public advisories and risk communication strategies for early implementation during such an event. A well-executed risk communication response effort will increase an organization's credibility.³⁸

MEDICAL TREATMENT OF CASUALTIES

In spite of the enormous challenge presented in the identification of chemical hazards, there are certain generalizations that can be made to simplify disaster medical response. Toxic chemicals can be categorized by their known health effects. For ease of case and incident

BOX 90-3 RECOMMENDATIONS FOR IMPLEMENTING EFFECTIVE EVACUATIONS

- Make populations aware of existing emergency operations plans well in advance of any potential industrial disaster.
- Ensure that evacuation warning messages include the following:
 - * Emphasis that the authorities will prevent looting
 - * Emphasis of the dangers of staying home
 - * Indication of a place to go and how to get there
- Facilitate the departure of families, even if all members are not present.
- Provide public transportation that is suitable for children and elderly and handicapped persons.
- Consider potential problems presented by pets and livestock and provide services for taking care of pets during evacuations.
- Facilitate access to medical care for evacuees, especially for special needs populations.
- Strictly enforce limitations on access to the restricted area after evacuation.
- Implement social support services.

management, a broad variety of hazardous chemicals can be divided into 13 basic categories (see Box 90-4).

Aside from an extremely limited number of antidote therapies, medical management of nearly all toxic chemical exposures involves mostly supportive therapy.²² Even if there may be an antidote available for a specific exposure, many times the clinician may not be able to identify the offending agent in enough time to guide effective therapy.

Thus, the acute health effects of a broad variety of hazardous chemicals, as categorized in Box 90-4, may actually be expected to invoke demands for medical resources that address a very narrow range of medical conditions. Table 90-2 represents four main basic medical conditions that can be expected to occur as major short-term sequelae following severe exposures to any of these chemical hazards. It then also identifies a mere

BOX 90-4 TOXIC MATERIALS CATEGORIZED ACCORDING TO GENERAL HEALTH EFFECTS

- Metals and metallic compounds
- Incendiaries
- Irritant gases
- Asphyxiant gases
- Metabolic asphyxiants
- Radiologic agents
- Teratogens
- Corrosives
- Explosives
- Oxidizers
- Pharmaceuticals
- Carcinogens
- Pesticides

TABLE 90-2 EMERGENCY MEDICAL CONDITIONS AND NEEDS ASSOCIATED WITH CHEMICAL EXPOSURES

SYNDROME AND CAUSATIVE AGENTS	MEDICAL THERAPEUTIC NEEDS
Burns and Trauma Corrosives, vesicants, explosives, oxidants, incendiaries, radiologics	Intravenous fluid and supplies Pain medications Pulmonary products Splints and bandages
Respiratory Failure Corrosives, military agents, explosives, oxidants, incendiaries, asphyxiants, irritants, pharmaceuticals, metals	Pulmonary products Ventilators and supplies Antidotes (when available) Tranquilizing medications
Cardiovascular Shock Pesticides, asphyxiants, pharmaceuticals	Intravenous fluids and supplies Cardiovascular products Antidotes (when available)
Neurologic Toxicity Pesticides, pharmaceuticals, radiologics	Antidotes (when available)

eight categories of emergency medical therapeutics that would become necessary to treat these four syndrome complexes.²²

CASE PRESENTATION

At 1:00 AM, a tank containing methyl isocyanate (MIC) located at a pesticide plant ruptures and releases its entire contents. The public siren is sounded only for a few minutes. The toxic plume extends as far as 5 miles from the plant and covers an area of 25 square miles. A thermal inversion traps the plume over the most highly populated areas of a nearby impoverished community of 800,000 people.

By 3:00 AM, all 40 tons of the lung-damaging MIC is released, leaving thousands of local residents dead and hundreds of thousands exposed. Over 80% of the deaths occur before people enter the medical care system. Most deaths occur due to anoxia and cardiac arrest as a result of pulmonary edema caused by the effects on lung tissue. Emergency response is ad hoc, chaotic, and limited by the lack of lighting and of street identification within the poor community.

Fifteen years later, the national Supreme Court directs the company operating the plant to pay a total of \$470 million in full settlement of all claims arising from the tragedy. Twenty years after the incident, the Supreme Court orders the national government to distribute the balance of compensation remaining from the chemical company settlement among the 566,876 survivors whose claims have been successfully settled. The average payout amount is equal to \$570 per person.

UNIQUE CONSIDERATIONS

Industrial chemical disasters are also unique in the degree of complexity that an event entails. In this case, the very nature of response changes as assessments become less certain and older forms of intelligence gathering become obsolete. Decision-making becomes less centralized and more interdependent and may be influenced by local and distant theaters of operation. Responders are forced to act in a collective and integrated fashion within an unconventional network of personnel also unfamiliar with this catastrophic breakdown phenomenon.^{22,39}

In addition, the public tends to judge all technologic hazards more harshly than natural hazards of a similar magnitude and to attach to them much more of a public concern and perception of risk.^{5,7,39-41} There are also special problems in chemical emergencies with respect to exactly how to handle the overwhelming numbers of mass media representatives.⁷ For this reason, risk communication and public information become critical components of the response to these incidents.

PITFALLS

Lack of Knowledge

One major pitfall involving industrial chemical disasters is the relative lack of knowledge regarding the adverse health effects of many of the chemicals that are currently on the market. More than 600 new chemical substances enter the marketplace each month.⁴² Researchers estimate that only 7% of all known chemical substances have been fully investigated.¹³ Measuring human exposure to chemical substances through laboratory sampling also has its limitations.¹ In some cases, consequences can be revealed only by means of formal, sometimes complex, and often long-term investigations.⁵

Lack of Familiarity

Another pitfall of industrial chemical disasters is a fundamental lack of familiarity among the medical community, including emergency care providers. Baxter⁴³ observes that health professionals are more used to planning for trauma than for mass chemical exposure. The direct effects of the disaster can be compounded by ineffective management or leadership, legal difficulties, economic or political limitations, and psychological stress.¹⁶

Lack of Community Preparedness

There is also a fundamental and endemic lack of preparedness among communities at risk for industrial chemical disasters.^{1,24-29} An additional impediment to local planning efforts is the fact that the most relevant resources rest in the hands of extra-community groups (i.e., state and federal assets) rather than with the community organizations that invariably are confronted with the immediate postincident response.⁷ Local Emergency

Planning Councils, mandated by the Superfund Amendment, often lack regular input by the healthcare community.

High Occupational Health Risk Posed to Responders

Workers and first responders are often the first and most frequently injured populations in the case of industrial chemical release events.^{1,37,42,44} Most injuries of this group of emergency personnel occur in the first few minutes of responding, with firefighters and police being the most frequent victims.⁴⁴ Injuries from hazardous substances emergency events are also becoming increasingly more common among hospital personnel as a result of secondary contamination.⁴⁵

Nerve Agent Attack

David Davis and David Marcozzi

DESCRIPTION OF EVENT

The prospect of nerve agent exposure during wartime and a terrorist event is a very real and well-documented concern.^{1,2} Still, the potential for nerve agent intoxication is not limited to intentional exposures. The well-described nerve agents tabun, sarin, soman, and VX were developed in the early part of the twentieth century as derivatives of pesticides with their initial intended uses as such. However, their prospect as chemical warfare agents was soon realized, and development to this end was undertaken. Currently, the commercial agricultural industry continues to use analogs of these precursor pesticides. Given current agricultural practices, the manufacturing, distribution, and application of these pesticides may also represent a significant potential for mass exposure to nerve agents.³

Nerve agents are anticholinesterases, which can be divided into three distinct categories: quaternary ammonium alcohols, carbamates, and organophosphates. Each of these classes has its distinctive characteristics, but all anticholinesterases achieve their toxic effects through inhibition of the enzyme acetylcholinesterase. Acetylcholine is an important neurotransmitter in the human nervous system. Under normal physiologic conditions, acetylcholine is hydrolyzed by acetylcholinesterase into acetate and choline. Anticholinesterases disrupt this reaction by forming stable complexes with acetylcholinesterase, resulting in preservation of the neurotransmitter.⁴ Consequently, widespread hyperactivity (with subsequent fatigue and failure) of cholinergic end organs ensues secondary to the accumulation of acetylcholine. Toxicity is related to hyperstimulation of nicotinic and muscarinic receptors in neurons, muscle, and exocrine glands. Nicotinic effects result from extensive sympathetic and parasympathetic ganglionic outflow as well as somatic neuromuscular junction hyperactivity in skeletal muscle. Muscarinic effects are the product of increased postganglionic parasympathetic stimulation of smooth muscles, exocrine glands, and neurons in the central nervous system (CNS).

Quaternary ammonium compounds inhibit cholinesterase activity through a fleeting ionic interaction that lasts only milliseconds, limiting the toxicity of these

agents. Carbamates are common components of many household insecticides. Carbamates inhibit acetylcholinesterase through the covalent bonding of the chemicals carbaryl group to the enzymes active site.⁵ Unlike the acetylated form of the enzyme, the carbamylated form is much more resistant to hydrolysis. However, the reaction is reversible because reactivation of acetylcholinesterase occurs spontaneously when the carbamate is hydrolyzed.⁶ Hydrolysis takes an average of 2 to 6 hours and is in part responsible for the limited toxicity of carbamates. The inability of carbamates to cross the blood-brain barrier also explains their lack of CNS effects.⁷ Exposure to these compounds usually occurs either through intentional ingestion, cutaneous absorption, or inhalation of droplets.

The organophosphates, which are technically organophosphorus esters, comprise the last and largest group of acetylcholinesterase inhibitors. A complete list of these agents is beyond the scope of this chapter, but they include pesticides such as diazinon, malathion, parathion, dichlorvos, and chlorpyrifos as well as the G-series and V-series nerve agents used as chemical warfare agents. The common denominator of this group of agents is their phosphoric acid backbone. A phosphorylated acetylcholinesterase is a remarkably stable complex and the reaction in effect irreversible, as normal physiologic chemistry does not allow for spontaneous hydrolysis. Furthermore, the enzyme will undergo “aging” if not reactivated.⁸ *Aging* refers to a conformational change of the phosphorylated acetylcholinesterase, rendering the enzyme permanently disabled.

Organophosphates may exist as powders, epoxies, and resins but are most commonly encountered as odorless, colorless liquids. They are also highly lipophilic substances. As such, transcutaneous absorption is the most frequently seen exposure for organophosphate pesticides. Evaporation of organophosphates can occur, however, and inhalation may lead to rapid development of systemic toxicity. In particular, the classically described G-agent nerve “gases” sarin (GB), soman (GD), and tabun (GA) possess sufficiently high enough vapor pressures to produce lethal vapor concentrations at room temperature.^{8,9} (These agents never actually boil at usual environmental temperatures but rather evaporate; *nerve gas* is therefore

a misnomer.) Vapor pressure represents the pressure at which the vapor and liquid phases of a substance will equilibrate in a closed system, or more simply, the point at which a liquid will cease spontaneous vaporization. In most cases, these agents will completely vaporize because their release is unlikely to occur in a closed area. Additionally, sarin, soman, and tabun are relatively volatile compared with other organophosphates. *Volatility* refers to the ease with which a substance will evaporate¹⁰ and correlates directly with speed of evaporation.

Another organophosphate nerve agent, VX, is the most potent chemical warfare agent; a single droplet of VX on the skin can be fatal. VX exists solely as a liquid with a low vapor pressure and volatility, making spontaneous evaporation highly unlikely.¹¹ However, it is well absorbed through the skin.

Organophosphates may be aerosolized with mechanical sprayers, during crop dusting, or from the combustion of an explosive device. As these agents persist in the environment, secondary vaporization or “off gassing” may occur.¹² This is an important fact to remember because although protective clothing will minimize dermal exposure, the agent may still evaporate and be inhaled.

PREINCIDENT CONSIDERATIONS

Hospital, community, and military preparedness for any massive chemical exposure is imperative. Decontamination strategies must be incorporated into disaster protocols. A more comprehensive outline of decontamination tactics can be found in Chapter 70. There are several caveats when preparing protocols to handle nerve-agent disasters.¹³

During nerve agent exposure, systemic absorption is continuous as long as the agent is in contact with epithelial surfaces or in transit through the skin. Respiratory exposure can be terminated either by masking the victim or by removing the victim from the incident site. Percutaneous absorption will continue as long as the agent is in contact with skin; moreover, agent already in transit through the skin is not removed by decontamination of skin surfaces. For this reason, skin decontamination is imperative and must begin as soon as possible. This is achieved by immediate removal (by adsorption, flushing, or both) at the incident site of any agent seen on the skin—local, or so-called “spot” decontamination, which may mean the difference between life and death for nerve agent casualties. Skin irrigation is accompanied or followed by prompt removal of all clothing. Irrigation of exposed skin and hair may be performed with saline or soapy water, although in mass-casualty situations, water will be the most well-tolerated, abundant, and readily available decontaminating solution. Sodium hypochlorite (i.e., household bleach) is no longer recommended as a dermal cleansing solution but is still the solution of choice for decontaminating equipment because it effectively neutralizes organophosphates. Eyes should be irrigated with water only. General recommendations are to spend 10 to 15 minutes irrigating the skin and eyes. However, in the event of a disaster related to nerve agents, practical decisions about length of irrigation will have to be made and

tailored to individual situations based on the severity of incident, the number of casualties, and the availability of resources.

Ideally, in cases of ingestion of organophosphate pesticides, gastrointestinal decontamination would also begin at the scene but will most likely be delayed until the patient reaches a healthcare facility. When available and indicated, activated charcoal (1 g/kg) should be administered orally or via nasogastric tube.

Emergency crews need to ensure adequate self-protection during the extrication, decontamination, and transport of casualties. Butyl or nitrile rubber gloves, boots, suits, and masks provide protection from nerve agent absorption; conventional latex and vinyl gloves do not.¹⁴ The importance of appropriate protective equipment and thorough decontamination should not be underemphasized. Attention to these details not only prevents rescue workers from becoming intoxicated through dermal contact with nerve agents but also prevents those healthcare workers downstream who will be providing definitive care for the patient from contacting the nerve agent and subsequently becoming casualties.

Military healthcare providers are faced with several unique challenges and options in preparing for nerve agent attack. First, soldiers must be trained to recognize a chemical attack and to don appropriate personal protective equipment properly and swiftly.¹² Second, if military intelligence suggests a high probability of attack with the nerve agent soman, soldiers may be pretreated with pyridostigmine bromide. Pyridostigmine is a carbamate that when administered before exposure to soman will functionally “protect” some of the acetylcholinesterase by reversibly binding to it. Subsequent spontaneous hydrolysis of the carbamate releases the enzyme for return to normal activity.^{15,16} Pyridostigmine is well tolerated with few side effects and is dispensed in a blister pack containing 30-mg tablets; one tablet is taken every 8 hours for a usual maximum of 14 days. Lastly, the U.S. military issues the MARK I autoinjector kit. Each kit contains one 0.5-mL preloaded autoinjectable syringe containing 2 mg of atropine and a 2-mL syringe containing 600 mg of the oxime 2-pralidoxime chloride. A combination autoinjector syringe, the Antidote Treatment Nerve Agent Autoinjector, which contains both atropine and 2-pralidoxime chloride, is in development. Soldiers should be familiar with indications for and administration of these kits.

POSTINCIDENT CONSIDERATIONS

Prompt recognition of the cholinergic crisis associated with nerve agent exposure is critical in directing treatment. Nicotinic effects include weakness, hypertension, hyperglycemia, local or generalized muscle fasciculations, tachycardia, and mydriasis, although mydriasis is almost inevitably overridden by miosis induced by hyperstimulation of muscarinic receptors. Muscarinic effects include diaphoresis, urinary incontinence, miosis, bronchorrhea, bronchospasm, emesis, lacrimation, loose stools, and salivation (remembered with the acronym DUMB BELLS).^{8,17} (Bradycardia is also a muscarinic effect

but in humans is usually overridden by tachycardia from nicotinic stimulation in sympathetic ganglia.) Since the end-organ response to excessive cholinergic stimulation is first hyperactivity and then fatigue and failure, another way of organizing these effects is to list effects from organ-system hyperactivity and then effects from subsequent organ-system failure. For example, overactivity of neurons in the brain causes seizures (manifested in an as-yet-unparalyzed patient as convulsions); subsequent fatigue and failure of the respiratory center in the medulla leads to central apnea. Similarly, increased stimulation of skeletal muscle produced twitching and fasciculations eventually followed by weakness and paralysis (usually flaccid paralysis). An important consideration is that any constellation of these symptoms may initially be present depending on the route of exposure and the dose of agent. Inhalation immediately leads to bronchorrhea and respiratory difficulty, whereas dermal contamination may manifest as local muscle fasciculations and diaphoresis before the onset of systemic symptoms. However, sudden collapse with apnea and convulsions may occur after high doses either from inhalation or percutaneous exposure; the difference is that, for a fatal dose, effects from skin exposure will be delayed for 20 to 30 minutes because of passage of the agent through the epidermis to the dermal vasculature. The mechanism of death from nerve agent exposure is primarily respiratory in nature as progressive bronchorrhea, bronchospasm, direct paralysis of the diaphragm, and especially central apnea. Confusion, seizures, apnea, and coma are ominous CNS symptoms indicative of severe intoxication.⁹

After recognition of the cholinergic toxidrome, post-exposure triage can aid in managing mass casualties and in directing initial medical treatment. Exposed victims should be triaged as mild, moderate, or severe based on their clinical presentation, which will depend in part on the type and route of exposure and the dose of agent (Table 91-1). Emphasis should be on recognizing the syndrome and broadly grouping casualties to facilitate

rapid medical treatment. Initial treatment will be based on triaging casualties into one of these categories.^{9,17,18}

Laboratory values are of little clinical utility in the immediate management of nerve agent poisonings. Erythrocyte-cholinesterase levels may be drawn and do correlate with serum cholinesterase levels after acute exposures, but this is not a readily available test and has much intersubject variability, making it most useful in occupational settings where an individual baseline can be determined for each worker. Plasma-cholinesterase levels measure butyrylcholinesterase, also called *pseudo-cholinesterase*, and may be used to monitor the return of serum cholinesterase activity during recovery. Initial medical treatment should always be clinically dictated. Initial electrocardiography may show either sinus tachycardia or bradycardia, although tachycardia is actually somewhat more common in patients with nerve agent injuries. Also, those patients with severe or chronic exposures to organophosphate pesticides may develop a delayed-onset polyneuropathy or chronic organophosphorus-induced delayed neurotoxicity with a stocking/glove distribution. This neuropathy may be permanent^{9,11} but appears to occur seldom if ever with nerve agents.

MEDICAL MANAGEMENT OF CASUALTIES

After primary decontamination, medical management of organophosphate exposure is directed at blocking cholinergic-receptor stimulation and reactivating acetylcholinesterase. Management of known quaternary ammonium or carbamate intoxication does not usually require specific medical therapy but rather general supportive measures, although atropine by itself has been used in cases of carbamate poisonings.¹⁹

Supportive care should always start with the ABCs (i.e., airway, breathing, and circulation) and appropriate

TABLE 91-1 NERVE AGENT SIGNS AND SYMPTOMS BASED ON SEVERITY AND ROUTE OF EXPOSURE*

SYMPTOM SEVERITY AND TRIAGE LEVELS	TYPE OF EXPOSURE	
	Liquid	Vapor
Mild	Localized fasciculations and diaphoresis; no miosis	Miosis; dim vision; rhinorrhea
Moderate	Mild symptoms and: gastrointestinal cramping; nausea/vomiting; generalized weakness and fasciculations	Mild symptoms and: salivation/lacrimation; wheezing; dyspnea; bronchorrhea; bronchoconstriction
Severe	Mild/moderate symptoms and: apnea; convulsions/seizures; confusion/coma; flaccid paralysis; bowel/bladder incontinence	Mild/moderate symptoms and: apnea; convulsions/seizures; confusion/coma; flaccid paralysis; bowel/bladder incontinence

*Note: The signs and symptoms of severe exposure may occur after progression through mild and moderate effects or may occur suddenly, depending on the dose. Effects from inhalation will be immediate; a latent period of 20 minutes to 18 hours is seen after liquid exposure; the length of this latent period is inversely correlated with dose.

advanced life support protocols. Aggressive airway management is often needed. Usually supplemental oxygen and suctioning of airway secretions is sufficient in cases of organophosphate-pesticide poisoning, although high doses of nerve agents will likely require endotracheal intubation and ventilatory support. Paralytic agents are rarely needed, but if necessary a short-acting competitive neuromuscular blocker such as vecuronium or rocuronium should be used. Avoid use of succinylcholine, which may have prolonged effects.^{4,8,9}

Atropine is a competitive cholinergic blocking agent and when administered will aid in alleviating muscarinic symptoms^{8,20} but will not control nicotinic symptoms such as muscle fasciculations, weakness, or flaccid paralysis. Initial dosing is based on symptoms and triaged categories of victims (Table 91-2). Atropine has a short half-life and can be given every 5 to 10 minutes at a dose of 2 mg in adults and 0.05 to 0.1 mg/kg in children. The maximal single dose for children should not exceed 1 mg. Administration of atropine should continue until airway resistance is minimized, respiratory secretions dried, and dyspnea resolved. Total doses of up to 1 to 2 g have been required in cases of intoxication with organophosphorus pesticides, but nerve agent poisoning should seldom require more than a total of about 20 to 30 mg of atropine, as long as oximes are also administered.

With organophosphate intoxication, definitive treatment is aimed at reactivating acetylcholinesterase. Reactivation is achieved through the administration of an oxime-containing compound. Oximes reactivate acetylcholinesterase by displacing the phosphate moiety from the enzyme. However, reactivation is not possible after aging. Although nerve agents begin aging almost immediately, the half-lives of aging are hours to days for most of the agents. The exception is soman, which has an aging half-life of approximately 2 minutes. Thus, oxime administration to a soman-poisoned patient after five half-lives (about 10 minutes) is unlikely to have any effect.^{17,20} Currently, pralidoxime chloride (2-PAM chloride) is the only oxime approved by the Food and Drug Administration (FDA) for use in the United States. Again, initial dosing is based on symptom severity. However, because of potential adverse effects from overdosage, repeat intramuscular administration of oximes after the initial 1800- to 2000-mg dose given to severely intoxicated adults should be delayed for an additional hour.

CASE PRESENTATION

You are called to the scene of an explosion that has rocked a crowded downtown park. Initial reports are vague and indicate several blast injuries. Additionally, there is speculation that a chemical agent was released during the explosion.

The first casualty that you see is a 35-year-old previously healthy businessman who walks into the triage area. He is complaining of a headache and blurry vision. His vital signs are stable, but you do notice that his pupils seem markedly constricted. Next, medics bring over an 8-year-old girl. She is actively seizing on arrival. Her vital signs include a pulse of 110, blood pressure of 95/60, and oxygen saturation of 85%. This patient has some minor superficial abrasions, is incontinent of bowel and bladder, is extremely diaphoretic, and is salivating profusely. As you order a benzodiazepine to treat the seizure, the medic who assisted with transporting the young girl collapses. He loses consciousness only transiently and on awakening seems confused. He is also complaining of difficulty breathing and feeling weak. In the interim, the police have identified debris from the explosion; this debris includes the remains of a duffel bag, an explosive device, and a canister of some sort.

Benzodiazepines are the treatment of choice for organophosphate-induced seizures. Prophylactic administration of benzodiazepines is recommended in all cases of severe organophosphate exposure to minimize the risk of subsequent seizures. Remember, although benzodiazepines do control convulsions, increased neuronal activity still consumes a significant amount of oxygen, and adequate oxygenation is imperative to preserve CNS function in severely exposed patients. Most experience is with diazepam, but other benzodiazepines including midazolam would also be appropriate. See Table 91-2 for recommended dosing.

Other medical therapies include inhaled nebulized ipratropium bromide, a synthetic analog of atropine. Ipratropium will be helpful in relieving bronchoconstriction and reducing airway secretions. There have been a few case reports of hemodialysis followed by hemoperfusion for direct removal of organophosphate compounds.^{8,15}

TABLE 91-2 RECOMMENDED INITIAL DOSING OF ANTIDOTES

	INFANTS (0-2 YEARS)	CHILDREN (<10 YEARS)	ADOLESCENTS	ADULTS	ELDERLY
Mild/Moderate Symptoms	Atropine, 0.05 mg/kg; pralidoxime, 15 mg/kg	Atropine, 1 mg; pralidoxime, 15 mg/kg	Atropine, 2 mg; pralidoxime 15 mg/kg	Atropine, 2-4 mg; pralidoxime, 600 mg	Atropine, 1 mg; pralidoxime, 10 mg/kg
Severe Symptoms	Atropine, 0.1 mg/kg; pralidoxime, 25 mg/kg; diazepam, 0.2-0.5 mg/kg	Atropine, 1 mg; pralidoxime, 25 mg/ kg; diazepam, 0.2- 0.5 mg/kg	Atropine, 4 mg; pralidoxime, 25 mg/ kg; diazepam, 0.2- 0.5 mg/kg	Atropine, 6 mg; pralidoxime, 1800 mg; diazepam, 10 mg	Atropine, 2-4 mg; pralidoxime, 25 mg/kg; diazepam, 0.5 mg/kg

Atropine and diazepam may be given intramuscularly (IM) or intravenously (IV). Pralidoxime may be given IM as a single dose or infused IV over 30 minutes.^{8,9,21}

For military exposures, soldiers will have to administer the Mark I kits to themselves or to severely exposed colleagues. Each kit contains one 0.5-mL autoinjectable syringe filled with 2 mg of atropine and a 2-mL autoinjector containing 600 mg of pralidoxime. Those incurring mild exposures receive one kit, moderate exposures two kits, and severe exposures three kits as well as 10 mg of diazepam.¹²

UNIQUE CONSIDERATIONS

A civilian nerve agent attack will invariably affect a diverse group of people. What cannot be predicted is how coexisting injuries and comorbidities will affect treatment and outcomes of those persons exposed to nerve agents, except that synergism is known to occur between nerve agents and other agents, including other chemicals, biologic agents, radiation, conventional wounds, and preexisting medical conditions.

While treating children, keep in mind that they possess several distinct physiologic characteristics that make them particularly susceptible to nerve agent poisoning. Children have lower basal levels of acetylcholinesterase, more permeable skin, and higher minute ventilation than do adults.^{22,23}

With regard to pregnancy, several studies and case reports have shown atropine to be safe during pregnancy. Currently, there is no evidence of atropine having increased teratogenic potential.²⁴ Atropine is an FDA pregnancy category C drug.²⁵ Experience with the oximes is much more limited. Only case reports on the use of pralidoxime during pregnancy exist. Thus far, there have been no reported instances of increased or unexpected teratogenesis related to pralidoxime use. Pralidoxime is also an FDA pregnancy category C drug.²⁵ Benzodiazepines have been studied more extensively and have been shown to increase the risk of teratogenesis.^{26,27} Consequently, benzodiazepines are FDA pregnancy category D drugs.²⁵

In the treatment of pregnant women, the potential benefits to the patient must always be weighed against the potential risks to the fetus. If the pregnant patient is known to have exposure to a carbamate, atropine may be the only pharmacologic therapy needed and will be safe. However, in the case of severe organophosphate exposure, none of the previously mentioned therapeutic interventions should be withheld. In mild to moderate organophosphate exposure, benzodiazepines are not indicated, although atropine and pralidoxime should still be used.

PITFALLS

Several potential pitfalls in response to a nerve agent attack exist. These include the following:

- Failure to immediately notify local, state, and federal authorities, including the Federal Bureau of Investigation and the Centers for Disease Control and Prevention, in the event of a suspected nerve agent attack.

- Failure to initiate decontamination immediately. Do not delay spot decontamination in favor of later full-body decontamination. Physical or mechanical removal of agent takes priority over the use of chemical decontaminants such as bleach. If soap is not immediately available, begin irrigation with copious amounts of water.
- Failure to use appropriate clinical end points for atropine administration. Administration of atropine should continue until respiratory secretions are clear and airway compromise has resolved. Inappropriate end points for atropine administration include miosis (which may persist for up to 2 months), heart rate, and nicotinic effects such as twitching or weakness.
- Failure to consider nerve agents as a possible etiology for respiratory distress or generalized weakness in the case of exposure to an unknown chemical agent.

Vesicant Agent Attack

Lara K. Kulchycki

DESCRIPTION OF EVENT

Vesicants are chemical warfare agents named for their ability to cause skin blisters, or *vesicles*. These chemicals produce severe damage to the eyes, lungs, and skin through direct contact or inhalation of vapor.¹ Multiple nations maintain vesicant stores because these agents are simple to manufacture and can incapacitate large numbers of people with a single deployment. The prototypical vesicant is mustard. Two types of mustard agents exist: the nitrogen mustards (HN-1, HN-2, and HN-3), known for their medicinal uses as chemotherapy drugs, and the sulfur mustards (H, HD, HT), which are known only for their combat applications. Subsequent discussion of *mustard* refers only to the sulfur compounds. Other variants of these agents are tabulated elsewhere.²

Mustard is a yellowish-brown, oily liquid with an odor comparable to that of mustard, garlic, or onion. It does not boil until 217°C (423°F) and thus is not mustard “gas,” but it freezes at 14°C (58°F); mustard-lewisite mixtures remain liquid at lower temperatures. It was heavily used in World War I and was outlawed by the Geneva Gas Protocols of 1925, but the United States was not a signatory to that agreement. Rumors of possible use of mustard by the German and Italian armies in World War II led to the secret production of mustard bombs by the United States to be used only if the Axis forces used them first. Although never intentionally used, a disastrous attack on a U.S. Liberty ship loaded with a secret cargo of mustard bombs occurred as part of an air attack on the Italian port of Bari in 1943, exposing many hundreds of Allied soldiers and sailors to this agent.³ It was used again in the Iran-Iraq war in the 1980s. It causes ocular, respiratory, and dermatologic symptoms that develop 1 or more hours after exposure. Eye effects range from tearing and conjunctival irritation to ocular pain, photophobia, corneal ulceration, and blindness. Mustard respiratory signs and symptoms include rhinorrhea, dysphonia, productive cough, hemoptysis, and dyspnea. Mustard burns are more likely to appear on warm, moist areas of the body such as the neck, axillae, and groin. Patients first notice skin erythema, burning pain, and intense pruritus, followed several hours later by vesication. Other mustard effects may include nausea, vomiting, tremor, ataxia, and

convulsions. Symptom onset is usually delayed for 2 to 12 hours after initial contact.

Since mustards are alkylating agents that interfere with nucleic acid synthesis, leukopenia can be a clinically significant problem. Drops in neutrophil counts usually appear by days 3 to 5 and can be precipitous, predisposing injured skin and airways to superinfection. Deaths, although uncommon, usually occur days after exposure from bronchopneumonia or sepsis. The case fatality rate from World War I was surprisingly low, approximately 3%. This preantibiotic statistic underscores that vesicants are maiming agents, intended to disable rather than kill and generating large numbers of casualties requiring extended medical care.

Lewisite (L) is an arsenical vesicant sometimes combined with mustard (HL). Lewisite is a colorless oily liquid, but with impurities it is amber and smells like geraniums. It causes symptoms very similar to those of mustard but is distinguished from mustard by its quick onset of discomfort, within seconds to a minute or two. Casualties may be less likely to receive blinding injuries from vapor since early-onset blepharospasm can limit exposure. Large exposures are notable for causing “lewisite shock” from increased capillary permeability, renal failure, and hepatic necrosis.

Phosgene oxime (CX) is not a true vesicant because it does not cause the blistering seen with mustard and lewisite. It is more precisely classified as an *urticant*, or nettle agent, and causes wheals and blanching comparable to nettle stings. It is not to be confused with phosgene (CG), a pulmonary irritant that smells like hay. Phosgene oxime is a colorless solid or yellowish-brown liquid with immediate corrosive effects. Patients experience instantaneous skin blanching and burning, eye pain, and respiratory distress. It is notable for causing pulmonary edema and pulmonary-vessel thromboses. There are no documented battlefield uses of this chemical, and consequently few data exist on the clinical course and optimal treatment regimens.

PREINCIDENT ACTIONS

Every community and each hospital should have a documented disaster plan for mass-casualty incidents and

release of toxic chemicals. Emergency personnel should be provided with, and trained in the use of, personal protective equipment and the implementation of the disaster response protocol.

POSTINCIDENT ACTIONS

Medical personnel coordinating a disaster response must notify appropriate local and regional healthcare providers as well as law enforcement and public health officials. If possible, a hotline should be established to disseminate information to the public.

First responders at the scene of a suspected chemical attack will need to create rapid scene control to prevent the spread of contamination and minimize the number of injuries. Any rescuer working in the hot zone will require personal protective equipment as well as a pressure-demand, self-contained breathing apparatus (SCBA) to guard against exposure to liquid and vaporized agents.

Vesicant absorption is both rapid and irreversible. Decontamination occurring after the first few minutes of exposure may be too late to prevent the eventual development of skin lesions (although lesion appearance is delayed, the damage from mustard begins within a few minutes) but may prevent systemic absorption of a lethal dose from liquid still in contact with the skin. Late decontamination can also prevent the incapacitation of first responders by liquid agent or off-gassing vapor from chemical attack victims.

Chemical casualties should be removed from the scene and brought to the designated decontamination zone. Patients' eyes should be flushed with water for 5 to 10 minutes. No ocular patches or occlusive dressings should be applied. All contaminated clothing must be removed and double-bagged, and the skin should be washed with either soap and water or dilute 0.5% sodium hypochlorite solution. If water is unavailable, absorbent materials such as flour or fuller's earth can be applied to soak up liquid agent on the skin; these substances should then be washed off after several seconds of contact. Contaminated equipment can also be cleaned with dilute sodium hypochlorite. After decontamination, patients can be transferred to the designated medical treatment facility, where they can be retrieved.

MEDICAL TREATMENT OF CASUALTIES

Initial medical treatment and stabilization may need to occur in the hot zone, especially for patients with other significant injuries, large chemical exposures, or preexisting airway disease. As always, a quick assessment of the ABCs (i.e., airway, breathing, and circulation) is the initial step.

Constructing a timeline of symptom onset can be crucial in determining the agent used in a chemical attack. Immediate onset of lacrimation, blepharospasm, and burning skin pain argues for the use of lewisite or phosgene oxime. A latent period of 2 to 12 hours is more consistent with the use of mustard. Despite active investigation, there are currently no sensitive, specific, and

readily available laboratory tests to confirm exposure to a particular vesicant,⁴ although urinary analysis for thiodiglycol, a metabolite of sulfur mustard, is available at military reference-laboratory facilities. Providers must keep in mind that the deployed weapon may have contained multiple chemicals, including nerve agents, each of which may require a different treatment algorithm.

Specific medical management guidelines for exposure to vesicant agents have been compiled by the Agency for Toxic Substances and Disease Registry, a division of the U.S. Department of Health and Human Services designated to assist with emergency medical response to release of toxic substances. Links to these clinical guidelines can be found on the Web site for the Centers for Disease Control and Prevention.⁵⁻⁷

Eye injuries require ophthalmic antibiotic ointments to prevent lid adhesion and infection, and mydriatic agents for analgesia if there is underlying iritis. Corticosteroid ointments are sometimes recommended to decrease inflammation, but these should be administered only after consultation with an ophthalmologist. Short-term visual incapacitation is common after vesicant eye injury, but most patients recover full function.⁸ Hence, reassurance for all but the most severely injured is both appropriate and humane.

Respiratory injuries are treated with supportive measures including oxygen, bronchodilators, and ventilatory support, as needed. Pulse oximetry and chest radiographs can aid in clinical assessment. Patients with preexisting reactive airway disease may have more severe reactions to inhalation injury and require careful monitoring. Antibiotics are best withheld until sputum cultures or other clinical evidence confirms infection with a specific organism. Productive cough is a common symptom of chemical bronchitis and by itself does not warrant the use of antibiotics. In severe respiratory injury, the airway can become plugged with necrotic debris and urgent bronchoscopy with deep suctioning may be needed.

Treatment of chemical burns is similar to that required for thermal injuries, including wound care, debridement, topical antibiotics, intravenous fluid replacement, and systemic analgesics. Vesicant skin burns are usually only partial thickness but take nearly twice the time to heal as comparable thermal injuries.^{9,10} Maintenance of strict wound hygiene and avoidance of secondary infection is crucial in patients incurring injury from mustard, since leukopenia is a delayed effect of exposure to higher doses. The use of systemic antibiotics should be avoided unless there is specific evidence of infection. Involvement of burn specialists would be appropriate for ongoing management of such patients.

Data from the Iran-Iraq war suggest that fluid losses occurring in conjunction with vesicant burns are less extreme than those encountered in the case of thermal burns of equivalent body surface area. Care providers must be cautious because overzealous fluid replacement can lead to pulmonary edema, further compromising respiratory function in patients with vesicant airway injury.^{1,11}

In case of vesicant ingestion, care providers should neither induce emesis nor attempt decontamination with activated charcoal. Symptoms of nausea and vomiting can be treated with standard antiemetic agents.

A set of routine laboratory tests, including a complete blood count (CBC) and serum electrolytes as well as kidney and liver function tests, is warranted for patients who will be admitted. The CBC is a baseline by which to measure the subsequent leukopenia of patients with mustard injury or the hemolytic anemia of lewisite patients. Kidney and liver function tests are particularly important in lewisite exposure since it is known to cause multi-organ failure.

Of the vesicants, only Lewisite has a specific antidote. The chelating agent British anti-lewisite (BAL), also known as dimercaprol, enhances urinary excretion of arsenic and improves clinical outcome in exposed patients.¹² The lewisite protocol suggests a dose of 2.5 to 5 mg/kg delivered intramuscularly (IM) every 4 hours for four doses. Dose frequency can be increased to every 2 hours in cases of severe poisoning. The drug is dissolved in peanut oil and is thus contraindicated in patients with peanut allergy. Water-soluble BAL analogs exist but are still experimental; they are unlikely to be readily available in the instance of a chemical disaster.¹³ Side effects to IM administration are both common and dose-related, leading many experts to recommend BAL be given only to patients with shock or significant pulmonary injury. Side effects include injection site reactions, hypertension, tachycardia, headache, nausea, vomiting, perioral and extremity paresthesias, anxiety, chest pain, and fever.¹⁴

Patients with mild symptoms should be observed for a period of about 24 hours. If symptoms have not progressed, the patients can be discharged with instructions to return if new manifestations appear.

CASE PRESENTATION

Your hospital's emergency department is put on alert for a report of a mass-casualty incident. An explosion occurred during a local sporting event. According to emergency medical services and firefighter personnel at the scene, victims reported a cloud of smoke with a strange garlic smell that permeated the stands after the blast. Victims closest to the explosion were found with a yellow, oily residue on their skin and clothing. The first of the injured will be arriving in your trauma bay within 5 minutes. No immediate identification of the attack agent is available.

UNIQUE CONSIDERATIONS

Patients may not show any initial signs of chemical injury. A variable delay in symptom onset can occur with different agents, variations in the amount and route of exposure, and various weather conditions. This latent period can cloud initial clinical evaluation and delay the onset of decontamination procedures. Even if first responders are vigilant and well trained, contaminated patients or equipment may gain entrance to hospitals and cause additional casualties. For sulfur mustard, knowledge of the latent period is useful in estimating absorbed dose because the

length of the latent period is inversely correlated with dose. For example, the appearance of respiratory signs and symptoms within 4 hours of inhalational exposure portends a poor outcome.

Proper management of a vesicant attack will require significant medical and financial resources, including facilities equipped for the prolonged hospitalization of casualties and consultation services with specialists in toxicology, burn surgery, ophthalmology, and pulmonary medicine. In addition, the psychological burdens to patients, families, and caregivers cannot be ignored. Crisis counseling for victims and debriefing for staff is a key component of the disaster response. Chronic medical sequelae, although beyond the scope of this chapter, will add to the toll of a chemical attack.

PITFALLS

Several potential pitfalls in response to a vesicant agent attack exist. These include the following:

- Failure to suspect chemical injury and initiate prompt decontamination because casualties do not yet exhibit the symptoms of vesicant injury.
- Failure to notify appropriate public health, local government, and law enforcement officials as soon as chemical attack is suspected.
- Failure to treat urgent injuries and respiratory compromise during decontamination.
- Failure to maintain a strict hot zone.
- Failure to recognize and treat concomitant exposures to other chemical weapons, such as nerve agents.
- Failure to appreciate the severity of vesicant burns on initial presentation.
- Failure to prevent overhydration in patients with chemical burns.
- Failure to withhold systemic antibiotics until there is specific evidence of skin or respiratory-tract bacterial infection.
- Failure to involve the appropriate specialty consultants, including toxicologists, burn surgeons, ophthalmologists, and pulmonologists.
- Failure to provide counseling and emotional support to victims and medical personnel in the event of a chemical attack.¹⁵

Respiratory Agent Attack (Toxic Inhalational Injury)

Stephen J. Traub

DESCRIPTION OF EVENT

Many chemical and biologic agents are capable of causing respiratory symptoms. Ricin (see Chapter 136) and the trichothecene mycotoxins (see Chapter 135) may cause pulmonary syndromes ranging from cough to acute pulmonary edema; *Bacillus anthracis* (see Chapter 102), the causative agent of anthrax, may cause a lethal pneumonitis; vesicant agents (see Chapter 92) may cause acute lung injury in addition to ocular and dermal toxicity; and the organophosphorous nerve agents (see Chapter 91) may produce suffocating pulmonary secretions. This chapter, however, is limited to a discussion of three agents that are gases under environmental conditions and whose main target organ is the lung. Phosgene (military chemical weapon designation, CG) and diphosgene (DP) have similar toxicities and are considered together; chlorine (no military chemical weapon designation) is considered separately. These toxicants cause a dose-dependent pulmonary syndrome that may range from a mild cough through reactive airways disease to acute lung injury and the adult respiratory distress syndrome.

Phosgene, also known as carbonyl chloride (COCl_2), is the reactive species formed by the decomposition of diphosgene. Both phosgene and diphosgene have relatively low water solubility and so are capable of diffusing deeply into the lungs, to the level of the alveoli, before reacting. The exact mechanism of toxicity of phosgene is incompletely understood but is thought to involve some combination or reaction with the amino or thiol groups of alveolar proteins or the phosphate groups of surfactant, reaction with water to form hydrochloric acid, or free-radical formation that then initiates further cellular toxicity.

The aqueous solubility of chlorine gas (Cl_2) is intermediate between the low values for the phosgenes and the high solubilities of strong mineral acids and bases. Not only can chlorine diffuse into the alveoli (like phosgenes) before exerting toxicity, but it can also irritate and damage the larger airways. Soldiers gassed with chlorine in World War I exhibited an almost equal distribution of large-airway and small-airway damage. The reaction of

chlorine gas with alveolar water generates several toxic species, such as hypochlorous acid, hydrochloric acid, molecular oxygen, and free-radical oxygen species. It is the oxygen species that are thought to mediate much of the alveolar pulmonary damage, whereas the acid species mediate the upper respiratory symptoms that may be seen in massive exposures (see below).

A respiratory agent attack could occur in almost any setting. Closed ventilation areas, such as a theater or a government building, intuitively seem particularly vulnerable to such attacks. These gases, however, may also be devastatingly effective in open areas, as occurred on the battlefields of World War I. They might also be used at large gatherings (such as sporting events) or on crowded city streets. All of these gases are denser than air and would thus stay at the level of the victims rather than quickly dissipating into the atmosphere.

Both phosgene and chlorine are used for industrial purposes and could easily be diverted for a large-scale terrorist attack.¹ Chlorine gas can also be produced by mixing household cleaning agents and is thus an inexpensive and easily produced chemical weapon that could inflict terror (if not mass casualties) in any crowded area such as a movie theater or subway.

Respiratory agent attack should be suspected when more than one person begins complaining of unexpected pulmonary symptoms. Tissue damage from these agents begins almost immediately. Depending on the dose to which the victims are exposed, however, effects may develop within minutes or be delayed for several hours. Upper-airway irritation and noise (i.e., coughing, sneezing, inspiratory stridor, and wheezing) are usually of short onset, whereas the dyspnea that heralds incipient pulmonary edema from alveolar damage is usually delayed for hours; the length of this latent period is inversely correlated with dose. Onset of dyspnea within 4 hours of exposure to phosgenes indicates a very high dose and portends a grave outcome. The odor or appearance of the air may also help to identify the event and causative agent. Phosgene is colorless but has the odor of freshly mown hay; chlorine gas is yellow and pungent and has a characteristic odor of bleach. The toxic effects of phosgene can occur at environmental levels of 1.5 to 2 ppm,

whereas the aroma is detectable at 2 to 3 ppm; hence, toxicity can occur without subject awareness.²

PREINCIDENT ACTIONS

Every hospital in the United States should have a plan in place to treat victims of a chemical agent attack. Such a plan should include, at the very least, a means to identify victims of a chemical agent attack, a procedure to triage them to appropriate areas, a decontamination plan, and a treatment strategy. The establishment of a pulmonary care team with respiratory therapists may be beneficial in the hospital response plan to assist in monitoring a surge of patients with respiratory complaints. In the event of a true attack, hospital response should include notification of local, state, and federal authorities.

There are no antidotes to poisoning from the phosgenes or chlorine and thus no specific stockpiles that must be kept on hand, although ample supplies of standard bronchodilators should be ensured. Treatment is supportive (see below).

POSTINCIDENT ACTIONS

Clinicians who suspect respiratory agent poisoning, or any chemical weapons attack, should immediately contact local, state, and federal authorities. Law enforcement, firefighters/hazardous materials and emergency medical services officials will coordinate scene control, triage, evacuation, and containment, which are crucial steps in the management of any chemical weapons attack. Because the site will likely be a crime scene, Federal Bureau of Investigation/law enforcement officials will control evidence gathering and chain of evidence.

The hospital chemical-exposure plan should be activated because more potential victims should be expected. The regional poison control center should also be contacted; the center may be aware of other cases at nearby hospitals and thus serve as a clearinghouse for epidemiologic information.³ It is also an indispensable resource for questions regarding diagnosis and management. In the United States, callers can be automatically connected to the closest regional poison control center by dialing 1-800-222-1222.

MEDICAL TREATMENT OF CASUALTIES

The initial approach to the victim of a respiratory agent attack begins with assessing and securing the patient's airway, breathing, and circulation.

- **Airway.** A victim with a massive exposure may present in obvious respiratory failure and need immediate intubation. All patients should be monitored for decompensation throughout treatment because progressive deterioration may necessitate intubation in a patient who initially appeared stable. Sudden stridorous airway sounds should generate immediate con-

cern for acute laryngospasm from newly generated hydrochloric acid from phosgene hydrolysis, and emergent airway management may be necessary.⁴

- **Breathing.** All patients should be placed on high-flow oxygen; this may be discontinued if the oxygen saturation is subsequently found to be normal by transcutaneous pulse oximetry or arterial-blood-gas analysis. Wheezing may be present even in patients with no history of reactive airway disease and should be treated with beta₂-selective agonists such as albuterol. Acute lung injury and the acute respiratory distress syndrome may occur after a respiratory agent attack and should be managed with low (6 ml/kg) tidal volumes in accordance with currently accepted standards.^{5,6}

- **Circulation.** Two large-bore intravenous lines (18 gauge or larger) should be placed to volume resuscitate the patient if necessary.

Once the airway, breathing, and circulation are secured, other treatment strategies may be considered depending on the agent involved.

- **Phosgenes.** Nonsteroidal anti-inflammatory drugs (NSAIDs)⁷ and corticosteroids⁸ are relatively benign interventions that may have a role in the treatment of poisoning by the phosgenes. Reasonable dosing regimens for NSAIDs are ibuprofen, 400 mg taken by mouth every 6 hours, or ketorolac, 30 mg given intravenously (IV) every 6 hours. A reasonable dosing regimen for corticosteroids is methylprednisolone, 1 mg/kg IV every 8 hours until pulmonary toxicity resolves, followed by an appropriate taper. IV isoproterenol⁹ and aminophylline¹⁰ have shown benefits in animal models, as has inhaled *N*-acetylcysteine.¹¹ These treatments, however, carry a significant risk of iatrogenic toxicity, lack any human data to support them, and cannot be recommended at this time.

- **Chlorine gas.** Corticosteroids, either inhaled¹² or IV,¹³ may help speed lung recovery in chlorine-gas poisoning. They should be given as soon as possible because the beneficial effects appear to decrease with time.¹⁴ A reasonable dosing regimen is methylprednisolone, 1 mg/kg IV every 8 hours until pulmonary toxicity resolves, followed by an appropriate taper. Nebulized sodium bicarbonate has been advocated as a means to neutralize the acidic species generated in the alveoli,¹⁵ but there are no data to support its use in patients with any more than trivial toxicity, and its routine use cannot be recommended.

UNIQUE CONSIDERATIONS

Liquids, such as nerve agents (see Chapter 91) or vesicant agents (see Chapter 92), are most lethal when allowed to evaporate or when aerosolized; as such, they require some form of dispersal mechanism (e.g., a small explosion or a machine to generate a spray) to achieve their maximum effect. True gases, such as the phosgenes and chlorine, require no such dispersal mechanism; they require only that the container be opened to the atmosphere or that they be synthesized in an open-air reaction (e.g., the mixing of cleaning supplies in a bucket).

CASE PRESENTATION

A disheveled subway rider with several bags of belongings is observed to be cleaning the interior of one of the subway cars during the afternoon commute. Although he clearly does not work for the subway, his actions seem harmless and he is not approached by the other riders. As he exits at one stop, no one notices that he has left behind several containers and a bucket under one of the benches.

Shortly after the subway pulls from the station, a rider notices a yellow gas with a pungent odor coming from the bucket. Panic quickly engulfs the car, as three passengers begin coughing and screaming that they “cannot breathe.” Another passenger activates the emergency brake, stopping the train. The passengers chaotically exit the car, and the resulting stampede is later determined to have caused more injuries than the gas attack.

Several persons are taken to the nearest emergency department complaining of coughing and burning of the eyes and mouth. Their symptoms, coupled with the history of a yellow gas and the unmistakable smell of bleach, lead the emergency department workers to conclude that the subway riders were victims of an attack with chlorine gas. The riders are decontaminated in accordance with the hospital chemical-exposure protocol. The emergency department notifies the local authorities, who state that they will contact the appropriate state and federal authorities.

The riders with pulmonary complaints are all observed for several hours and discharged. Examination of the crime scene reveals a bottle of drain opener (active ingredient: sulfuric acid) and chlorine bleach, both purchased from a local drugstore. When mixed together, the two liquids generated chlorine gas.

The phosgenes and chlorine are also somewhat unique in that their toxicity is primarily pulmonary (although chlorine gas may also cause significant ocular and mucous-membrane irritation). Other chemical agents may have pulmonary toxicity, but this is a secondary effect. The toxicity of vesicant agents is primarily dermal, and the toxicity of nerve agents is primarily related to the peripheral and central nervous systems.

PITFALLS

Several potential pitfalls in response to a respiratory agent attack exist. These include the following:

- Failing to consider the phosgenes and chlorine as potential agents of attack.
- Failing to obtain important historical information, such as the presence of an odor of freshly mown hay (phosgene) or bleach (chlorine) or the presence of a yellow-colored gas (chlorine).
- Assuming that respiratory complaints in patients from a mass-casualty incident are due to smoke inhalation.

- Failing to notify local, state, and federal authorities when a respiratory agent attack is suspected.
- Failing to observe victims of respiratory agent attack closely to monitor for deterioration of their conditions.
- Failing to recognize that patients without signs, symptoms, or laboratory evidence of pulmonary damage may nevertheless have been exposed to a pulmonary agent such as the phosgenes or chlorine. Such patients should be observed carefully (ideally, for at least 8 to 24 hours) for the development of dyspnea and pulmonary edema.
- Failure to prospectively account for all active and spare ventilators in the hospital, and failure to have a source of backup ventilators on short notice, in the event of a surge of patients with respiratory failure from a respiratory agent attack.

Cyanide Attack*

Mark E. Keim

DESCRIPTION OF EVENT

Cyanide—much of it in the form of salts, such as sodium, potassium, and calcium cyanide—is widely used in industry. Hundreds of thousands of tons of cyanide are manufactured annually in the United States alone. The cyanides of military (and possibly terrorist) interest are the volatile liquids hydrogen cyanide (North Atlantic Treaty Organisation designation, AC) and cyanogen chloride (CK).¹

A covert cyanide attack involving food or water contamination with ingestion as a route of exposure would likely initially present in a manner similar to that of a covert biologic attack. In this sense, the first indications of attack may be an unusual cluster of cases or a more diffuse increase in the number of patients presenting with an initially unknown illness. In this covert scenario, forensic and/or epidemiologic investigation may be necessary to confirm the cause of the event. Obviously, an abruptly high incidence, a close temporal relationship, or a more focal cluster of cases will increase the suspicion of a common causative agent.

Cyanide released as a liquid or an aerosol can pose a liquid hazard via penetration through even intact skin, but the greater risk in a terrorist attack is the inhalation of aerosol, vapor, or gas. A cyanide attack involving inhalational exposure is more likely to present in a manner similar to that of other hazardous-material (HazMat) release events, with a well-localized incident scene and an associated cluster of attack victims. In this scenario, an accurate and timely history of the event will be important in guiding response decision-making and clinical diagnosis. Lethal concentrations of cyanide vapor or gas typically kill rapidly, dissipate quickly, and leave no toxic residue. It must not be forgotten that smoke-inhalation casualties from any terrorist scenario, even one using only conventional weapons, may also exhibit cyanide toxicity.^{2,3}

*The material in this chapter solely reflects the views of the author. It does not necessarily reflect the policies or recommendations of the Centers for Disease Control and Prevention or the U.S. Department of Health and Human Services.

PREINCIDENT ACTIONS

The Importance of Local Preparedness

Preparation for the 1996 Olympic Games in Atlanta demonstrated an ability to stockpile and mobilize resources (including chemical antidotes) given sufficient advance notice.⁴ Since then, the development of specialized chemical and biologic incident-response teams within the National Disaster Medical System as well as the pharmaceutical reserve and delivery systems of the Strategic National Stockpile have augmented regional and national capacity.

However, with chemical releases (and especially cyanide), lethal effects can occur within minutes after exposure. The characteristically rapid onset of cyanide toxicity offers only a very narrow window of opportunity for clinical intervention, thus limiting the potential effectiveness of resources other than those that are immediately available at the community first-responder level. The inclusion of cyanide antidote in prehospital formularies is nearly nonexistent in the United States due to the inherent toxicity and narrow therapeutic range of currently available medications.⁵ Unfortunately, hospital preparedness for many chemical emergencies and disasters is also reportedly inadequate.⁶⁻¹⁰ One particular study noted a decrease in hospital-based availability of cyanide antidotes in a major U.S. city between 1996 and 2000.¹⁰

The character of HazMat risk has also changed in the wake of recent acts of terror. Emergency responders, including both law enforcement and emergency medical services care providers, are not only potential victims but potential targets.^{11,12} Several publications have recently agreed that, “At the community level, planning for chemical-biologic catastrophes begins with development of local health resources.”¹³⁻¹⁵ Boxes 94-1 and 94-2 list recommendations for preincident actions that can be undertaken to mitigate the potential impact of a terrorist attack involving cyanide.

POSTINCIDENT ACTIONS

Scene Safety

The first step in the response to any HazMat release incident is to limit any further exposure to the victims, as well

BOX 94-1 PREINCIDENT ACTIONS RECOMMENDED FOR HEALTHCARE PROVIDERS (INCLUDING PEDIATRICIANS) AND FACILITIES TO PREPARE FOR AND MITIGATE THE IMPACT OF TERRORIST ATTACK USING CYANIDE

- Participate in community efforts to establish response plans.¹³
- Assist in developing protocols for offices and healthcare facilities.¹³
- Assume a key role in identifying sentinel cases of illness after a suspected chemical release.¹³
- Assist in developing local critical-incident stress-management programs (to include first responders as well as adult and child victims).¹³
- Educate hospital administrators and care providers in issues of adult and pediatric disaster management, including medical response to chemical events, occupational health, and personal protection.^{10,13}
- Use local health departments and poison control centers as resources and central clearinghouses for toxicologic information to be given to the public and healthcare personnel.^{13,16}

BOX 94-2 PREINCIDENT ACTIONS RECOMMENDED TO HOSPITALS AND LOCAL AND NATIONAL GOVERNMENTS TO PREPARE FOR AND MITIGATE THE IMPACT OF TERRORIST ATTACK USING CYANIDE

- Continue to develop coordinated plans (including specific protocols for management of adult and pediatric casualties) for dealing with the consequences of a chemical event.¹³
- Include personnel skilled in evaluating and treating children in disaster-response teams.¹³
- Include pediatric healthcare facilities in all aspects of preparation.¹³
- Support research into behavioral consequences (including those involving children) of chemical threats.¹³
- Promote investigations that may further the acceptance of hydroxocobalamin as indicated for the treatment of cyanide poisoning.⁵
- Work to ensure that adequate supplies of antidotes are available, that they are efficacious, and that dosages are established for all ages, especially for elderly and pediatric patients.¹³
- Provide financial support and incentive to create specialized areas such as isolation zones and decontamination rooms.^{10,13}
- Base selection and maintenance of a local stockpile of pharmaceutical antidotes on an assessment of the vulnerability of the hospital, the hazard profile of the community, and when available, the threat analysis of the intelligence community.¹⁰
- Enforce existing Occupational Safety and Health Administration regulations and Joint Commission on Accreditation of Healthcare Organizations guidelines to help protect prehospital and hospital workers dealing with hazardous waste and emergency operations.^{10,17,18}
- Provide economic incentives for hospitals that implement such engineering controls that would be effective during chemical emergencies.¹⁰
- Ensure that federal legislation addresses compensation for hospitals that experience mass-casualty incidents and encourages hospitals to design emergency departments to better serve the surge in demand common to mass-casualty incidents.¹⁷
- Expand hospital preparedness from planning within the context of a single hospital organization to planning by the hospital to become part of a community-wide initiative to address mass casualties.^{19,20}

as to others, including first responders. Despite an increased awareness of chemical terrorism among first responders, in one simulated chemical weapons release in New York City, first responders entered the site without adequate personal protective gear.²¹ Despite an extensive pre-staging of national assets in preparation for potential terrorist use of mass-casualty weapons at the 1996 Atlanta Olympics, many medical and investigational responders entered Olympic Centennial Park immediately after the bomb explosion and before any chemical hazard characterization. A thorough assessment of scene safety is paramount to any subsequent rescue activities. Rescuers should also keep in mind the possibility of secondary devices meant to injure the first responders.²²

Termination of Exposure and Decontamination

Once the scene has been declared safe for entry or the proper personal protective equipment is employed, the next step is to remove the victims from the area of any potential further exposure. No decontamination is necessary if it is known that the cyanide exposure was in the form of vapor or gas. The health risk from vapor released from clothing contaminated by cyanide gas, vapor, or fine aerosol is not significant. Simple removal of outer clothing will provide an added precaution against any such potential for exposure but should not delay the initiation of emergency medical therapy.

In the case of direct dermal exposures to liquid or dry cyanide compounds, contaminated clothing should be removed immediately and the skin should be decontaminated using copious amounts of water or soap and water. There may also be instances when cyanide contamination is combined with conventional wound injuries. In these cases, bandages are removed in the decontamination area and the wounds are flushed. Dressings and tourniquets are replaced with new ones. Splints are thoroughly decontaminated (but removed only by a physician).¹ The new dressings are removed in the operating room and submerged in 5% sodium hypochlorite or placed into a plastic bag and sealed. Cyanide is quite volatile, so it is extremely unlikely that liquid cyanide will remain in a wound. The risk from vapor off-gassing from chemically contaminated fragments and cloth in wounds is very low and not significant. A chemical protective mask is not required for surgical personnel.¹

The 1978 mass suicide in Jonestown, Guyana, dramatically illustrates the potential for mass casualties due to cyanide ingestion. In the case of cyanide ingestion, gastrointestinal decontamination should include gastric lavage, cathartics, and activated charcoal. Responders should also take personal protective precautions to avoid dermal exposures to cyanide-contaminated emesis or gastric contents.

MEDICAL TREATMENT OF CASUALTIES

Mechanism of Toxicity

The cyanide ion can rapidly bind with certain metallic complexes, particularly those containing cobalt and trivalent iron. Cyanide can combine with the ferric iron in the cytochrome-oxidase complex in mitochondria, thus preventing intracellular use of oxygen. The cell must then switch to anaerobic metabolism, creating lactic acid and metabolic acidosis and leading to progressive tissue hypoxia to the point of cell death. The organs most sensitive to this hypoxia are the central nervous system and the heart.

Therapy

The primary goal of therapy is to remove cyanide from the cytochrome-oxidase complex. Methemoglobin has a high affinity for cyanide, and cyanide will preferentially, although only temporarily, bind to methemoglobin instead of cytochrome oxidase. Amyl nitrite and sodium nitrite are used to induce methemoglobinemia.¹ However, induction of methemoglobinemia can result in serious side effects, especially in children.²³ Methemoglobin levels should be monitored and not be allowed to exceed 35% to 40%.²⁴

A secondary goal is to bind cyanide irreversibly so that it cannot reenter mitochondria. This detoxification is produced by administration of sodium thiosulfate,

which binds to cyanide irreversibly in a one-way reaction that is catalyzed by the enzyme rhodanese and that produces thiocyanate, which is rapidly excreted by the kidneys.

Amyl nitrite, sodium nitrite, and sodium thiosulfate are commercially available in the form of a cyanide antidote kit (CAK). The CAK itself is not without its own inherent toxicity and adverse effects. Sodium nitrite can cause severe hypotension.²⁵ High thiocyanate levels (>10 mg/dL) have been associated with vomiting, psychosis, arthralgias, and myalgia. Anaphylaxis is a rare event. The most serious potential adverse effect from the use of CAK is the production of toxic levels of methemoglobin, although concentrations greater than 40% are identifiable by the appearance of cyanosis and can be treated by the administration of methylene blue. The methemoglobin-induced decrease in the oxygen-carrying capacity of the blood has led to recommendations of caution when the CAK is used to treat smoke-inhalation victims,²⁶ but risks of nitrite use in this situation may be overstated.²⁷ Moreover, waiting for laboratory confirmation of cyanide exposure before beginning to administer the CAK may represent a potentially fatal delay in life-saving intervention. Nevertheless, fatal methemoglobinemia from an iatrogenic overdose of sodium nitrite has claimed the life of at least one child who consumed a sublethal dose of cyanide.²³

Hydroxocobalamin has been recognized as an antidote for cyanide toxicity for over 40 years.²⁸⁻³⁰ It is in active use in France as an antidote for cyanide intoxication, and excellent data about its efficacy, safety, and adverse reactions are available. Hydroxocobalamin reacts stoichiometrically with cyanide to form cyanocobalamin (vitamin B₁₂). Hydroxocobalamin is rarely used in the United States as a cyanide antidote,³¹ but after the publication of articles advocating its use for cyanide disasters,⁵ several pharmaceutical companies are investigating the feasibility of formulation for such use in the United States.

Supportive care for cyanide toxicity is also an important goal during the resuscitative phase of therapy and usually involves oxygenation and sodium bicarbonate for correction of the metabolic acidosis.³² Anticonvulsants such as benzodiazepines are used to control seizures.³³

Table 94-1 provides a list of recommendations for detection, decontamination, and therapy for cyanide toxicity.

Triage of Cyanide Mass Casualties

Mass-casualty events may necessitate the triage of casualties. In most cases, given the rapidity of the effect of cyanide, by the time the responder arrives on the scene of an aerosol or vapor release, the casualties will be asymptomatic, exhibiting acute effects, recovering from acute effects, or dead. Table 94-2 lists a triage scheme that may be applied to these four categories.³⁴

CASE PRESENTATION

An evening memorial service was held in a church hall. The meeting was attended by 60 men, women, and children. Everyone was seated in the middle of the hall. During the service, most of those present began to experience dizziness, lightheadedness, nausea, and weakness. Within minutes, a 54-year-old man seated near the back of the hall lost consciousness and fell off his chair. An ambulance was called. Within the next few minutes, many of those in the hall also became unconscious, starting with those seated immediately surrounding the 54-year-old casualty. On entering the hall, one emergency medical technician (EMT) complained of feeling dizzy and stumbled to the ground. His partner, who had not yet entered the hall, noted the mass casualties inside and immediately called for backup before entering to rescue his fallen comrade.

Thereafter, a fleet of ambulances was dispatched to the scene. After they had arrived, police and ambulance services established that a large number of people, including both of the previously dispatched EMTs, were affected. A major incident was declared, and the local HazMat response team was dispatched while police established and maintained a perimeter around the scene.

After the arrival of the HazMat response team, an entry was made into the open doors of the building and all 62 patients were found to be inside. Twelve patients, including one of the EMTs, were conscious and breathing but weak. Twenty-eight patients, including one EMT, were apneic and convulsing, although all still had a pulse. Ten patients were unconscious but breathing. Twelve patients were apneic and asystolic. The HazMat response team opened all doors and windows to the room and immediately removed everyone but the 12 asystolic patients.

Fifty patients were transferred to a warm zone for removal of outer clothing before evacuation. Thirty-eight patients were triaged for immediate transport to the hospital. While en route, oxygen therapy was initiated for all 38 patients, several of whom also required assisted ventilation. At the hospital, 28 patients were found to be dead on arrival, eight patients remained unconscious but breathing, and two had regained consciousness. The hospital had enough CAKs on hand to care for one patient. Antidotal therapy was initiated for one patient, and the rest were treated with 100% high-flow oxygen. All eight recovered. The entire community was shocked and deeply saddened by this event. The surviving EMT expressed profound remorse for not having saved his partner.

UNIQUE CONSIDERATIONS

During World War I, both AC and CK were used as chemical warfare agents. Neither form of cyanide was highly successful as a weapon, partly because of the incomplete filling of projectiles and partly because of the use of bursting charges that set most of the hydrogen cyanide on fire.

AC is formed when a cyanide salt is mixed with an acid. Hydrogen cyanide is a liquid that boils at 25.6°C (78.1°F) but evaporates rapidly at usual temperatures. The vapor and gas are lighter than air and persist for only

a few minutes in the open atmosphere. These factors made AC difficult to disperse in a lethal concentration using relatively small payloads on the open battlefield.

CK is similarly released when a saturated solution of potassium cyanide salt is mixed with chlorine. Cyanogen chloride boils at 13.8°C (56.8°F), and its vapor and gas are heavier and less volatile than AC. The toxicity of CK is similar to that of AC, but CK had the additional mucosal-irritant and pulmonary effects of its chlorine component.

During World War II, the Nazis used AC absorbed onto Zyklon B, a dispersible pharmaceutical base, as a means for prisoner extermination within the confined space of death-camp gas chambers. During the 1980s, Iraq is reported to have used cyanide-like agents in incidents involving Syria,³⁵ Iraqi Kurds,³⁶ and possibly Iran.³⁷ The largest industrial chemical disaster in world history occurred in Bhopal, India, in 1984. The Bhopal disaster killed over 2500 persons and affected an additional 200,000 to 300,000.³⁸ Although methyl isocyanate contains a cyanide moiety, methyl isocyanate itself is primarily a pulmonary agent that causes pulmonary edema at moderate doses and has additional irritative effects on larger (central) airways at higher doses.^{38,39}

AC is still used in modern gas chambers for capital punishment in a process involving the reaction of cyanide salts with acid. Precursors of AC were also found in several Tokyo subway restrooms in the weeks after the 1995 sarin nerve agent attack in that city.¹ Cyanide has been implicated in the covert poisoning of commercial foodstuffs¹ and drug products,⁴⁰ and terrorists are reported to have expressed an ongoing interest in the use of cyanide compounds—including chemicals from industrial sources—as weapons.^{41,42}

Inhalation and ingestion are the most likely routes of exposure in mass casualties during a terrorist event. Dermal toxicity can occur with cyanide but is less likely to affect large numbers compared with inhalation or ingestion. Dispersing a respirable aerosol in the open atmosphere requires a high-energy-generating system to produce the small particle size, appropriate weather conditions to ensure that the aerosol cloud stays near the ground, and adequate concentrations of the agent to produce the toxic effect.¹ The release of cyanide vapor or gas within an enclosed public space or building would likely maximize its potential toxicity and minimize the difficulty of its deployment for inhalational exposure. However, a large amount of liquid is required to produce vapor sufficient to cause mass casualties.¹ Introduction of cyanide, probably as cyanide salts, into the food and water supply may be another feasible scenario that could seek to exploit the physical and toxicologic characteristics of cyanide. Inhalational exposure to lethal concentrations of cyanide gas usually kills within minutes. Odor thresholds for AC are highly variable, and 40% to 60% of adults cannot detect its characteristic smell of bitter almonds.^{43,44} CK may be more readily detectable by the victim because of its chlorine-like irritation of the eyes, lungs, and mucous membranes. After exposure to lower concentrations, or exposure to lethal amounts via ingestion, the effects are slower to develop.

TABLE 94-1 OVERVIEW OF RECOMMENDATIONS FOR DETECTION, DECONTAMINATION, AND THERAPY OF CYANIDE EXPOSURES

Likely method of dissemination	1. Liquid, aerosol, vapor, or gas 2. In water or food
Odor	Bitter almonds (although description is variable)
Vapor heavier than air	AC: No CK: Yes
Persistency in soil >24 hours	Nonpersistent
Detection equipment	Military: <i>AC vapor or gas:</i> M256A1 kit, ICAD <i>CK vapor or gas:</i> M256A1 kit Commercial: Draeger CDS kit
Skin decontamination solution ²⁸	Wet decontamination is usually not necessary for vapor exposure. For liquid or solids: water with or without soap (preferred); 0.5% sodium hypochlorite solution (bleach water) (usually not necessary).
Onset of symptoms	Immediate
Mild effects	Dizziness, nausea, feeling of weakness
Severe effects	Gasping, syncope, seizures, apnea, asystole
Adult therapy ²⁹	Amyl nitrite: 1 amp (0.2 mL) for 30 to 60 seconds along with 100% oxygen until IV access is obtained Sodium nitrite: 300 mg (10 mL 3% sol) IV over 5 to 20 minutes; slow infusion if patient develops hypotension Sodium thiosulfate: 12.5 g (50 mL) IV delivered over 10 minutes; repeat at half initial dose in 1 hour if symptoms persist Lorazepam: 4 mg IV/IM over 2 to 5 minutes and repeated as needed
Pediatric therapy ²⁹	Amyl nitrite: Pediatric dose not established Sodium nitrite: 0.33 mL/kg of 10% solution IV over 5 to 20 minutes, not to exceed 300 mg Sodium thiosulfate: 1.65 mL/kg of 25% solution over 10 minutes, not to exceed 12.5 g; repeat in 1 hour at half initial dose if symptoms persist Lorazepam: 4 mg IV/IM over 2 to 5 minutes; repeat as needed
Supportive therapy	Assisted ventilation

TABLE 94-2 TRIAGE RECOMMENDATIONS FOR CYANIDE MASS CASUALTIES³⁰

TRIAGE CATEGORY	CLINICAL SIGNS	RECOMMENDED INTERVENTION
Minimal	Conscious and breathing	No antidotes, no oxygen
Immediate	Convulsions and apnea	Antidotes and oxygen
Delayed	Unconscious but breathing	Antidotes and oxygen
Expectant	No cardiac activity	No care unless resources are available for resuscitation

Ingestion of a lethal dose of cyanide may allow for a 15- to 60-minute window of survival time during which antidote may be administered, although loss of consciousness has been reported in as little as 1 minute following ingestion of a high dose of liquid cyanide or cyanide in solution.

PITFALLS

There are several factors that may complicate a timely and accurate diagnosis in the event of a cyanide attack. These include the following:

1. Cyanide toxicity is not a common patient presentation and clinicians may have little or no experience in diagnosis. Sublethal symptoms are often non-specific, and lethal exposures may present as nonspecific cardiorespiratory arrest.
2. Measurements of blood cyanide levels are almost never available during the treatment phase, although laboratory determination of a decreased arteriovenous oxygen gradient can usually be performed relatively quickly and can serve as a valuable indicator of exposure.
3. Cyanide levels tend to fall in stored samples because of the short half-life of the compound.

Signs and symptoms of cyanide toxicity are often relatively nonspecific and may offer little indication of the causation in absence of other historical data. Early signs and symptoms may include transient hyperpnea,

headache, diaphoresis, flushing, weakness, vertigo, dyspnea, and findings of central nervous system excitement progressing to seizures. With high inhalational doses, gasping may be nearly immediate and may progress to collapse, apnea, and convulsions within 30 to 60 seconds, with death ensuing within 6 to 8 minutes. In the case of CK exposure, victims may also complain of irritation of the eyes and mucous membranes. Cyanide casualties are classically described as having flushed skin rather than cyanosis, but many patients are nevertheless cyanotic.⁴³ The telltale odor of bitter almonds may not be always be appreciated because 40% to 60% of the population lacks the gene that enables detection of this odor.^{44,45} Late-appearing indications of central nervous system depression, such as coma and dilated pupils, are prominent but nonspecific signs of cyanide intoxication.

Antimuscarinic Agent Attack

Fermin Barrueto, Jr. and Lewis S. Nelson

DESCRIPTION OF EVENT

There are five recognized muscarinic receptor subtypes (M1 through M5) located primarily within the parasympathetic nervous system and the brain. Peripherally, they are located postsynaptically on secretory organs and glands; and within the CNS, they are concentrated in various areas such as the striatum, the cerebral cortex, and the hippocampus. Muscarinic antagonists such as atropine, scopolamine, hyoscyamine, and 3-quinuclidinyl benzilate cause a constellation of signs and symptoms known as the *antimuscarinic*, or *anticholinergic*, toxidrome, because cholinergic activation of end organs is partially blocked. The clinical presentation is in general the opposite of that seen in the cholinergic crisis induced by nerve agents. The peripheral antimuscarinic effects are well described and include mydriasis, loss of visual accommodation leading to blurred vision, drying of mucous membranes, urinary retention, anhidrosis, hyperthermia, tachycardia, and hypertension. The central anticholinergic effects include confusion, delirium, memory loss, paresthesias, speech difficulty, characteristic hallucinations (e.g., concrete, describable, and Lilliputian—that is, decreasing in size over time), disrobing, picking and plucking (so-called phantom behaviors, or “woolgathering”), and, with very high doses, seizures.¹

It is precisely these central effects for which antimuscarinic chemical warfare agents were developed. The anticholinergic toxidrome is sometimes summarized as being exemplified by patients who are “blind as a bat” (from mydriasis and paralysis of accommodation), “dry as a bone,” “hot as a hare,” “red as a beet,” and “mad as a hatter”—the first four representing peripheral effects and the final description referring to effects in the central nervous system (CNS). These agents are classified as *incapacitating*; that is, they are neurotoxic but not typically lethal. The intent of dispersing these agents is to prevent a military force from performing its duties efficiently or to disrupt a military or civilian infrastructure. A similar syndrome can be seen after the ingestion of jimson weed due to natural scopolamine-like agents found in the seeds; this plant could theoretically be used as a source for antimuscarinic agent.

Although atropine is the prototypical antimuscarinic agent, 3-quinuclidinyl benzilate, or QNB (North Atlantic

Treaty Organisation [NATO] code, BZ), is the prototype for use as an incapacitating agent because of its physicochemical properties (which allow it to be dispersed easily and which make it resistant to heat and persistent in the environment for weeks), its potency, and its high safety ratio.¹ BZ was produced in the United States in the early 1960s and received its NATO code either because it was a benzilate or because of the “buzz” associated with its use (it was also known as “Agent Buzz”).^{1,2} Destruction of U.S. stockpiles of BZ began in the 1980s when it was realized that this agent was unpredictable and had little practical utility.² BZ is now primarily used as a research marker in Alzheimer’s disease.^{3,4}

BZ is an odorless crystalline solid that can be absorbed by many routes (e.g., intramuscular, intravenous, inhalation, oral, transdermal), but a chemical attack would likely involve inhalation of aerosol or ingestion of contaminated food or water.² This agent is a more potent competitive antagonist of muscarinic acetylcholine receptors than is atropine. The onset of peripheral antimuscarinic signs and symptoms after inhalation of an aerosol is usually between 20 minutes and 4 hours after exposure but can be delayed if delivery occurs by other routes.² Hallucinations appear approximately 6 hours after exposure and may persist for up to 3 to 4 days. BZ is very potent but has a wide safety profile, with an IC_{50} (the concentration-time product at which half of an exposed group will become incapacitated) of only 112 $mgzmin/m^3$ but an LC_{50} (the concentration-time product at which 50% of those exposed will die) of 200,000 $mgzmin/m^3$ —a safety factor of nearly 2000²; its intraperitoneal LD_{50} (the dose at which 50% of those exposed will die) in mice is 18 to 25 mg/kg .⁵

It has been alleged that Bosnian Serbs used BZ in July 1995 against 15,000 Bosniak civilians fleeing from Srebrenica to Tuzla.⁶ Although survivors experienced hallucinations and believed that they were victims of a chemical attack, some believe that stress, starvation, and exhaustion were more likely causes.⁶

PREINCIDENT ACTIONS

The temporally related presentation of a group of patients with the combination of peripheral and CNS

signs and symptoms of the antimuscarinic toxidrome should raise the suspicion of a chemical attack with an antimuscarinic agent. Such an event should prompt notification of local and state health departments. The local hospital disaster plan should be implemented immediately so that proper measures can be taken for decontamination, prevention of secondary exposures, and efficient management of a mass-casualty event. The availability of the antidote, physostigmine, should be checked, and the number of patients who could be treated in the event of a mass exposure should be ascertained.

POSTINCIDENT ACTIONS

Physical examination, history, and epidemiology are the primary tools to assist with diagnosis. Hospital-based laboratory confirmation of BZ is not readily available, and no standard laboratory tests will assist with the diagnosis. A gas chromatography/mass spectrometry confirmatory urine test is available through health authorities,⁷ although the results will not be available in a clinically relevant fashion. Clinical response to the administration of physostigmine can be a practical diagnostic aid.

MEDICAL TREATMENT OF CASUALTIES

Initial treatment involves removing patients from the exposure. The removal of clothes and decontamination of skin with water is indicated if the exposure occurred through ambient aerosol exposure or from transdermal exposure but is not indicated if contaminated food was the source. Standard precautions with the addition of eye protection and neoprene or butyl rubber gloves should be used by healthcare providers to prevent secondary exposure.² Assessment of the patient's hemodynamic status and airway are necessary; however, the most challenging issue may be controlling the patient's agitated delirium. Behavioral control should be easily accomplished by titrating a benzodiazepine, such as diazepam, lorazepam, or midazolam, to sedation along with judicious use of soft physical restraints. It should be remembered that use of physical restraints can exacerbate body heat retention from excess muscular activity, if a patient is attempting to resist restraint, and may contribute to hyperthermia. Benzodiazepines should be in plentiful supply for most hospitals and can be as practically efficacious as the antidotal use of physostigmine.⁸ Antipsychotic sedatives such as haloperidol are probably best avoided or used only in combination with benzodiazepines. Patients can die from too high a dose of BZ, from self-injury related to hallucinations or illusions, or from heat stress caused by anhidrosis. Careful attention to body temperature should always be a component of supportive care of patients who have been exposed to BZ.

The antidote to poisoning by an antimuscarinic agent is physostigmine, an acetylcholinesterase inhibitor. Physostigmine, a nonpolar tertiary-amine carbamate, crosses the blood-brain barrier, reversibly binds with tissue acetylcholinesterase in postsynaptic membranes, and

temporarily increases the concentration of acetylcholine in the synapse. This extra acetylcholine competes with BZ for occupancy of postsynaptic muscarinic receptors and helps to overcome the cholinergic blockade induced by BZ.⁸ Although physostigmine is clinically beneficial, its reversible binding mandates multiple repeat intramuscular dosing every 30 to 60 minutes (or careful calibration of an intravenous drip) and makes its use labor-intensive and practical only with a few patients at a time. For example, a patient given 6.4 mg of BZ intramuscularly required 200 mg of physostigmine over 72 hours to maintain normal functional competence.⁹ Although safe when used in small titrated amounts and with frequent clinical reassessment, physostigmine can cause cholinergic effects such as dyspnea, apnea, bradycardia, and seizures if administered too rapidly. In a mass-casualty incident, physostigmine and the personnel to administer it and to monitor its use would be in short supply. In these situations, benzodiazepines would be best for safe, rapid, and effective management.

Vomiting should not be induced if the agent has been ingested. The use of orally activated charcoal in this situation, although likely safe in an alert patient, has not been evaluated. Clinical laboratory investigation, including cerebrospinal fluid analysis, should be performed as indicated, at least until the diagnosis is clear. This will allow

CASE PRESENTATION

Over a period of 48 hours, 12 patients who are known to abuse heroin presented to a single hospital emergency department with agitated delirium. Their vital signs revealed mild hypertension, tachycardia, and temperature elevation to 38.3°C (101°F) in several patients and to 40°C (104°F) in a few. Their physical examinations showed markedly dry skin and mucous membranes along with a mumbling incoherent speech and random movements on the stretcher. Their pupils were in most cases large (6 mm), a finding that was particularly atypical for heroin users, who generally have notably small pupils. Several patients were unconscious, and after receiving naloxone, developed an agitated delirium similar to that described in this chapter. Patients were restrained, sedated with benzodiazepines, cooled as needed, and given fluids intravenously.

An outbreak of encephalitis was initially considered, and several patients had lumbar punctures to obtain cerebrospinal fluid for analysis, which always yielded normal results. When the possibility of an anticholinergic agent was being considered, one patient was evaluated for possible contraindications to physostigmine administration and was then given 2 mg of physostigmine intravenously over 5 minutes. This patient, who initially was delirious and hallucinating, became alert, oriented, and able to give a history of insufflating what he had believed to be heroin. A sample of this heroin was obtained and analyzed by public health authorities, revealing synthetic scopolamine. (This case was adapted from an epidemic in the United States 1995-1996.¹⁰)

FIGURE 95-1. Hydrolysis of 3-quinuclidinyl benzilate (BZ) will occur at pH > 11.

the clinician to exclude other diagnoses, including infectious etiologies, because these patients will often present with temperature elevation (due to psychomotor agitation and anhidrosis) and an altered mental status.

- Failure to restrain potentially disruptive patients who have been exposed to BZ
- Failure to recognize the potential for heat stress in anhidrotic patients who have been exposed to BZ

UNIQUE CONSIDERATIONS

Complications resulting from exposure to BZ include acute-angle closure glaucoma secondary to the mydriasis, rhabdomyolysis due to psychomotor agitation, ileus, urinary retention requiring Foley catheterization, pneumonia or hypoxia due to prolonged stupor or aspiration, and heat damage from heat retention secondary to anhidrosis.

3-Quinuclidinyl benzilate is a bicyclic ester that will hydrolyze in an alkaline solution of pH > 11 to benzilic acid and 3-quinuclidinol within minutes; both of these hydrolysis products are much less toxic than the parent compound (Figure 95-1).^{5,11} This may be relevant in decontamination of surfaces and medical equipment.

PITFALLS

Several potential pitfalls in response to a nerve agent attack exist. These include the following:

- Disorganization of hospital and local emergency medical services, should they become overwhelmed by many patients with agitated delirium
- Failure to recognize that numerous patients requiring attention (including restraint in many cases) will mandate efficient allocation of hospital resources and personnel to avoid resource depletion and staff exhaustion
- Inadequate decontamination of patients exposed externally, resulting in secondary exposure to health-care workers, particularly rescue workers and paramedics
- Failure to be diligent in identifying other injuries when confronted with multiple patients
- Failure to suspect the diagnosis of an antimuscarinic agent, resulting in the administration of medications with antimuscarinic effects (e.g., haloperidol) that may worsen the patient's condition

LSD, Other Indoles, and Phenylethylamine Derivative Attack

Fiona E. Gallahue

DESCRIPTION OF EVENT

d-Lysergic acid diethylamide (LSD), an indole alkylamine, also known as LSD-25, was discovered by Albert Hofmann in 1938 while he was working for Sandoz Company. In 1943, Hofmann became intoxicated by LSD through accidental exposure, and 3 days later he intentionally took LSD. His experience with LSD paved the way for neuropsychiatric studies using LSD and later, in 1951, for U.S. Central Intelligence Agency (CIA) experimentation with human subjects using LSD and similar mind-altering drugs. The results of most of these CIA experiments are still classified, but some documents that have been made available describe how the American government intended for LSD to be used as a weapon. Psilocin and psilocybin, indole alkylamines derived from hallucinogenic mushrooms, were also considered and allegedly tested. Mescaline, a phenylethylamine derivative derived from the peyote cactus, was also reportedly selected for testing on human subjects. Because these substances have cross-tolerance and similar side effects and treatment, and because they were once considered by the American government as potential chemical weapons, we will narrow our focus to these hallucinogens rather than including the entire spectrum of phenylethylamine derivatives (e.g., 3,4-methylenedioxyamphetamine [MDA] and related amphetamines) or the other indole alkylamines (e.g., bufotenine, ibogaine).^{1,2}

LSD, mescaline, peyote, psilocin, and psilocybin have all been classified as Schedule I drugs since the passage in 1970 of the Controlled Substance Act. These agents have somewhat similar (although not identical) effects but differ in potency: 1000 mcg of mescaline is equivalent to 1.0 mcg of LSD or 100 mcg of psilocybin.³

LSD, the most potent of these drugs, is generally taken orally at doses between 1 and 16 mcg/kg. There is a proportional relationship between the dose and the psychophysiologic effect of LSD, with 50 to 100 mcg constituting a mild dose, 100 to 250 mcg representing a moderate dose, and 250 to 500 mcg considered to be a strong dose.^{4,5} LSD is odorless and tasteless and is usually ingested orally, although it can be smoked, snorted, or injected. It has a plasma half-life of 100 minutes but can

be detected in plasma or urine for up to 3 days, and it is metabolized in the liver, with urinary excretion of metabolites.⁶ The clinical effects begin within 30 to 60 minutes and peak at 2 to 4 hours; the majority of the symptoms resolve within 12 hours.^{5,7,8} Studies conducted in simulated military settings demonstrated that even well-trained units become totally disorganized after ingesting total oral doses of less than 200 mcg.⁹ Affected persons usually cannot carry out a series of instructions or concentrate on a complex task, but they might be capable of isolated impulsive actions. Behavior is said to be unpredictable although well coordinated.⁹

Although LSD has an LD₅₀ (the amount needed to kill 50% of an exposed group) of 14,000 mcg (nearly 30 times the 500-mcg strong dose), LSD is not considered a safe drug.¹⁰ Acute psychotic reactions have been reported. Trauma resulting from accidents or self-destructive behavior, suicide, or homicide can occur; deaths from LSD are more likely from these effects than from the direct toxicity of the compound.^{1,7,11}

LSD resembles serotonin chemically and acts on serotonin and dopamine receptors. Sympathomimetic effects commonly seen with LSD intoxication include dilated pupils, tachycardia, hypertension, and hyperreflexia.^{5,6} The mind-altering properties of LSD can cause euphoria, anxiety, and paranoia with intense visual and auditory hallucinations that tend to be abstract, colorful, expansive, and often ineffable (in contrast to the concrete, lilliputian, and easily describable hallucinations from anticholinergic compounds). Synesthesia (sensory crossover) is frequently present, although tactile hallucinations are uncommon.^{6,7} Abnormalities of serotonin-induced platelet aggregation may result in abnormal clotting and poor clot retraction. Although cardiovascular complications are infrequent, reports exist of supraventricular tachycardia and myocardial infarction.⁶ Severe manifestations of toxicity include hyperthermia, seizures, and rhabdomyolysis.⁸

Mescaline is a hallucinogenic alkaloid derived from the North American peyote cactus and that also occurs in several species of the genus *Trichocereus* of South American cacti. Mescaline, or 3,4,5-trimethoxyphenylamine, can be taken directly from the peyote cactus or derived synthetically. The ritual use of mescaline-containing cacti is

documented from the sixteenth century; mescaline itself was first isolated from peyote in 1896 and was first synthesized in 1918. Peyote is commonly ingested in the form of brown discoid "mescal buttons," which are the sun-dried crowns of the cactus. Each button may contain 45 to 100 mg of mescaline. The hallucinogenic dose is 5 mg/kg. Taken orally, mescaline is rapidly absorbed from the gastrointestinal tract and has an unpleasantly bitter taste. It can also be taken intravenously with similar side effects and with a similar duration of effects. (The popular Mexican liquor called *mescal* does not come from peyote and does not contain mescaline.)

The effects of mescaline begin within 30 minutes to 2 hours of ingestion and peak at about 4 hours, with a total duration of 8 to 14 hours. Like LSD, mescaline is metabolized in the liver and excreted in the urine. Clinically, the effects are similar to those of LSD but with the additional initial symptoms of nausea, vomiting, sweating, generalized discomfort, dizziness, and headache, all of which generally occur during the first hour after ingestion and shortly before the onset of hallucinogenic effects. Large doses can produce hypotension, bradycardia, and respiratory depression.^{5,7}

Psilocybin (4-phosphoryloxy-*N,N*-dimethyltryptamine) and psilocin (4-hydroxyl-*N,N*-dimethyltryptamine) are members of the indole alkylamine hallucinogens derived from tryptophan. These drugs were first isolated in 1958 from hallucinogenic mushrooms used by Mexican Indians for centuries. Psilocybin is more resistant to oxidation than psilocin and retains its activity in dried mushrooms. Psilocin is approximately 1.5 times as potent as psilocybin, but otherwise these two drugs are pharmacologically similar; in fact, psilocin is the active metabolite of psilocybin in the body. A 100-mcg dose of psilocybin is equivalent to 1 mcg of LSD and 1000 mcg of mescaline. The LD₅₀ of intravenous psilocybin has been reported to be 280 mg/kg.³

Peyote mushrooms can be ingested raw, dried, as a brew, or stewed. The dose to produce hallucinogenic effects in nontolerant adults is approximately 6 to 12 mg. Little correlation has been found between clinical effects and the number of mushrooms ingested. Approximately 50% of the hallucinogenic compounds are absorbed via the gastrointestinal tract, and distribution occurs to most tissues, including the brain; most excretion is renal. Signs and symptoms develop within 30 to 60 minutes, with the psychedelic effects peaking between 30 minutes and 2 hours and lasting from 3 to 15 hours.^{3,5,10} Both compounds primarily affect serotonergic neurotransmission. Clinical effects of the drug are mostly sympathomimetic and include pupillary dilation, piloerection, tachycardia, and hyperreflexia. The hallucinations are usually visual but may be auditory or tactile. Both dysphoria and euphoria are commonly reported mood alterations. Nausea, cramping, abdominal pain, and a sensation of swelling of parts of the body are potential adverse responses. Deaths from psilocin and psilocybin are rare but have been reported from ingestion by a 6-year-old child who experienced hyperthermia and status epilepticus.⁵

All of these drugs have cross-tolerance to each other; the tolerance develops rapidly (within days) without the

development of physical dependence and also regresses rapidly, within 3 to 4 days of withdrawal.

Flashbacks, or recurrences of hallucinogenic imagery days to years after the initial experience, have been described often with LSD but also with mescaline. Their etiology is unknown, but these flashbacks do decrease in their intensity with time and can be treated adequately with benzodiazepines in significantly affected patients. Flashbacks can be precipitated by triggers such as stress, exercise, and illness.⁵

LSD chemically resembles serotonin and interacts with the 5-hydroxytryptamine, or 5-HT, receptor. As might be expected, there is evidence (from a small retrospective cohort study by Bonson and Murphy¹²) of cross-reactivity between LSD and various antidepressants. In this study, patients taking selective serotonin-reuptake inhibitors (SSRI agents) and monoamine oxidase inhibitors reported decreased responses to LSD, whereas those taking tricyclic antidepressants and lithium experienced increased responses. Psilocybin also chemically resembles serotonin, and similar interactions might be expected between psilocybin and these antidepressants.

Since LSD is the most potent of these agents, the most difficult to detect (being odorless and tasteless), and the compound that was reportedly most tested by governmental agencies in the 1960s, this agent may be the most likely of the indoles and phenylethylamine derivatives to be used in an attack.¹³

Difficulties in covert distribution of LSD limit its utility as a chemical weapon. The compound could be released into water, but impossibly high quantities would be needed to contaminate a large water source such as a reservoir. Moreover, chlorine in concentrations found in water-treatment plants can deactivate LSD by oxidation. Delivery distal to such treatment facilities is possible but also impractical (because of dilution) even for someone intent on targeting a single building.¹ LSD could also be delivered in an aerial drop so that a bomb filled with LSD would explode at ground level or several feet above the ground. The local population would become intoxicated through inhalation.¹ LSD could potentially be aerosolized, but it would have to be dispersed relatively close to the intended targets, a mode of delivery that might be acceptable to some but perhaps not all terrorists, depending on the situation. With a particle size of approximately 5 microns, the ID₅₀ (the dose that incapacitates 50% of the exposed population) was estimated to be 5.6 mcg/kg, approximately twice the ID₅₀ of the parenteral route.⁹

If an immediate effect in a particular location is desired, the fact that LSD has a latent period of 30 minutes or longer might be a disadvantage, since exposed victims might well have moved to different areas by the time that they begin hallucinating. However, this delay in action might be advantageous in a covert release of agent. Another potential problem is the fact that SSRI antidepressants are used commonly in the American populace and might have protective effects in these patients. Nevertheless, biologic variability is likely to ensure that a significant proportion of intended victims will still be affected.

PREINCIDENT ACTIONS

Hospitals and emergency personnel should be well trained for the event of a potential chemical weapons attack. Protocols for these events should include removal of the victims from the contaminating source and the use of protective equipment to avoid inhalation, ingestion, or transdermal exposure to the toxicant. Although person-to-person transmission of LSD from a terrorist attack would not be expected, aerosolized LSD could theoretically remain on skin, clothing, or environmental surfaces; whether secondary aerosolization would be significant for this compound would depend on a multitude of as-yet-uninvestigated variables. If settling of aerosolized product on skin or clothing is of concern, washing of the skin with water (with or without soap) and washing of clothes would likely suffice. Since LSD detection equipment is not readily available, the detection of small amounts covertly released into the environment could be difficult.

POSTINCIDENT ACTIONS

LSD and similar hallucinogenic agents in a mass-casualty event should be relatively easy for most clinicians to detect clinically, given the onset of action of approximately 30 to 60 minutes, the sympathomimetic effects, and the types of hallucinations induced. LSD intoxication would be difficult to distinguish from poisoning by the other psychedelic indoles and by phenylethylamine derivatives, but management of all these types of cases is similar. The differential diagnosis also includes acute panic reactions, schizophrenia, and exposure to phencyclidine (PCP), amphetamines, and anticholinergic compounds.¹⁴ The appropriate authorities should be contacted to identify and eliminate the contaminating source.

MEDICAL TREATMENT OF CASUALTIES

Treatment is usually supportive, and patients can often be managed adequately without medications if they can be reassured and treated in a calm, quiet area.¹⁵ Some patients with more severe agitation may require medication. In this situation, a moderately long-acting benzodiazepine such as lorazepam 2 mg or diazepam 5 mg administered intravenously would be the best choice. Although haloperidol 5 mg given intramuscularly/intravenously or 10 mg given orally can also be used effectively for LSD-induced agitation not responding adequately to benzodiazepines, it should not be used routinely for drug-induced hallucinations. Haloperidol and the phenothiazines are contraindicated for patients with anticholinergic poisoning, which could be mistaken for LSD psychosis without a careful examination.

CASE PRESENTATION

A number of patients are brought from an insurance office in the middle of the week to your emergency department with the complaint of “agitation.” On arrival, they appear to be hallucinating. Some are intensely panicked, whereas others appear to be distracted and calm.

You examine one of these patients, a 40-year-old administrative assistant with no past medical history. She has no complaints, although some of her answers to you are incoherent and inappropriate. On examination, her blood pressure is 160/90 mm Hg, her heart rate is 110 beats per minute, and her oral temperature is 37.8°C (100.0°F). Her pupils are dilated, she is slightly diaphoretic but otherwise well, and she seems relatively calm in the quiet area to which she has been taken.

A few minutes later, one of her coworkers, who has been positioned near the busy ambulance bay, starts thrashing around requiring benzodiazepines for sedation. Another coworker, who had left the office for a meeting but returned to find a number of his colleagues in this state, asks to speak with you. In trying to recall any unusual events in the office, he mentions a bottled-water delivery from a new supplier today. Shortly after your conversation, you get a call notifying you to expect another group of patients who are “agitated” from a legal office in the same building as your current group of agitated patients. Later, while discussing the cases with a coworker, you find out that the legal office also had a bottled-water delivery that day.

UNIQUE CONSIDERATIONS

Because LSD can be oxidized by large amounts of chlorine, contaminated water sources could potentially be appropriately treated and used safely.

Because LSD, mescaline, and psilocybin are rapidly metabolized and are excreted primarily in the urine, these drugs can be most easily detected in the urine through an immunologic method such as the enzyme multiplied immunoassay technique (EMIT) for confirmatory testing.¹⁶

Some studies have suggested that SSRI agents may decrease the severity of the effects of LSD and psilocybin. In certain situations, it may be useful to consider using SSRIs as protective medications for personnel at high risk for being exposed to LSD. However, more testing needs to be done before a definitive recommendation can be made.

PITFALLS

Several potential pitfalls exist in responding to an attack. These include the following:

- Failure to notify the appropriate agencies to find the source of the contaminating drug
- Failure to use proper protective equipment in removal of patients, causing additional victims

- Failure to remove hallucinating patients to a quiet, controlled area
- Failure to consider amphetamines, anticholinergic agents, schizophrenia, and acute panic reactions in the differential diagnosis
- Use of haloperidol for hallucinations without being certain of the cause

ACKNOWLEDGMENTS

I would like to especially thank Dr. Lewis Nelson, Dr. Robert Hoffman, and Mary Ann Howland, PharmD, from the New York Poison Control Center for their help and support.

Opioid Agent Attack

Rick G. Kulkarni

DESCRIPTION OF EVENT

In cultivation since circa 300 BCE, pure opium is a mixture of alkaloids extracted from the sap of unripened seedpods of *Papaver somniferous* (the Asian, or opium, poppy). Opiates, such as heroin, codeine, and morphine, are natural derivatives of these alkaloids. Synthetic opium-like narcotic compounds, such as oxycodone, meperidine, and fentanyl and its derivatives (e.g., carfentanil and sufentanil) are also available. Originally, *opioid* meant a synthetic narcotic not derived from opium, but the term is increasingly applied to opiates as well as to synthetic narcotics; *opiate* is still reserved for the naturally occurring alkaloids with a morphine or thebaine backbone.^{1,2}

The postsynaptic binding of opioids to receptors in the central nervous system (CNS) and in the gastrointestinal tract leads to hyperpolarization of neuronal cell membranes, inhibition of neurotransmission, and, depending on the affected cell population, either depression or excitation of end organs. The physiologic effects of opioids are mediated principally through three major kinds of opioid receptors: OP1 (δ), OP2 (κ), and OP3 (μ). All three types of receptors can mediate analgesia and respiratory depression, but OP1 (δ) receptors are responsible primarily for spinal analgesia, OP2 (κ) receptors are more selective for sedation (although they also mediate miosis, analgesia, and respiratory depression), and OP3 (μ) receptors are the most important for respiratory depression, miosis, constipation, and euphoria (with subsequent dependence in chronic users).³ The opioid antagonists (e.g., naloxone, nalmefene, naltrexone) have greater affinity for OP3 (μ) receptors than for OP1 or OP2 receptors and are all effective in reversing the respiratory depression associated with acute opioid overdoses. Naltrexone, however, is usually reserved for the treatment of opioid addiction.^{1,2}

CLINICAL PRESENTATION

Opioid toxicity characteristically presents with a depressed level of consciousness and should be suspected when the clinical triad of CNS depression, respiratory depression, and pupillary miosis are present. The

differential diagnosis of miosis also includes clonidine, cholinergic crisis (from cholinergic agents, organophosphorous pesticides, or nerve agents), phenothiazines, phencyclidine, and sedative-hypnotic drugs as well as pontine and subarachnoid hemorrhage. However, pupillary dilatation can be seen in hypoxic opioid patients as well as in persons exposed to mixtures containing both an opioid and an anticholinergic agent such as atropine or scopolamine. Drowsiness, euphoria, ventricular arrhythmias, and acute mental status changes are frequently seen. Often, intoxication leads to respiratory impairment with bradypnea and hypopnea. In moderate-to-severe opioid intoxication, the respiratory rate can be as low as four breaths per minute; and frank respiratory arrest can occur. Generalized seizures are infrequent and occur mostly in infants and children because of initial excitation of the CNS. Nystagmus is also infrequent but has been reported.^{1,2}

LIKELY AGENTS IN AN ATTACK

Oral ingestion and respiratory exposure are the two most likely routes of absorption in an opioid agent attack. Both routes provide easy absorption for most opioids. Peak effects are reached by 90 minutes after ingestion and within 10 minutes of inhalation.⁴ The synthetic opioid fentanyl and its derivatives as a group are the most likely agents to be used in a terrorist attack (Table 97-1).⁵ Their high potency (approximately 10 to 10,000 times that of morphine) and the fact that they can be aerosolized to induce unconsciousness and long-lasting respiratory depression in animals make them ideal agents in this regard.⁶⁻⁸

PREINCIDENT ACTIONS

Preparedness is the single most important action that can be taken to prevent mass casualties from an opioid attack. The critical factors in minimizing the number of casualties in such an attack are as follows: (1) reaching casualties as soon as possible; (2) securing the airway; (3) implementing assisted ventilation either noninvasively or invasively; and (4) rapid treatment with the

TABLE 97-1 CHARACTERISTICS OF OPIOIDS, INCLUDING FENTANYL DERIVATIVES

AGENT	OPIOID POTENCY (COMPARED WITH MORPHINE)	THERAPEUTIC INDEX*
Morphine	1	70
Meperidine	0.5	5
Fentanyl	300	300
Sufentanil	4500	25,000
Alfentanil	75	1100
Remifentanil	220	33,000
Carfentanil	10,000	10,600

*Therapeutic index = median lethal dose (LD₅₀)/lowest median effective dose (ED₅₀).

specific opioid antagonist naloxone. Recognition of the use of opioid agents as the primary contributing factor to the state of the victims is paramount, and in view of the relatively high profile given to chemical warfare agents such as nerve agents, a number of unconscious victims with respiratory depression (or apnea) and miosis who are not responsive to nerve agent antidotes should initiate the suspicion of other causes, including opioid agent attack. Communities at high risk for such an attack must familiarize their first responders, including firefighters, police personnel, and emergency medical technicians/paramedics, with the typical presentation and the differential diagnosis of a person exposed to such agents. In addition, consideration should be given to equip such personnel not only with devices to assist ventilation but also with naloxone.

Training and equipping of healthcare facilities in high-risk metropolitan areas for the treatment of a large number of patients exposed to an opioid agent is also an important link in the chain of adequate preparedness. Although there are no official position statements from government agencies or professional organizations addressing this specific possibility at this time, hospital disaster committees should include this topic in their general emergency preparedness plan. At a minimum, high-risk areas should be able to provide on-scene emergency medical services (including fast rescue and supportive care during transport), noninvasive and invasive artificial ventilation to affected persons, and sufficient doses of naloxone.^{1,2}

POSTINCIDENT ACTIONS

Once an opioid agent attack is identified, a preformulated action plan must be activated immediately. An attack with an opioid agent will likely take place in an enclosed area containing hundreds of people. Implementation of the facility evacuation plan is the first step to isolate persons not already under the effects of the agent and to remove them from the affected area.

For those persons who are affected, rescue personnel wearing personal protective equipment should imple-

ment rapid control measures even before the arrival of medical personnel. These measures are fundamental for three important reasons:

1. Proper positioning of the patient in the left-lateral-decubitus position can prevent aspiration of gastric contents and can minimize the risk of the tongue falling back to occlude the airway.
2. The ability of the medical rescue team to deliver artificial ventilation and naloxone can be severely limited if the victims cannot be accessed easily (for example, victims sitting in the middle seats of rows in a theater may be difficult to reach where they are).
3. Without intervention, the ensuing confusion can create a situation in which persons are not properly categorized or treated.

Because local supplies of antidotes can be rapidly depleted in a mass-casualty situation, additional stocks of naloxone should be requested early from adjoining communities.^{1,2}

Appropriate local, state, and federal public-health and law-enforcement authorities should be notified.

MEDICAL TREATMENT OF CASUALTIES

Treatment should be tailored to the clinical presentation of victims. For those who are awake and not disoriented, the only intervention necessary may be to escort the victims into an open area outside the zone of contamination. Those who are sleepy or just lethargic but who are easily arousable should also be escorted to an open area and kept under observation for progression of symptoms. Patients who are unconscious but still breathing should also be moved to an open area and administered adequate intramuscular doses of naloxone in 2.0-mg increments (0.1 mg/kg for pediatric patients) to awaken them. The onset of antidotal effects after intramuscular naloxone administration is 1 to 3 minutes, with maximal effects observed within 5 minutes. Repeat doses are indicated for partial response and can be repeated as often as needed. Because the clinical half-life of naloxone is between 20 and 60 minutes, assigned medical staff should observe patients for a period of no less than 1 hour to ensure that opioid effects do not recur. Nalmefene, if available, could be used in intramuscular doses of 0.5 to 1.0 mg, with a maximal efficacy seen at a total dose of 1.5 mg.

Finally, those patients who are unconscious with significantly depressed respirations or who are frankly apneic should receive immediate artificial ventilation, preferably with noninvasive techniques such as a bag-valve-mask device connected to 100% oxygen. They should also be given naloxone until they are awake and breathing spontaneously. These persons should be triaged and transported to local hospitals for continued administration of naloxone as needed and for further monitoring for at least 12 to 24 hours.

All affected victims should be examined and assessed for blunt trauma from possible falls resulting from

opioid-induced unconsciousness. If there is concern regarding neck injury or head injury, the patient should be placed on a backboard and into a cervical collar and should be transported to a local hospital for further evaluation and treatment.

Although opioids have not been used directly by terrorists in large-scale attacks, the potential of these agents to create mass casualties is illustrated by their use in October 2002 by Spetsnaz commando units of the Russian Federal Security Service (FSB) against Chechen terrorists who had taken control of a theater in Moscow.^{9,10} Minister of Health Yuri Shevchenko later identified the agent used as a fentanyl derivative, and it has been speculated that this opioid compound had been aerosolized either alone or in combination with an anesthetic agent. Approximately 120 hostages died. Shevchenko asserted that over a thousand doses of “antidote” were available and were used, but many casualties appear to have been removed from the theater and placed into positions, either on the ground or in buses, in which their airways were not secured.^{9,10} This incident demonstrates that use of an opioid agent on a large group of people can represent a major medical disaster and that proper evacuation of casualties and careful attention to airway and ventilation can be matters of life and death quite apart from the issue of antidotes. An attack can quickly overwhelm limited medical resources available in the affected area. Proper preparation and planning can help save lives in a catastrophic event.¹¹⁻¹³

UNIQUE CONSIDERATIONS

An opioid agent attack will likely take place in a closed space filled with hundreds of people because this combination presents an ideal opportunity for causing mass casualties. Because respiratory depression is the usual mechanism of death from opioid intoxication, absolutely crucial elements of response will include speed in reaching victims, evaluation of airway and breathing, and maintenance of airway and ventilation during and after evacuation from the scene. Naloxone should be administered as soon as is practical but is not so important in the immediate response as securing and maintaining an open airway and ensuring adequate ventilation. Naloxone stocks may become quickly depleted during an outbreak, and early consideration should be given to ordering more antidote.

Awareness for blunt trauma from falls sustained due to unconsciousness induced by the opioid agent and from potential mass hysteria during exit from an enclosed space should be considered.

Recognition by first responders, hazardous-materials teams, and other rescue personnel of the clinical picture of opioid exposure in humans and of the essentials of speedy rescue, appropriate evacuation, and the primacy of airway support and ventilation can make the difference between a relatively good outcome and a catastrophe involving hundreds of casualties. Although there have been no reported incidents of a terrorist attack

CASE PRESENTATION

The grand opening of a new concert hall in Los Angeles is today. The auditorium has a maximum capacity of 800 patrons and accommodates an additional 200 performers and support staff. During the first intermission, several patrons in the back of the concert hall report hearing a hissing sound. Two security-staff personnel are called to the scene of the noise and locate three large canisters hidden behind the curtains and vigorously discharging an odorless substance into the hallway. Before they can remove the canisters, they succumb to the unknown gas and fall unconscious to the floor. Moments later, several of the patrons in the vicinity of the reported noise begin to slump into their seats or to sit down in the hallways. Others complain of nausea and begin to vomit. In a few minutes, more patrons begin to experience similar symptoms in a progressive fashion toward the front of the stage. Approximately 5 minutes after the first group of people have begun to experience symptoms, the majority of the persons in the theater are unconscious. The performers and those at the front of the stage have panicked and are rushing for two clearly marked exits at the front of the concert hall.

Hazardous materials staff arrive at the scene, which was cordoned off by the police within 10 minutes of the first report. Entering the concert hall in personal protective equipment, they find hundreds of unconscious victims.

Many of the victims are not breathing. When the unit commander notes pinpoint pupils in every victim he examines, he immediately suspects a nerve agent attack and radios the operational commander to have nerve agent antidotes brought to the scene. Rescue team members inside the hall pull victims from their seats, move them to the aisles, and then remove them from the concert hall. Outside, the victims are placed on their sides to prevent aspiration of gastric contents, and their airways are secured. Two of the apneic patients are successfully intubated by paramedics, and artificial ventilation by bag-valve-mask is begun with no significant airway resistance noted. The lack of airway resistance and the failure of victims to respond to nerve agent antidotes leads to a consideration of the differential diagnosis of pinpoint pupils and to the possibility of an opioid agent attack. Naloxone from arriving ambulances is administered via intramuscular injection first to the apneic but not intubated patients, and when spontaneous respiration resumes within 2 or 3 minutes of injection in two of these patients, this finding is reported to the hospital and additional naloxone is requested. Most of the unconscious persons wake up and resume adequate respirations, but approximately 80 persons are declared dead at the scene despite receiving large amounts of naloxone. An additional five persons are declared dead at local hospitals. None of the rescuers are affected or succumb to the agent.

involving an opioid agent, the possibility of such an attack cannot be excluded. Increased vigilance among enclosed venues capable of holding hundreds of people is indicated.

PITFALLS

Several potential pitfalls in response to an opioid agent attack exist. These include the following:

- Failure to create a plan for mass treatment in the event of an attack
- Failure to staff and supply a high-risk area with adequate stocks of naloxone
- Failure to recognize or report an attack from an opioid agent
- Misdiagnosis of a victim of an opioid agent attack as one of nerve agent attack
- Delay in reaching casualties with respiratory depression or apnea
- Failure to position victims properly and to attend to airway and ventilation issues
- Failure to recognize the clinical presentation of opioid toxicity and to institute specific antidotal treatment with naloxone

Riot-Control Agent Attack

Sam Shen

DESCRIPTION OF EVENT

Riot-control agents are commonly known as “tear gas,” irritants, harassing agents, and lacrimators. These agents are used by the military for training purposes and by law enforcement officers for riot control. The North Atlantic Treaty Organization (NATO) has assigned these compounds two-letter codes. The agents include 1-chloroacetophenone (NATO code, CN), *o*-chlorobenzylidene malononitrile (CS), bromobenzylcyanide (CA), and dibenz (b,f)-1:4-oxazepine (CR). Oleoresin capsicum (OC), an oily extract of the capsaicin found in pepper plants, is also used by law enforcement officers and, often mixed with CN, in products for personal protection. Because of their long chemical names, they are generally referred to by their NATO codes except for OC, which is often called *pepper spray*. These compounds are similar in the following respects¹:

- Production of sensory irritation causing severe discomfort
- Quick onset of action
- Short duration of effects after exposure
- High safety profile (ratio of lethal to effective dose)

Diphenylaminearsine, or adamsite (DM), is an agent that causes vomiting and is also used for riot control, but it differs in several aspects¹:

- Its onset of action is delayed for several minutes after exposure.
- It produces nausea, vomiting, diarrhea, abdominal cramping, and other systemic effects (including headache and depression) in addition to the mucosal irritation characteristic of the other riot-control agents.
- It produces less severe effects on the skin.

When properly used, these agents can cause extreme discomfort and temporarily disable the victim.² Due to the high safety profile of these compounds, riot-control agents are an attractive option for incapacitation by military and law enforcement personnel. They are sometimes called *nonlethal*, or *less-lethal*, agents because their intent is to incapacitate rather than to produce serious injury or death and because of their high safety ratios; however, it should be kept in mind that a sufficiently high dose can prove fatal.

The first widely used agent was CN, which was developed in 1871; in about 1912, ethylbromoacetate was used to control riots in Paris.¹ As Mace, CN was also subsequently marketed for personal protection. Subsequent agents were developed that produced similar results but possessed better safety profiles, higher potencies, or both.³ CS is more potent and less toxic.³ It is the agent most commonly used today and was introduced for common civil use in 1967.^{4,5} CA was developed toward the end of World War I but is rarely used today. CR is the newest compound in this class and is the most potent, with a high safety profile and such low volatility that its effects deep in the lungs are minimal.¹ DM is primarily a vomiting agent but will be discussed as a riot-control agent because of its similar effects and management steps.

Riot-control agents are liquids or solids (“tear gas” is a misnomer) and can be dispersed as fine droplets or particles or in solution. They may be combined with an explosive substance in grenades or released as a smoke of particles from handheld devices.^{6,7} Consequently, the effects are from direct contact with skin, eyes, or mucous membranes and from inhalation.

EFFECTS OF RIOT-CONTROL AGENTS

Riot-control agents are nonlethal when used properly. Reports of death are infrequent and are usually due to toxic pulmonary damage leading to pulmonary edema.² Symptoms usually occur within 1 minute of exposure and last approximately 30 minutes.⁶ These agents have minimal long-term effects.⁵ The predominant systems affected are the eyes, nose, lungs, and skin.³

Eyes

The eye is extremely sensitive to irritants. Exposure to an agent will produce an intense burning sensation leading to tearing, blepharospasm, photophobia, and conjunctival injection.^{6,8} The victim will subsequently close his or her eyes reflexively. Although the vision of the victim will be near normal, the blepharospasm will hinder the ability of the victim to see. Most of these effects disappear in 20 minutes, although conjunctivitis may persist for 24 hours.³

In addition to the sensory effects, the ejection of the agent particles can cause blunt trauma to the cornea, and small particles can be embedded in the tissue of the eye.

Nose

If riot-control agents make contact with the mucous membranes of the nose, they will produce rhinorrhea, sneezing, and burning.^{3,8}

Lung

One of the more serious effects of riot-control agents involves the airways. In addition to a burning sensation, irritation of the bronchial lining can produce bronchoconstriction, coughing, and dyspnea. Effects from higher doses include pulmonary edema and chemical pneumonitis.² The agents can also worsen underlying lung disease such as asthma or chronic obstructive pulmonary disease.²

Due to numerous reported deaths in custody patients who had been exposed to OC, many of whom had been restrained, pulmonary function testing was studied in normal subjects given OC or placebo to inhale. OC does not result in abnormal spirometry, hypoxemia, or hypoventilation in either the sitting, or prone-maximal restraint position.⁹

Skin

If riot-control agents make contact with the skin, they will produce erythema and a burning or tingling sensation.² Prolonged exposure can produce vesicles and burns similar to thermal burns. These symptoms are exacerbated in hot or humid weather.²

Metabolic System

Some studies have suggested that CS can be metabolized to cyanide in peripheral tissues.^{2,10} However, the risk of cyanide toxicity from inhalational exposure to CS appears to be minimal.¹

Gastrointestinal System

Exposure can produce nausea, vomiting, and diarrhea.² DM is the riot control agent responsible for predominantly gastrointestinal symptoms in addition to mucosal irritation.

Pregnancy

One animal study showed no significant effects from CS on pregnancy.^{2,8}

PREINCIDENT ACTION

The effects of riot-control agents are usually self-limiting. Therefore, victims often will not seek medical care initially. Victims may seek assistance if symptoms persist or if complications develop. Emergency medicine physi-

cians should wear impermeable gloves and goggles to avoid exposure to the agents before treating casualties.^{3,6} Facilities should be prepared for the disrobing and showering of patients before they enter the emergency department.⁸

POSTINCIDENT ACTION

Since the agents are released into the air, evacuation is important to eliminate further exposure. Therefore, victims must be advised to do the following¹¹:

- Immediately leave the scene where riot control agents were released.
- Move to an area where fresh air is available.
- Move to higher ground, since riot-control agents can linger as dense, low-lying clouds.

MEDICAL TREATMENT OF CASUALTIES

There is no antidote for riot-control agents. Their effects are self-limiting and usually last no more than 15 to 30 minutes, although erythema of the skin may persist longer.¹ Medical management consists primarily of supportive care for each affected system. Initially, it is important to decrease any possible further contact with the agents through the following decontamination methods¹¹:

- Remove clothing that may have agent particles on it. Do not pull clothing over the victim's head. Instead, clothing should be cut off to minimize potential further contact.
- The victim should be washed with copious amounts of soap and water even though wetting of the skin may temporarily increase the severity of the burning sensation from the agent.

The specific management steps are directed to each system affected.

Eye

The first step involves blowing dry air into the eyes to help the dissolved agents vaporize.⁶ This should be followed by irrigation of the eyes with cold water or saline. If irrigation is performed before drying the eyes, one can prolong the burning sensation in the eyes. Although 5% sodium bisulfite was once recommended for treatment of exposure, its use is no longer advised.¹² A careful slit-lamp examination should be performed to evaluate for corneal impaction injuries secondary to the blast of the agent particles. If a corneal injury is present, any visible foreign bodies should be removed and topical antibiotics should be prescribed.

Lungs

The most serious complications occur in the lungs. Initially, humidified oxygen can provide relief. Inhaled beta-2 agonists may be given for dyspnea and bron-

chospasm.⁶ Because the clinical onset of pulmonary injury, especially pulmonary edema, can be delayed, patients should be admitted for observation. Victims should also be admitted if they have respiratory complaints or underlying lung disease.²

Skin

Any solid powder or smoke particles should be gently brushed from the skin. After copious irrigation with soap and water (a measure that may be briefly painful), burns should be treated the same as any other types of burns. If dermatitis or erythema persists, topical steroids or antipruritic agents may be applied.^{2,6}

- Failure to blow dry eyes before irrigating them with water or saline after exposure
- Failure to brush affected skin before washing with soap and water to eliminate further exposure
- Use of bleach for skin decontamination¹³
- Failure to admit patients with respiratory symptoms or underlying lung disease
- Failure to decontaminate any patient with riot-control agent contamination before loading onto a medical helicopter; the spread of such agents around the cockpit during flight could immobilize the pilot and endanger the lives of the patient and crew

CASE PRESENTATION

There has been an ongoing strike by workers at a local factory. The local news has reported that many protesters have become disruptive and violent. In fact, law enforcement officers were called to the site of the factory strike to restore order. Unfortunately, there were too many demonstrators to control safely. As the crowd of angry factory workers became more agitated, they began throwing objects at the police. Consequently, the officers had to use riot-control agents to contain the situation.

In the emergency department, emergency medical services personnel start to bring you patients complaining of shortness of breath, tearing, and burning sensation in their eyes, nose, and skin.

UNIQUE CONSIDERATIONS

Riot-control agents are fast-acting compounds that cause significant discomfort but are nonlethal when used properly. Whereas other chemical agents may cause worsening of symptoms over time, symptoms of riot-control agents often recede with time. Death is rare and, when it occurs, usually ensues from pulmonary complications. Symptoms will improve over time without long-term sequelae, so supportive care is the main treatment.

PITFALLS

Several potential pitfalls exist in treating injuries involving riot-control agents. These include the following:

- Failure to evacuate victims from area of exposure
- Failure to remove clothing or any materials that may have come in contact with the agents from the victims

Nicotinic Agent Attack

Sage W. Wiener and Lewis S. Nelson

DESCRIPTION OF EVENT

Nicotine has long been recognized as a toxin in humans by reason of its action as a direct agonist at the nicotinic family of acetylcholine receptors (a family in fact defined by the affinity for nicotine). These receptors are present at the neuromuscular junction (NMJ), in both sympathetic and parasympathetic ganglia, and in the central nervous system (CNS).¹

More recently recognized nicotinic acetylcholine receptor agonists include epibatidine and anatoxin-a, among others.¹⁻³ Epibatidine is derived from the skin of the *Epibatobades* frog (a species of “poison dart” frogs) and has been studied as an analgesic that acts through incompletely understood central nicotinic cholinergic pathways.⁴ Anatoxin-a is found in species from several genera of cyanobacteria (formerly known as blue-green algae).³ It should not be confused with *amatoxin*, a cyclopeptide RNA polymerase inhibitor found in several hepatotoxic mushrooms, or with *anatoxin-a(s)*, a cyanobacterial toxin that acts purely as a cholinesterase inhibitor without accompanying nicotinic agonist activity (the *s* refers to the *salivation* caused from excess acetylcholine at muscarinic receptors).

Anatoxin-a and epibatidine differ from nicotine primarily in potency. The LD₅₀ (the dose required to kill 50% of those exposed) of anatoxin-a is 200 to 250 µg/kg body weight (mouse, ip),³ and the LD₅₀ of epibatidine (rat, iv) is less than 125 nmol/kg.⁵ By comparison, a lethal dose of nicotine is estimated to be between 0.5 and 1.0 mg/kg in humans.⁶ Epibatidine is also more specific than nicotine at the ganglionic and CNS subtypes of nicotinic receptor and does not act at the NMJ.¹ Another difference between these agents is that in vitro, epibatidine appears to have some agonist action at muscarinic acetylcholine receptors as well.⁷ It is unclear, however, whether muscarinic effects would be seen clinically after human exposure.

Although nicotine has never been known to be developed as a chemical weapon by any government, it has been weaponized more than once by domestic criminals. In 1997, Thomas Leahy was found to possess ricin and botulinum toxins as well as a spray bottle filled with nicotine sulfate dissolved in dimethyl sulfoxide (an organic solvent also known as DMSO). Because his

intent with the other agents was difficult to prove, he was initially only charged and convicted for the weaponization of the nicotine sulfate, although he subsequently pled guilty to the other charges.⁸ Another incident of domestic terrorism involving nicotine is discussed in the case at the end of this chapter. Neither epibatidine nor anatoxin-a is known to have been developed for state, terrorist-group, or individual use.

The potential for the use of nicotine in a chemical attack is enhanced by its many possible means of delivery and routes of absorption. Nicotine freebase is an oily liquid but is relatively unstable in air. Nicotine salts, however, are solids that are readily dissolved in water or organic solvents. Therefore, these salts could potentially be dispersed as an aerosol of liquid or powder. Nicotine can be absorbed transdermally, as evidenced by “green tobacco sickness.” In this illness, acute nicotine toxicity occurs in those who harvest wet tobacco without protection for their skin.⁹ Nicotine patches for smoking cessation take advantage of this principle. Clearly, if nicotine were suspended in a solvent with good dermal penetration (DMSO would be an option) and then aerosolized, the potential for systemic toxicity from dermal exposure would be great. Nicotine is also stable to pyrolysis and may be absorbed through inhalation, as in tobacco smoking. Nicotine is orally bioavailable, and numerous case series exist of children with nicotine toxicity from ingestion of tobacco products.¹⁰⁻¹⁸ Much less is known about the absorption and bioavailability of epibatidine and anatoxin-a through different routes. Epibatidine is available as an off-white powder and is soluble in organic solvents including alcohol. Anatoxin-a is a light brown solid that is soluble in water. Anatoxin-a appears to cause illness through ingestion in animal models.¹⁹ Few data exist regarding the oral bioavailability of epibatidine or the inhalational absorption of either toxin. One feature of anatoxin-a that might make it ill-suited to chemical terrorism is that it is susceptible to photolysis, rapidly breaking down in the presence of sunlight.²⁰ Thus, while an incident involving contamination of food is possible, an incident involving outdoor dispersion of an aerosol seems extremely unlikely.

The clinical effects of nicotinic poisoning depend in part on the route of absorption. Most data have been gathered in the context of exposure through ingestion, in

which significant nausea and vomiting are early features. In one review of 143 children with symptoms after ingestion of cigarettes or cigarette butts, 99% (138 children) vomited; 74% (104 children) did so within 20 minutes.¹⁰ These features are also seen in toxicity from dermal absorption, but they may not be the first sign of exposure. Other early findings include dizziness and dyspnea. In one reported case of dermal exposure, dizziness, dyspnea, “unsteadiness,” and nausea occurred within 30 minutes.²¹ Flushing and pallor of the skin have both been reported after nicotine exposure, and diaphoresis may be present as well.^{11,12,14} Cardiac effects include both hypertension and hypotension as well as palpitations and dysrhythmias ranging from sinus bradycardia and sinus tachycardia to sinoatrial block, atrial fibrillation, and asystole.^{10,12-14,16,17} These seemingly contradictory effects are better understood when one considers that the effects of nicotine on the autonomic nervous system are mediated through its action at both sympathetic and parasympathetic ganglia. Which effects predominate in any individual patient can be difficult to predict. Nicotine also acts as a depolarizing neuromuscular blocker at the NMJ.¹ Thus, early muscle spasms and fasciculations may occur, followed by weakness, hypotonia, and even flaccid paralysis.^{10,12,13} Nicotinic cholinergic agonism in the CNS leads to seizures and altered mental status. In children, both lethargy and irritability have been reported after tobacco ingestion.^{10,14,16} Patients with less severe poisoning may present with headache or dizziness.^{10,11,15} Seizures are uncommon in typical cases of cigarette ingestion and when present suggest a more severe exposure.¹⁰ Severe exposures can lead to permanent neurologic devastation.²²

Little is known about clinical findings in humans after poisoning with epibatidine or anatoxin-a; there are no reported cases. Presumably, because of the greater potency of these agents, patients would clinically resemble those with severe nicotine toxicity. If epibatidine were used, it is possible that muscarinic findings would be present as well, which would make the distinction from nerve agent poisoning even more challenging; however, the absence of neuromuscular signs and symptoms might actually clarify the diagnosis.

PREINCIDENT ACTIONS

Disaster planning and education are the most important preincident actions that can be taken in preparation of an attack involving cholinergic agents. Coordination between the U.S. Department of Agriculture, the Food and Drug Administration, and law enforcement and counterterrorism agencies is likely to facilitate early detection of incidents involving food and water contamination. Syndromic surveillance of emergency department triage complaints may also play a role because food and water contamination may initially appear as gastrointestinal (GI) illness. Although atropine is already stockpiled in many hospitals because of preparations for nerve agent attack, this measure is unlikely to be helpful because muscarinic effects will be inconsequential in most patients. Other than basic preparedness for chemical terrorism such as personal protective equipment and

decontamination facilities, no specific physical infrastructure or supplies are required in the hospital for preparation for a nicotinic agonist attack.

Technology originally developed for workplace monitoring exists for detection of small amounts of nicotine in the air.²³ It is also possible to test water supplies for cyanobacteria,³ and anatoxin-a can be detected by gas chromatography with an electron-capture detector.²⁴ In the future, it may be possible to deploy chemical detectors in strategic sampling locations to provide early warning of a chemical attack.

POSTINCIDENT ACTIONS

The most important actions after a nicotinic agent attack (besides rescue and care of exposed patients) are prompt notification of the appropriate authorities and decontamination of affected areas. This differs little from the response to other types of chemical attack. If anatoxin is known to have been the agent involved, maximizing exposure of the involved area to sunlight will help to rapidly destroy the toxin; anatoxin-a spontaneously degrades in direct sunlight, with a half-life of about 1 hour.²⁰

MEDICAL TREATMENT OF CASUALTIES

Although nicotinic cholinergic antagonists exist, there are no clinical data on their use in human poisoning with nicotinic agents. In addition, of the ganglionic blockers, hexamethonium and trimethaphan are not available for clinical use, and mecamlamine is available in tablet form only, making it unsuitable for use in an emergency. Furthermore, nicotinic cholinergic antagonists at the NMJ are not useful to treat paralysis, as they are themselves paralytic agents. There is thus no useful antidote to nicotine or nicotinic-agonist exposure, and supportive care is the mainstay of therapy.

As in most chemical-attack scenarios, rapid removal of just that clothing that has been soaked and of agent visible on the skin (local, or “spot,” decontamination) is crucial to prevent continued absorption and should be accomplished in concert with attention to airway, breathing, and circulation. Patients without a secure airway or who need ventilatory support need these interventions at approximately the same time that local decontamination is being done and before full-body disrobing and decontamination. Mouth-to-mouth ventilation should never be performed because it can pose risks to the rescuer, particularly after a GI exposure.²⁵ For full-body decontamination, removal of the patient’s clothes, shoes, belt, watch, and jewelry should be followed by irrigation of the skin with copious amounts of water with or without soap (soap may be useful for oily substances such as nicotine freebase or any of these agents dissolved in an organic solvent).

Hemodynamic support should include intravenous fluid boluses followed by vasoconstrictor agents such as norepinephrine as needed to treat hypotension.

Therapy for hypertension should be approached with caution, because hemodynamic collapse may be precipitous.²⁶ In the absence of end-organ effects of severe hypertension, pharmacologic intervention should probably be avoided. Dysrhythmias should be managed according to the usual practice. Seizures should be treated with benzodiazepines or barbiturates. Other anticonvulsants are unlikely to be helpful and are not indicated. Vomiting should be managed with antiemetics, and oral activated charcoal should be administered, particularly after GI exposures.²⁷ Because nicotine exhibits a certain degree of enteroenteric circulation, oral activated charcoal even after dermal or inhalational exposure could theoretically be of benefit.²⁶

Suspected cases should be reported to the regional poison control center. Poison control centers can recognize developing epidemics, assist with patient management, and help contact other health and law enforcement authorities in the event of an attack. Because symptoms occur early after exposure, minimal observation is required for patients who present with no clinical abnormalities.

Poisoning by a nicotinic agonist may be difficult to distinguish from nerve agent poisoning, and it is possible that patients exposed to these agents might conceivably be treated in the field with Mark I kits containing atropine and pralidoxime. If possible, this should be avoided. Although there may be some role for atropine in patients with bradycardias, bronchorrhea, or other severe muscarinic symptoms, there is no role for pralidoxime, an oxime cholinesterase reactivator. In

fact, aggressive oxime therapy may do more harm than good because pralidoxime is itself a weak cholinesterase inhibitor with the potential to cause cholinergic excess.

UNIQUE CONSIDERATIONS

The most notable feature of nicotinic-agonist poisoning is its similarity to poisoning by cholinesterase inhibitors such as organophosphate pesticides and nerve agents. Enhanced parasympathetic outflow (with resulting muscarinic effects) due to ganglionic stimulation may further confuse the clinical findings and mimic organophosphate poisoning. Without identification of the product at the scene, it is unlikely that this distinction will be possible in the event of a chemical attack. Failure to respond to atropine and oximes (or worsening of symptoms with oxime therapy) may be the only clue. Fortunately, as there is no specific therapy for nicotinic-agonist poisoning, chemical attacks with these agents are otherwise managed as are any generic chemical exposure; good decontamination and supportive care is the only therapy needed.

PITFALLS

Several potential pitfalls exist in responding to a cholinergic agent attack. These include the following:

- During disaster planning and provider education, failure to consider the possibility of nicotinic agonists as mass-casualty chemical agents
- Failure to consider a chemical attack with a nicotinic agonist after an epidemic of a GI illness
- Misdiagnosis of nicotinic-agonist poisoning as poisoning by organophosphate pesticides or nerve agents
- Administration of atropine therapy to patients with nicotinic-agonist poisoning and with no significant muscarinic signs or symptoms
- Administration of oxime therapy to patients with nicotinic-agonist poisoning
- Failure to involve public health and law enforcement authorities when a chemical attack is suspected
- Failure to call the regional poison control center to report cases and to get assistance with management

CASE PRESENTATION

In 2003, a total of 18 patients from four different families developed nausea, vomiting, dizziness, and burning of the mouth after eating ground beef. One of the patients required evaluation in the emergency department for atrial fibrillation. The pattern of illness suggested contamination at a single store rather than at a meat-processing plant. A recall was issued for approximately 1,700 pounds of ground beef with sell-by dates including the 3 days potentially involved. Samples of the ground beef were sent for analysis. Although testing for food-borne pathogens was negative, it was quickly determined that the samples contained nicotine at a concentration of 300 mg/kg of ground beef. Since a lethal dose of nicotine is about 50 mg, about one-third pound of beef would have represented a life-threatening ingestion. Investigators thus became suspicious of contamination with a nicotine-containing pesticide because these were widely available in the community. However, none of these pesticides was used or sold in the store where the contamination occurred. Several weeks later, a man formerly employed as a meat cutter in the supermarket was arrested and charged with poisoning the meat with Black Leaf 40, a pesticide containing 40% nicotine. A public health notice was issued, and 148 people were interviewed after reporting illness; 92 were ultimately determined to have suffered illness consistent with nicotine poisoning.⁶

Anesthetic-Agent Attack

Kinjal N. Sethuraman and K. Sophia Dyer

DESCRIPTION OF EVENT

In the 1830s, ether, the earliest anesthetic agent, began to be used for sedation and pain control in the United States.¹ Today, however, ether and various other anesthetics such as chloroform and cyclopropane are no longer in use because of the danger of explosion and the potential for fatal consequences from their use. Initially, they were replaced by nonflammable agents such as halothane and nitrous oxide; however, halothane itself, because of its hepatotoxicity and cardiotoxicity, has now been largely superseded by halogenated ethers such as isoflurane and enflurane. These drugs are typically delivered via inhalation after intravenous sedation. A major advantage of inhaled anesthetics for anesthesiologists is that the level of sedation can be rapidly modified to remain within the therapeutic window and to achieve desired analgesia, amnesia, muscle relaxation, and paralysis.²

Anesthetic agents are not known to have been used on the battlefield or by terrorists, but recently an event in Russia brought the issue of the topic of anesthetic agents as potential mass-casualty weapons into sharp focus.^{3,5} In 2002, a “knockout gas,” bluish-gray in color and with a sweet taste, was used by the Russian Army to incapacitate Chechnyan hostage-takers while elite Spetsnaz forces of the Russian army attempted to rescue 800 hostages in a Moscow theater.⁶ It has been speculated that the gas contained halothane or another anesthetic agent mixed with an opioid compound (see Chapter 97).^{7,8} One hundred twenty-seven hostages, including several children, died from the gas. It was reported that the gas was released for over 20 minutes at an unknown concentration. The preincident health of some of the victims may have led to the high mortality rate, but some hostages had virtually no response to the agents.⁷ Hospitals that received victims of the attack were allegedly not informed of the gases used and thus had to experiment with reversal agents.^{8,9} As television footage shows, many affected hostages removed from the theater were placed onto the ground or onto buses in positions that risked airway compromise and underscored the necessity of attention to airway and breathing in these casualties quite apart from considerations of specific antidotal treatment.⁷

Although newer anesthetic gases are relatively safe, older agents have several properties that could make them appealing for criminal purposes:

- Ease of availability
- Portability
- Volatility
- Mass dissemination
- Rapid onset of action
- Low warning properties
- Potential to incapacitate or kill
- Possible use of remote trigger
- Novel to first responder
- Can also be used as explosives in high concentrations

In this chapter, we will focus on some of the more common agents.

If a terrorist attack occurs with any agent, first responders need to be well prepared. The response team needs to act quickly to triage, evacuate, and attend to airway and breathing in affected casualties and to determine which agent or agents were used, the agent concentration, and the method of distribution. The odor, taste, color, signs, and symptoms will vary by agent. Therefore, interviewing victims can be helpful in identifying the gas or gases used. Since these agents share significant inhalational hazards with a quick onset of action, they could pose a hazard both to original victims and also first responders.

CHARACTERISTIC PROPERTIES OF POTENTIAL TERROR AGENTS

The following agents are described as examples of the range of physicochemical properties and effects of the many compounds that have been used as inhalational anesthetics. Clinicians should always be aware of potential interactions from combinations of agents, as in the Moscow theater incident. Attention to presenting symptoms, descriptions by victims, and information from hazardous materials specialists can aid in clarification of the chemical used.

Victims of inhaled anesthetic agents will experience confusion, relaxation, dizziness, drowsiness, and various respiratory symptoms that can include choking, a burning sensation in the mouth or nose, and respiratory

distress. Less water-soluble agents such as nitrous oxide will stealthily cause effects in the smaller, peripheral airways but less pronounced skin, mucous-membrane, or central-airway damage.¹⁰

The mean alveolar concentration (MAC) is used as a measure of the strength of an anesthetic. It represents the *minimum* concentration necessary to cause unresponsiveness in 50% of the general population.¹¹ Simply put, the higher the MAC, the less potent the gas. The MAC is influenced by many factors including age of victim, the victim's comorbidities and metabolism, combination with another anesthetic or analgesic agent, and preexposure vital signs.² The solubility of an anesthetic in blood is described by the blood-gas partition coefficient (BGPC), which expresses, in liters, the amount of an agent that will dissolve in 1 liter of blood exposed to air containing the anesthetic. The lower the BGPC, the faster the onset of an anesthetic and the faster it will wear off.

Diethyl Ether

Diethyl ether (C₄H₁₀O) is a flammable, volatile, colorless liquid with a sweet taste and ethereal odor.¹² It is soluble in alcohol, acetone, benzene, and chloroform. Its boiling point is only 94°F (34.5°C). When exposed to fire or heat, ether releases carbon monoxide; exposure to light causes ether to break down into flammable peroxides.¹² Ether, with a BGPC of 12, is more soluble in blood than either halothane or nitrous oxide. The MAC of ether is 2.0%. Because of the explosive nature of ether, the National Fire Protection Association has given ether a flammability rating of 4, corresponding to an extreme fire hazard.¹³ Although ether works well as an anesthetic, its propensity to explode prompted anesthetists to find alternative inhaled agents such as chloroform, cyclopropane, and halothane.

Anesthesia induction occurs at a concentration of 100,000 to 150,000 ppm and is maintained with 50,000 ppm.¹³ Very small doses to eyes or skin can cause corneal injury and burns.¹⁴ Toxic exposures to ethers (as with other anesthetics) can occur through inhalation, eye or skin contact, and ingestion. The effect of ether is dose dependent. Symptoms consist of skin, eye, and mucosal irritation leading to an increase in bronchial secretions. Dizziness, drowsiness, bradycardia, hypothermia, or acute excitement may also occur. Laryngospasm, loss of consciousness, and death may result. The after-effects of emergence from ether-induced anesthesia include nausea, vomiting, and headache.¹⁵

Newer ethers are halogenated and include enflurane, desflurane, and sevoflurane. They are not flammable, have fewer side effects, are efficient as anesthetic agents, and cause less end-organ damage.¹ They may be potentially used by terrorists as incapacitating agents.

Nitrous Oxide

Nitrous oxide (N₂O)¹⁶ is a weak anesthetic (MAC of 105) often combined with other agents to produce adequate analgesia and anesthesia. Induction and maintenance of anesthesia require very high concentrations of nitrous oxide, and hypoxia may result if high concentrations of

oxygen are not coadministered. During minor procedures, lower concentrations are used for sedation. Nitrous oxide is found commonly in aerosol sprays, and its abuse potential is accordingly high. Prolonged use can cause peripheral nerve damage, psychosis, perceptual impairment, and hyperpyrexia.¹⁷

Nitrous oxide administered in high doses has been found to cause arrhythmias, malignant hyperthermia, seizures, pneumomediastinum, and subcutaneous emphysema. Nausea and vomiting are early signs of nitrous oxide toxicity.¹⁸

Chloroform

Chloroform (CHCl₃)¹⁸ is a colorless, volatile chlorinated hydrocarbon that is often mixed with ethanol. It has a sweet, burning taste and a pungent odor. As a byproduct of chlorination, chloroform is present in low concentrations in chlorinated water¹⁹ but exposure to these low concentrations is insufficient to cause anesthesia. It is also produced from the reduction of carbon tetrachloride (CCl₄) with moist iron.

Although no longer used as an anesthetic,¹ chloroform is still used as an intermediate in chemical syntheses. One of the Freon refrigerants is an example of the current use of chloroform. Moreover, chloroform has been widely popularized as a knockout agent to induce consciousness when poured onto a handkerchief or other cloth and held over the mouth and nose. And its well-known use for this purpose may make it a more likely choice for terrorists for either small-scale or mass-casualty use.

The toxic dose of chloroform is 7 to 25 mg/dL (0.59 to 2.1 mmol/L).²⁰ At inhaled concentrations of less than 1500 ppm, physical effects of dizziness, tiredness, and headache are reported; and anesthesia occurs at a range of 1500 to 30,000 ppm. Chloroform causes irritation to the respiratory tract. It will cause dry mouth, sedation, confusion, and loss of consciousness within 5 to 10 minutes, and unconsciousness may last up to 30 minutes after removal from exposure. Fatalities occur after 5 to 10 minutes at doses of 25,000 ppm or greater by inhalation.²⁰

Death can occur from cardiac arrest and hepatic toxicity with peak elevation of hepatic enzymes 3 to 4 days after exposure and a subsequent return of liver-function tests to normal in survivors.²⁰ Pulmonary toxicity from intravenous injection of chloroform peaks after 3 days. Renal and hepatic toxicity may also occur from phosgene (COCl₂), a byproduct that results from exposure of chloroform to sunlight and air (see Chapter 95).²¹ Other byproducts include hydrochloric acid (HCl), carbon monoxide (CO), inorganic chloride, and formaldehyde.²¹ Pulmonary exposure to HCl and phosgene can result in pulmonary edema, bronchial pneumonia, and subsequent lung abscesses.

Victims exposed to chloroform need supportive care, including cardiac and pulmonary monitoring in an intensive care unit as clinically indicated. While there is no antidote for chloroform, liver toxicity in animals may be prevented by using N-acetylcysteine (NAC) after exposure, since chloroform and its byproducts deplete glutathione stores.^{20,22} However, no studies have evaluated the use of NAC for this purpose in humans.²³

Cyclopropane

Cyclopropane (C_3H_6) is a hydrocarbon ring that was discovered in 1882; it began to be used as an anesthetic in 1933.¹ It is extremely flammable and is thus no longer used clinically. Cyclopropane, a gas at room temperature, is caustic to eyes but not to the skin. At concentrations greater than 40%, cyclopropane causes irritation to the eyes and respiratory tract. Its density is greater than air, and if released into the environment, it will hug the ground.¹⁴ At higher concentrations, it causes nausea, disorientation, dizziness, and incoordination. If released in a closed area, cyclopropane, as is the case with all hydrocarbons, will displace oxygen and cause asphyxiation.²⁴

Autopsy results from accidental death after cyclopropane ingestion showed hemorrhagic edema of the lungs.¹⁴ Cardiac output, stroke volume, and heart rate are all affected by high concentrations of cyclopropane, but these parameters return to normal a few minutes after the agent is removed.²⁵ Cyclopropane causes decreases in renal blood flow and glomerular filtration rate.²⁶ Malignant hyperthermia from cyclopropane has been reported; it can be resolved with cooling and perhaps by the administration of dantrolene.²⁷ Cyclopropane has also been shown to alter cognitive function, especially the ability to learn, for up to a week after exposure.²⁸

Halothane

Halothane ($C_2HBrClF_3$) continues to be used occasionally as an anesthetic, analgesic, and amnesic. Halothane is a colorless, volatile, nonflammable liquid unique for its sweet taste and odor. It is the most potent inhaled anesthetic, with a MAC of 0.77.² The MAC is commonly reduced by administering a coagent. The MAC for patients who are older, hypothermic, hypotensive, or hypoxic will be lower.²⁹ Halothane is highly soluble in both blood and fat; this behavior accounts for its prolonged emergence from anesthesia.² When exposed to light, heat, flames, and acids, halothane will decompose into other toxic fumes or metabolites (e.g., bromide, chlorine, and fluorine). The dose used for anesthesia ranges between 5000 to 30,000 ppm,³⁰ or 0.5% to 3% concentration in oxygen.^{31,32} Even if victims are exposed to less than 5000 ppm, they will show impaired manual dexterity and word-finding difficulties.

Acute exposure to this agent causes severe irritation to all exposed areas. Hypotension, dizziness, somnolence, lethargy, and changes in mental status are all potential symptoms. Exposure to halothane may lead to hepatic failure, cardiac arrhythmias, and malignant hyperthermia.^{31,33,34} Liver failure from other halogenated anesthetics is less common. Long-term, chronic exposure to halothane can increase the risk of some cancers and can increase rates of spontaneous abortions and of congenital abnormalities in newborns of exposed mothers.³⁵

Diagnosis of halothane toxicity is based mainly on history, physical examination, and basic laboratory analyses. Attributing hepatic failure to halothane is difficult, since the clinical presentation is identical to other causes of hepatitis. An assay for halothane-related antibodies is available for experimental use but is not practical in emer-

gency or disaster settings. Halothane metabolites can be detected in the urine up to 1 week after exposure.³¹

PREINCIDENT ACTIONS

Because terrorist attacks are for the most part unpredictable, it is important for emergency medical services, law enforcement, and local, state, and national agencies to be prepared for any type of attack at any given time. For attacks using anesthetic agents, the focus should be on rapid access to casualties, prompt evacuation, careful attention to airway and ventilation (especially during transport and positioning), general supportive care, identification of agent, and ample supply of reversal agents. In Moscow, although the Russian military had an “antidote” (probably naloxone) to the agents used, claims were made that there were not enough medical personnel to administer the drug.⁷ There are no antidotes to ether, chloroform, cyclopropane, or halothane, and the importance of attention to airway, breathing, and circulation cannot be overemphasized.

The first gas masks were developed as a response to the use of inhaled gases at Ypres during World War I.³ In any given situation, appropriate respiratory protection should be worn by emergency medical services personnel, healthcare workers, and law enforcement personnel until the area in question has been cleared of inhalation risk. Many first-responding agencies may not have the available detection equipment to identify exactly the type of anesthetic gas used or even the general class of anesthetic gases used, thus making it even more important to use proper equipment. The typical canister respirator either with a full face piece or partial face piece, which is very portable and varying in comfort, will not offer protection in an atmosphere of depleted oxygen. If oxygen displacement has occurred, a supplied air respirator (either through a tank or air line) is the only appropriate respiratory protection. Many portable sensors are available for measuring ambient oxygen concentrations, either as individual items or components in other detection equipment. Several companies market canister respirators for application in event of the use of weapons of mass destruction. In general, these products are not specifically tested against many of the anesthetic agents discussed in this chapter, as of the time of this writing. An organic vapor canister might trap some of these agents, with the obvious exception of the inorganic nitrous oxide. However, this will depend on concentration values within the acceptable range. In addition, the canister testing information should be evaluated to see whether it has been tested against the known agent. Given that this might be difficult to accomplish in a critical time period, a self-contained breathing apparatus will offer the best protection for an unknown environment.

POSTINCIDENT ACTIONS

As with any potential exposure to an inhalational toxin, protection of the victims from further exposure and guarding against exposure in responders is vital. If in

doubt as to the type of chemical, the highest level of respiratory protection is recommended—in many cases, this is a supplied air respirator. Because some of these products are volatile, precautions against direct flame and any equipment that could potentially generate a spark are prudent. The most important immediate actions to take are to reach victims (who may already be apneic) as soon as possible, to ensure a patent and protected airway, to increase ventilation, to decrease exposure, and to provide oxygen to victims.

MEDICAL TREATMENT OF CASUALTIES

It is important to interview survivors and gather as many data as possible to determine the agent used. The volatility of anesthetic agents may decrease the utility of air samples, but such samples can help to identify other agents that may have been used in combination with the agents. It is important to consider the potential of a mixture of agents even after the identification of a specific agent. Once victims are at a hospital, laboratory studies that can be obtained relatively quickly can be helpful in the management of exposed patients. These studies include arterial-blood-gas and carboxy-hemoglobin determinations, liver-function tests, a complete blood count, and a comprehensive metabolic panel. A chest radiograph is also useful in the setting of suspected chemical pneumonitis or pulmonary edema, although dyspnea is usually the first indicator of incipient pulmonary edema.

CASE PRESENTATION

It is a hot and humid summer day on a holiday weekend in Baltimore. Air conditioners are working overtime. The threat of rain forever looms overhead, as it always seems to do in the mid-Atlantic region of the United States. As shopping continues to be a national pastime, several hundred shoppers have packed into a local mall. Security is nonexistent due to budget cuts and the economic slump.

Nearly 20 men holding machine guns, wearing masks, and carrying cylinders that could be mistaken for helium tanks easily enter the mall. They strategically release the gas in the cylinders into the air-conditioning system.

After a few minutes, people with asthma start feeling their chests tighten. Others start to choke, as their eyes burn. Still more involuntarily fall asleep. Those near the doors try to run outside for fresh air, but the electrically controlled doors are locked shut.

The masked men make their presence known to the few who are fighting off the weight of their eyelids. They have taken the mall over for two purposes: to steal, and to make it known to the Westerners that they are not safe.

PITFALLS

Several potential pitfalls exist in response to an anesthetic opioid nerve agent attack. These include the following:

- Failure to recognize that an attack has taken place
- Failure to reach potentially apneic patients as soon as possible
- Failure to attend adequately to airway, breathing, and circulation in casualties before, during, and after transport to medical treatment facilities
- Failure to notify proper local, state, national, and international agencies
- Failure to identify the agent or agents used
- Failure to follow the identification of a specific chemical agent by consideration of the possibility of simultaneous use of an anesthetic agent
- Failure to remove igniting factors or flammable objects from scene
- Failure to use gloves and appropriate respiratory protection
- Failure to evacuate or ventilate area
- Failure to notify hospitals
- Failure to have enough personnel available

chapter 101

Introduction to Biologic Agents

Andrew S. Nugent and Eric W. Dickson

On Aug. 6, 1945, at 8:16 AM, the detonation of “Little Boy” over the city of Hiroshima, Japan, ushered in the age of nuclear weapons and warfare. The first known use of the second element of NBC (nuclear, biologic, and chemical) weapons of mass destruction is not as dramatic nor as well documented but likely took place in 6th century BC, when the Assyrians used rye ergot to poison the wells of their adversaries.¹ Knowing a good idea when they saw it, Scythian, Roman, Greek, and Persian archers tipped their arrows with manure and other biologic agents circa 400 to 300 BC. Many other uses of human sickness to wage war followed; perhaps the most destructive occurred when the Tartars used trebuchets to hurl plague-infected corpses into the city of Caffa in the year 1346. Sailors fleeing the ensuing epidemic may have inadvertently initiated the Great Plague by spreading the illness to Genoa, Italy (although this has been recently questioned).²⁻⁴ Biologic warfare was not limited to the “Old World.” Pizzaro, the British, and the Americans used smallpox-infected blankets to produce mass casualties among their adversaries.⁵

U.S. research into offensive biologic weapons continued until 1969, when President Richard Nixon renounced the use of biologic weapons as killing or incapacitating agents. Although most nations signed the Biological Weapons Convention in 1975, many experts believe that biologic weapons programs still exist in Russia, North Korea, and until recently, Iraq. It is estimated that 10 countries have stockpiled biologic weapons either now or in the recent past.⁶ Since the early 1980s, the risk of the use of biologic weapons has increased dramatically with the rise of modern terrorism because these agents are relatively easy and inexpensive to make and weaponize and have the potential to kill large numbers of individuals, while sowing terror into millions of survivors.

The organisms and toxins that can be used as biologic weapons have been categorized by the U.S. Centers for Disease Control and Prevention (CDC) into three categories (A, B, and C [Table 101-1]). Agents classified as Category A by the CDC are of the highest priority because of the risk of their imminent use. Each of the Category A agents is easily disseminated, may result in much mortality, and has the ability to cause public panic, outcomes that are perceived to be among the main goals of a terrorist attack. All other significant bacteria that could possibly be used as bioweapons fall into the CDC’s

Category B; these are moderately easy to disseminate and have much less potential for severe mortality, although morbidity may be high. Category C is reserved for emerging infectious illnesses that may be bioengineered in the future as weapons.

Beyond the psychologic impact of a biologic weapon attack, several conditions must be met in order for a biologic agent to be useful as a weapon; lethality and infectivity of an organism alone are not sufficient. For example, Ebola is highly transmissible unless proper precautions are used and has a high mortality rate. However, Ebola does not persist in the environment and kills too quickly to allow for widespread exposure to infected individuals. This limits dissemination (e.g., formation of an epidemic) in the population. Thus, Ebola is unlikely to make an ideal weapon unless weaponized in a form that rapidly infects a large segment of the population.

With that in mind, several criteria must be met for an organism or toxin to be an effective biologic weapon, including the following: (1) the organism or toxin must be easily obtainable, culturable, and stable in the environment; (2) the organism or toxin must have the ability to be weaponized with a delivery system that allows widespread dissemination and/or be highly transmissible (by human, insect, or animal vector) while also allowing time for individuals to infect others in society; (3) the organism or toxin must be able to incapacitate or kill a large segment of the population (e.g., there is no innate resistance or easy treatment).

The first barrier to weaponization is delivery. Biologic agents can be delivered by several routes: inhalation of an aerosol, such as with anthrax; ingestion, such as with enterohemorrhagic *Escherichia coli*; or transcutaneously (e.g., the use of plague-infected fleas in Manchuria during World War II). Delivering and disseminating biologic agents effectively is not easy. Distribution via explosive device can reduce the efficiency of the delivered organisms to as low as 5%. However, it is not only delivery to a location that is important. Aerosolized particles that are too large will settle out of the atmosphere, and particles that are too small will not be trapped effectively in the lung, reducing infectivity. For this reason, aerosolized particles must be between 1 and 10 μm , and an efficient delivery system must be used; aerosolization using compressed gas can achieve 70% efficiency.⁷ Weather and

TABLE 101-1 CDC CATEGORIES OF BIOLOGIC WEAPON AGENTS

CATEGORY	DEFINITION	AGENTS
A	Organisms that pose a high risk to national security because they are easily disseminated or transferred from person to person, they can result in high mortality rate and have the potential for major public health impact, may cause public panic and social disruption, and require special action for public health preparedness.	<i>Bacillus anthracis</i> (anthrax) <i>Yersinia pestis</i> (plague) <i>Francisella tularensis</i> (tularemia) Botulinum toxin Variola (smallpox) Viral hemorrhagic fevers (Marburg, Ebola, etc.)
B	Organisms that are moderately easy to disseminate, result in moderate morbidity and low mortality rates, and require the CDC's diagnostic capacity and enhanced disease surveillance.	<i>Brucella</i> (brucellosis) <i>Coxiella brunetti</i> (Q fever) <i>Rickettsia rickettsii</i> (Rocky Mountain spotted fever) <i>Vibrio cholerae</i> (cholera) <i>Shigella dysenteriae</i> (shigellosis) <i>Salmonella</i> species (salmonellosis) <i>Salmonella typhi</i> (typhoid fever) <i>Burkholderia mallei</i> (glanders) <i>Burkholderia pseudomallei</i> (melioidosis) <i>Chlamydia psittaci</i> (psittacosis) <i>Escherichia coli</i> 0157:H7 and others(enterohemorrhagic <i>E. coli</i>)
C	Emerging pathogens capable of being engineered for mass dissemination in the future due to availability, ease of production and dissemination, and potential for high morbidity and mortality resulting in a major health impact.	Hantavirus, flavivirus, and others

electrical charge are other barriers to the effective dispersion of a biologic agent. For example, rain will remove particles from the atmosphere, and high wind speed can disperse an agent away from the intended target, whereas low wind speed will allow the aerosol to settle too rapidly. Electrical forces affect distribution as well. There is a natural electrostatic attraction between particles and surfaces. Unless compensated for, this electrostatic charge limits aerosolization. The problem of electrostatic charges can be overcome but is difficult and requires expertise.⁸ Alternatively, electrostatic charge can be used as an advantage when designing environmental filtering systems.^{9,10} Because of the variability of outdoor conditions, an indoor release of a biologic agent may be more desirable for terrorists since it requires a smaller amount of the agent and can be targeted to a specific population of interest (as was accomplished with anthrax in the Hart Office building in 2001). Conversely, an indoor release is not as likely to cause mass casualties unless the organism is highly infective during an asymptomatic incubation period and can be disseminated person to person.

A second route of delivery is by oral ingestion. There are barriers to the effective transmission of biologic agents in the water system, primarily the use of water purification in the United States. For this reason, the release of a biologic agent in the water supply may be less effective than contaminating the food supply.

The archetype for biologic weapons is anthrax. Anthrax is easily obtainable, easily weaponized, stable when released (spores can persist in the environment for up to 40 years), and highly lethal. One hundred kilograms of aerosolized anthrax spores have the potential to kill up to 3 million people. Because of efficient delivery, the lack of person-to-person infectivity and limited secondary aerosolization are not barriers to its effective use as a biologic weapon. Thus, even though it is unlikely that infection will persist or spread much beyond the initial casualties, anthrax still makes an ideal weapon.

SURVEILLANCE

The role of surveillance is a subject of much debate. Surveillance depends on the recognition of occurrences of diseases/organisms/symptoms beyond that which would be expected as a background rate or outside of a disease's natural range. One of the major weaknesses in surveillance systems is the lack of sensitivity and specificity. Even though it is critical to detect the presence of a pathogen, it is also important to avoid mobilizing a response to false-positive tests. A second weakness is that by the time symptom or organism surveillance is able to pick up a pattern of illness in a community, the illness may already be well established. Environmental monitoring, on the other hand, has the potential to identify pathogens before they become ensconced in the community. Environmental monitoring includes the routine monitoring of food and water supplies as well as the general environment. Autonomous monitoring devices are available (August 2004) that perform testing (e.g., on air) at a predefined interval for infectious, chemical, and radiologic agents.¹¹ More information on surveillance is available at the CDC Web site (www.cdc.gov) and in *Morbidity and Mortality Weekly Report*.¹² Readers with an interest in worldwide surveillance may wish to subscribe to ProMed-mail (www.promedmail.org), which is a free mailing list that reports symptomatic outbreaks of known diseases and unidentified symptom complexes worldwide.

Each of the chapters in Section 10 will review the likely scenario and consequences of an attack with a specific biologic agent. Much of the information provided is based on our understanding of the agent's pathogenicity in nature. In many cases, how a given agent will behave when delivered as a weapon is extrapolated from these data. Early recognition and isolation minimize morbidity and mortality of the primarily exposed and reduce secondary infection. For the clinician, this is implemented by early identification of a cluster of patients with similar symptoms or the occurrence of a

TABLE 101-2 DIFFERENTIAL DIAGNOSIS OF SYNDROMES POSSIBLY CAUSED BY BIOLOGIC WARFARE AGENTS

SYNDROME	CATEGORY A BIOTERRORISM DISEASES	CATEGORY B BIOTERRORISM DISEASES	CATEGORY C BIOTERRORISM DISEASES	NATURALLY OCCURRING DISEASES

disease outside of its normal range. Table 101-2 provides a summary of the symptoms and a differential diagnosis that are observed during a possible bioterrorism attack.¹³

chapter 102

Bacillus Anthracis (Anthrax) Attack

Christo C. Courban

DESCRIPTION OF EVENT

Anthrax, a category A bioterrorism agent, is a zoonotic disease caused by *Bacillus anthracis*, an aerobic, nonmotile, spore-forming, gram-positive bacillus that is ubiquitous in soil. Anthrax is primarily a disease of herbivores, including sheep; cattle; goats; horses; and, less commonly, pigs.

The first known description of anthrax (approximately 1400 BC) is in the Old Testament where it represented the fifth plague on Egypt, the killing of the Egyptian cattle. The “Black Bane” outbreak (named after the black eschars caused by cutaneous anthrax) took place in Europe in the 1600s and killed 60,000 people and many more cattle. In 1881, Robert Koch definitively identified *B. anthracis* as the cause of cutaneous anthrax, making it the first disease for which a microbial cause was identified. Soon thereafter, Pasteur developed an effective vaccine. Despite all efforts, anthrax remains a sporadic problem in Africa, the Middle East, some parts of South America, and Asia.

B. anthracis makes an almost perfect biologic weapon—it is easily weaponized; can be aerosolized; has a high mortality rate; and the spores are highly resistant to drying, heat, gamma radiation, ultraviolet light, and many disinfectants. Additionally, the spores can remain dormant in the environment for up to 40 years. Several countries have developed weaponized anthrax, which was used during WWII by the Japanese in Manchuria. It is estimated that the release of 100 kg of anthrax spores in a major city could lead to up to 3 million deaths, making anthrax potentially as lethal as a hydrogen bomb. For comparison, it is estimated that Iraq had 8500 L of concentrated *B. anthracis* in 1991, all of which was subsequently destroyed. Concern about the use of anthrax spores as a biologic weapon was heightened dramatically in 1979 when an epidemic of inhalation anthrax occurred downwind of a weapons research facility in Sverdlovsk, Russia, with cases occurring up to 50 km away and almost 6 weeks after the release. Indeed, anthrax was used as a biologic weapon in 2001 when anthrax spores were disseminated via the U.S. Postal Service along the Eastern Seaboard of the United States. Twenty-two cases of anthrax were identified, half of which were inhalation type anthrax and half cutaneous, resulting in five fatalities among those with inhalation anthrax.

Transmission

Anthrax infection occurs by three methods: contact with broken skin, inhalation of spores, and ingestion. Naturally occurring infections are due mainly to contact with infected animals or animal products, such as hides or poorly cooked meats. Historically, the number of inhaled spores required to cause infection in 50% of individuals was thought to be approximately 10,000. More recent data suggest that as few as 1 to 3 spores may be sufficient to cause disease, depending on particle size. This estimate is tempered somewhat by the observation that many hide and wool workers are exposed to high concentrations of aerosolized spores on an ongoing basis with subsequent infection occurring only in a minority of individuals. There is no person-to-person transmission of anthrax, with the exception of the cutaneous form, which can be spread by skin contact.

Virulence

The virulence of anthrax is dependent on its ability to produce three distinct proteins: lethal *factor* (LF), protective antigen (PA), and edema *factor* (EF). Edema *toxin*, formed when edema *factor* and protective antigen bind, interferes with water homeostasis, causing severe, localized edema seen in cutaneous anthrax. Edema *toxin* also inhibits neutrophil function, impairing the host's ability to defend itself against infection. Lethal *toxin* is also composed by the binding of two subunits: the lethal *factor* and protective antigen. Lethal toxin is responsible for, among other things, the release of TNF-alpha and interleukin B-1, which are responsible for the systemic reaction leading rapidly to death. One area of investigation has been the search for an inhibitor that can block the binding of protective antigen with lethal factor and edema factor, thus preventing the formation of lethal toxin and edema toxin.

Inhaled Anthrax

Inhaled anthrax is the most serious form likely to occur after a bioterrorism event. Inhalational anthrax victims typically present 1 to 5 days after exposure, with a median incubation time of 4 days.¹ However, cases have

occurred up to 6 weeks after exposure to anthrax spores (thus the suggestion for prolonged prophylaxis). Inhaled anthrax does not cause a true pneumonia. Rather, the lungs act only as a portal for infection. After the inhalation of anthrax spores into the alveoli, the spores are picked up by macrophages that transport them to the mediastinal and peribronchial lymph nodes. Activated spores divide rapidly, causing hemorrhagic mediastinitis and subsequent dissemination to the rest of the body via the blood, causing toxemia and sepsis.²

Presenting complaints are that of a nonspecific flulike illness, often including occasional nonproductive cough, fevers, chills, sweats, malaise, myalgia, and chest discomfort. Rhinorrhea is notably absent. If untreated, this prodrome can last for 48 to 72 hours, after which the patient's condition may improve before a severe and precipitous decline. Within 24 to 48 hours of the onset of respiratory disease, patients develop bacteremia, with disease progression to hemorrhagic mediastinitis, pleural effusions, and septic shock. Patients often become dyspneic and cyanotic, with increasing chest and/or abdominal pain and diaphoresis. Stridor may also be present because of obstruction of the trachea by enlarged lymph nodes. Up to 50% of patients with pulmonary anthrax develop meningitis with associated subarachnoid hemorrhages. The detection of hemorrhagic cerebrospinal fluid with gram-positive bacilli and polymorphonuclear pleocytosis can aid in making the diagnosis.³

Chest radiographs characteristically show a widened mediastinum with pleural effusions and relative sparing of the lung parenchyma. Computed tomography (CT) of the chest should be considered if inhalation anthrax is suspected and the diagnosis is in doubt. CT scan is more sensitive and specific for detecting mediastinal lymphadenopathy, in which there is a normal white cell count or a mild leukocytosis with a left shift.⁴

The differential diagnosis of inhalational anthrax is wide and includes mycoplasma, influenza, legionella, tularemia, and psittacosis. *Characteristics that differentiate anthrax from influenza and other influenza-like illnesses include the following:* wide mediastinum on radiograph (70%), pleural effusion (80%), absence of rhinorrhea (only 10% of patients with anthrax infection will have rhinorrhea), absence of sore throat (found in only 20%), dyspnea (80%), and nausea and/or vomiting (80%). Before September 2001, inhalation anthrax was estimated to have a mortality rate of up to 95%. With modern antibiotics and aggressive supportive care, the mortality rate has been reduced to 50%. This reduction in mortality is attributed to prompt recognition of the disease, aggressive concomitant antimicrobial therapy, and improvements in supportive care techniques. However, in the face of a major attack, medical services will likely be overwhelmed and it will not be possible to provide intensive care for all cases. Thus, the mortality of cases may be higher than 50% and possibly approach 95%.

Cutaneous Anthrax

As seen during 2001, cutaneous anthrax is likely to occur regardless of the mode of attack. Cutaneous anthrax represents 95% of background cases of anthrax in the United

States. Cutaneous anthrax presents as a painless pruritic papule generally appearing 1 to 7, but up to 12, days after exposure in an area of compromised skin integrity. Within 48 hours, vesicles containing a serosanguineous fluid surround the papule, with extensive associated edema. The vesicles rupture, necrose, and enlarge, forming the characteristic painless, black (hence "anthrax" from the Greek "anthracis," or coal), ulcerated lesion. Debridement of such lesions should be avoided because this may facilitate bacteremia. However, with concurrent administration of antibiotics, this prohibition does not extend to diagnostic skin biopsies, which is part of the recommended evaluation for cutaneous anthrax.⁵ The eschar dries and falls off in 1 to 2 weeks, leaving little or no scar. Lymphangitis and painful lymphadenopathy associated with systemic symptoms occur in some patients. Mortality is due to systemic invasion and may be as high as 20% of those with cutaneous anthrax without treatment. Even though antibiotics do not affect the course of the local eschar, they can prevent systemic infection. The differential diagnosis of cutaneous anthrax includes ecthyma gangrenosum, brown recluse spider bite, orf, and glanders among others. *The presence of purulence suggests an etiology other than anthrax unless there is a secondary infection.*

Gastrointestinal Anthrax

Gastrointestinal anthrax occurs 2 to 5 days after ingestion of poorly cooked, contaminated meat or poisoned food sources. Patients generally develop ulcers in the mouth, esophagus, terminal ileum, or cecum. Symptoms initially include nausea, vomiting, fever, and abdominal discomfort that progress rapidly to bloody diarrhea and signs suggestive of peritonitis. Gastric ulcers with associated hematemesis, hemorrhagic mesenteric lymphadenitis, and massive ascites may also occur.⁶ Gastrointestinal anthrax can mimic an acute abdomen, ascites with peritonitis, and a perforated viscus. The mortality rate of gastrointestinal anthrax approaches 100%. It has been suggested that early aggressive therapy may reduce the mortality rate. However, the diagnosis is often overlooked until the patient's condition is already terminal.

Specimen Collection and Organism Identification

Anthrax is so prolific that the organism may be seen on a Gram stain of blood. Cultures of blood, pleural fluid, and cerebrospinal fluid may be used to identify the organism in suspected cases. Surveillance cultures in exposed individuals (e.g., nasal swabs) are used as an epidemiologic tool and should not be routinely obtained. If possible, cultures should be obtained prior to the initiation of antibiotic therapy, since blood can be sterilized after only one or two doses of antibiotics. The organism can be easily cultured on 5% sheep blood agar or MacConkey's agar; growth can be expected in 6 to 24 hours. *Treatment should be initiated on clinical grounds. Withholding treatment while waiting for culture results will lead to increased mortality.* Although initial identification of the organism can be done in a local laboratory, specialized

testing must be done in one of the laboratories certified to do so. More information about these laboratories is available at www.bt.cdc.gov/labissues.

Identification of anthrax spores at the site of an attack is problematic. Handheld identification devices generally require 10,000 or more spores. Additionally, there is a cross-reactivity between *B. cereus* and other bacillus species. Several rapid identification techniques have been developed since 2001, including a nucleic acid-based test that can identify as few as 10 spores within 4 hours, a polymerase chain reaction (PCR) based test, and others.

Autonomous detection systems (ADS) that perform a PCR or immunoassay test at a defined interval (e.g., 1.5 hours) have been developed for anthrax and are being deployed in 300 high-speed mail handling facilities. Further details about ADS, including necessary criteria for deployment, can be found at the Centers for Disease Control and Prevention Web site (www.cdc.gov/mmwr/preview/mmwrhtml/rr53e430-2a1.htm).

Isolation

There are no data suggesting that person-to-person transmission of inhalational anthrax occurs; hence, patients with suspected anthrax may be hospitalized in a standard hospital room with standard universal precautions. Contact precautions should be used with patients who have cutaneous lesions because direct exposure to vesicle secretions of such lesions may result in secondary cutaneous infection.⁷

MEDICAL TREATMENT OF CASUALTIES

Guidelines for therapy are subject to change and may vary at the time of an anthrax attack. This is because weaponized *B. anthracis* may be engineered to be resistant to multiple antibiotics. A summary of current treatment suggestions is found in Tables 102-1 and 102-2.

TABLE 102-1 INHALATIONAL ANTHRAX TREATMENT PROTOCOL^{*,†} FOR CASES ASSOCIATED WITH BIOTERRORISM ATTACK

CATEGORY	INITIAL THERAPY (INTRAVENOUS) ^{‡§}	DURATION
Adults	Ciprofloxacin 400 mg every 12 hrs [¶] or Doxycycline 100 mg every 12 hrs [¶] and One or two additional antimicrobials [§]	IV treatment initially. Switch to oral antimicrobial therapy when clinically appropriate: Ciprofloxacin 500 mg po BID or Doxycycline 100 mg po BID Continue for 60 days (IV and po combined) [¶]
Children	Ciprofloxacin 10-15 mg/kg every 12 hrs ^{**††} or Doxycycline: ^{¶,‡‡} >8 yrs and >45 kg: 100 mg every 12 hrs >8 yrs and <45 kg: 2.2 mg/kg every 12 hrs <8 yrs: 2.2 mg/kg every 12 hrs and One or two additional antimicrobials [§]	IV treatment initially. Switch to oral antimicrobial therapy when clinically appropriate: Ciprofloxacin 10-15 mg/kg po every 12 hrs ^{‡‡} or Doxycycline: ^{‡‡‡} >8 yrs and >45 kg: 100 mg po BID >8 yrs and <45 kg: 2.2 mg/kg po BID <8 yrs: 2.2 mg/kg po BID Continue for 60 days (IV and po combined) ^{§§}
Pregnant women ^{§§}	Same for nonpregnant adults (the high death rate from the infection outweighs the risk posed by the antimicrobial agent)	IV treatment initially. Switch to oral antimicrobial therapy when clinically appropriate. [‡] Oral therapy regimens same for nonpregnant adults.
Immunocompromised persons	Same for nonimmunocompromised persons and children	Same for nonimmunocompromised persons and children.

(From Centres for Disease Control and Prevention: Update: investigation of bioterrorism-related anthrax and interim guidelines for exposure management and antimicrobial therapy. *Morb Mortal Wkly Rep.* 2001;50:909-19.)

[†]For gastrointestinal and oropharyngeal anthrax, use regimens recommended for inhalational anthrax.

[‡]Ciprofloxacin or doxycycline should be considered an essential part of first-line therapy for inhalational anthrax.

[§]Steroids may be considered as an adjunct therapy for patients with severe edema and for meningitis based on experience with bacterial meningitis of other etiologies.

[¶]Other agents with in vitro activity include rifampin, vancomycin, penicillin, ampicillin, chloramphenicol, imipenem, clindamycin, and clarithromycin. Because of concerns of constitutive and inducible beta-lactamases in *Bacillus anthracis*, penicillin and ampicillin should not be used alone. Consultation with an infectious disease specialist is advised.

^{||}Initial therapy may be altered based on clinical course of the patient; one or two antimicrobial agents (e.g., ciprofloxacin or doxycycline) may be adequate as the patient improves.

^{**}If meningitis is suspected, doxycycline may be less optimal because of poor central nervous system penetration.

^{**†}Because of the potential persistence of spores after an aerosol exposure, antimicrobial therapy should be continued for 60 days.

^{††}If intravenous ciprofloxacin is not available, oral ciprofloxacin may be acceptable because it is rapidly and well absorbed from the gastrointestinal tract with no substantial loss by first-pass metabolism. Maximum serum concentrations are attained 1-2 hours after oral dosing but may not be achieved if vomiting or ileus is present.

^{‡‡}In children, ciprofloxacin dosage should not exceed 1 g/day.

^{‡‡‡}The American Academy of Pediatrics recommends treatment of young children with tetracyclines for serious infections (e.g., Rocky Mountain spotted fever).

^{§§}Although tetracyclines are not recommended during pregnancy, their use may be indicated for life-threatening illness. Adverse effects on developing teeth and bones are dose related; therefore, doxycycline might be used for a short time (7-14 days) before 6 months of gestation.

TABLE 102-2 CUTANEOUS ANTHRAX TREATMENT PROTOCOL* FOR CASES ASSOCIATED WITH BIOTERRORISM ATTACK

CATEGORY	INITIAL THERAPY (ORAL) [†]	DURATION
Adults [*]	Ciprofloxacin 500 mg BID or Doxycycline 100 mg BID	60 days [‡]
Children [*]	Ciprofloxacin 10-15 mg/kg every 12 hrs (not to exceed 1 g/day) [†] or Doxycycline: [§] >8 yrs and >45 kg: 100 mg every 12 hrs >8 yrs and <45 kg: 2.2 mg/kg every 12 hrs <8 yrs: 2.2 mg/kg every 12 hrs	60 days [‡]
Pregnant women ^{*,}	Ciprofloxacin 500 mg BID or Doxycycline 100 mg BID	60 days [‡]
Immunocompromised persons [*]	Same for nonimmunocompromised persons and children	60 days [‡]

(From Centres for Disease Control and Prevention: Update: investigation of bioterrorism-related anthrax and interim guidelines for exposure management and antimicrobial therapy. *Morb Mortal Wkly Rep.* 2001;50:909-19.)

^{*}Cutaneous anthrax with signs of systemic involvement, extensive edema, or lesions on the head or neck requires intravenous therapy, and a multidrug approach is recommended (see Table 102-1).

[†]Ciprofloxacin or doxycycline should be considered first-line therapy. Amoxicillin 500 mg po TID for adults or 80 mg/kg/day divided every 8 hours for children is an option for completion of therapy after clinical improvement. Oral amoxicillin dose is based on the need to achieve appropriate minimum inhibitory concentration levels.

[‡]Previous guidelines have suggested treating cutaneous anthrax for 7-10 days, but 60 days is recommended in the setting of this attack, given the likelihood of exposure to aerosolized *B. anthracis*.⁶

[§]The American Academy of Pediatrics recommends treatment of young children with tetracyclines for serious infections (e.g., Rocky Mountain spotted fever).

^{||}Although tetracyclines or ciprofloxacin are not recommended during pregnancy, their use may be indicated for life-threatening illness. Adverse effects on developing teeth and bones are dose related; therefore, doxycycline might be used for a short time (7-14 days) before 6 months of gestation.

Because of the lack of adequate central nervous system penetration by doxycycline, ciprofloxacin should be the drug of choice for central nervous system anthrax.^{3,8} This recommendation may be extended to all patients with inhalational anthrax, given the high rate of associated meningitis. Penicillin, cephalosporins, and trimethoprim-sulfamethoxazole should not be used for treatment because of resistance. Chest tube drainage of the recurrent, often hemorrhagic, pleural effusions has been shown to lead to quite dramatic clinical improvement and should be strongly considered.

Treatment of Exposed Individuals

Treatment is not advocated for asymptomatic persons unless public, health, or law-enforcement authorities have ascertained that there is a risk of exposure. Ciprofloxacin 500 mg orally twice daily for 60 days is recommended (Table 102-3). In addition to antibiotics, some authorities have recommended 3 doses of vaccine at diagnosis and at 2 weeks and 4 weeks after exposure.⁹ Boosters should be given at 6, 12, and 18 months and yearly thereafter. Vaccination of exposed individuals may be prudent and may be recommended in the event of an attack. It is likely that amoxicillin can be used in children and pregnant women as a prophylactic drug since many strains of anthrax are sensitive to penicillin. Again, these recommendations¹⁰ are subject to change based on recommendations made at the time of an incident.

The majority of patients who receive prophylaxis cannot tolerate the therapy. At 30 days, as few as 40% of individuals were noted to be taking prophylactic medications (this was 70% of high-risk exposures). Common side effects at 14 days include "severe" gastrointestinal

symptoms (13%-19%); fainting, dizziness, and lightheadedness (7%-13%); and heartburn and gastroesophageal reflux disease (8%).^{9,10}

PREINCIDENT ACTIONS

Personal protective equipment should be available. Stockpiling of antibiotics in local or national stores and rapid distribution systems can prevent delays in postexposure antibiotic prophylaxis. Prophylactic vaccination is indicated only in individuals who will be repeatedly exposed to anthrax spores, such as those in Bioterrorism Level B laboratories, those working with imported raw hides, and wool and cleaning crews.

POSTINCIDENT ACTION

Reaerosolization of *B. anthracis* spores is uncommon. Cleansing of the skin, potentially contaminated clothing, and the environment may reduce the risk of acquiring cutaneous and gastrointestinal forms of disease.¹¹

For decontamination, sporicidal solutions, such as commercially available bleach or 0.5% hypochlorite solution (a 1:10 dilution of household bleach), should be used. These substances may be corrosive to some surfaces. Dressings from cutaneous lesions are considered a biohazard.

It is the responsibility of the treating physician to report all suspected or confirmed cases of anthrax to the local and state public health departments and laboratories as well as the local police department. Updated information regarding these requirements can be found

TABLE 102-3 INTERIM RECOMMENDATIONS FOR POSTEXPOSURE PROPHYLAXIS FOR PREVENTION OF INHALATIONAL ANTHRAX AFTER INTENTIONAL EXPOSURE TO *BACILLUS ANTHRACIS*

CATEGORY	INITIAL THERAPY	DURATION
Adults (including pregnant women and immunocompromised persons)	Ciprofloxacin 500 mg po BID or Doxycycline 100 mg po BID	60 days
Children	Ciprofloxacin 10-15 mg/kg po Q 12 hrs ^a or Doxycycline: >8 yrs and >45 kg: 100 mg po BID >8 yrs and ≤45 kg: 2.2 mg/kg po BID ≤8 yrs: 2.2 mg/kg po BID	60 days

^aCiprofloxacin dose should not exceed 1 g per day in children. (From *Morb Mortal Wkly Rep.* 2001; 50:909-19.)

on the Centers for Disease Control and Prevention's Web site at www.bt.cdc.gov.

UNIQUE CONSIDERATIONS

Isolation of the source of infection may be valuable for public health and law enforcement officials. If, for example, an envelope is the source of infection, the source

CASE PRESENTATION

An envelope containing anthrax is sent to a member of Congress. There are several infected individuals. Other sources of anthrax are found in the mail throughout the country. Because of concern about anthrax, every person who finds a white powder presents to the emergency department convinced he or she needs antibiotic prophylaxis for anthrax or at least cultures, as do close relatives and co-workers and everyone who was in the mall last Saturday when someone scattered baking soda. The emergency department is overwhelmed by the walking well. What are some of the steps necessary to manage this event?

should be placed in a plastic bag. If a plastic bag is not available, the source should be covered with a sheet or other barrier. All windows in the infected building should be closed, the ventilation system should be turned off, and exposed individuals should be instructed to remove possibly contaminated clothing and shower before presenting to the emergency department.

PITFALLS

- Failure to remain vigilant.
- Failure to treat for an adequate length of time and with multidrug regimens.
- Failure to consider inhalation anthrax as the cause of flulike symptoms.
- Failure to notify appropriate authorities in suspected or confirmed cases of anthrax.

Yersinia Pestis (Plague) Attack

Jeremiah D. Schuur and Jonathan Harris Valente

DESCRIPTION OF EVENT

A bioterrorism event leading to multiple cases of the plague would likely result from airborne dispersal of a weaponized form of *Yersinia pestis* and would cause a pulmonary variant of the plague called *pneumonic plague*.¹ During World War II, in two separate incidents, the Japanese dropped clay pots filled with *Y. pestis*-contaminated rice and fleas over the Chinese cities of Shusien in Chekiang province and Changteh in Hunan province. This tactic led to outbreaks of bubonic plague.^{2,3} However, this would not be the optimal way for terrorists to spread the plague because bubonic plague requires a bite from a flea. In addition, bubonic plague is not spread directly from person to person like the pneumonic form.

Pneumonic plague may occur as a secondary pneumonia due to hematogenous spread from bubonic plague. This is the most common form of naturally occurring pneumonic plague. Primary pneumonic plague occurs after inhalation of aerosolized *Y. pestis* bacilli, either from person-to-person transmission or via an intentional attack. Pneumonic plague is rapidly progressive and can spread from person to person via aerosolized droplets. The incubation period for pneumonic plague (1 to 6 days) is shorter than that of the bubonic form (2 to 8 days).^{4,5} Control of the disease would be complex because affected people without knowledge of the exposure could spread disease by travel to other regions.⁶⁻⁸

Pneumonic plague presents clinically as a rapidly progressive respiratory syndrome that is often associated with fever, cough, shortness of breath, chest pain, hemoptysis, malaise, myalgia, nausea and vomiting, sputum or blood cultures with gram-negative rods, and radiographic findings of pneumonia. Chest roentgenograms of patients with pneumonic plague usually show patchy bronchopneumonic infiltrates as well as segmental or lobar consolidation with or without confluence. They may show cavitory lesions or bilateral diffuse infiltrates characteristic of acute respiratory distress syndrome.⁹

It has been estimated that if 50 kg of weaponized *Y. pestis* were released as an aerosol over a city of 5 million people, pneumonic plague could occur in as many as 150,000 persons, 36,000 of whom would be expected to die.¹⁰

PREINCIDENT ACTIONS

An intentional plague outbreak should be considered one of the most likely bioterrorism scenarios for which emergency providers need to prepare. Pneumonic plague would most likely occur naturally as a complication of bubonic plague in the setting of a major bubonic plague outbreak.¹¹ *Y. pestis* is not stable in the environment, and it is readily destroyed by drying and sunlight exposure. If *Y. pestis* were released into the air in a bioterrorism attack, it would likely survive for less than an hour. Due to these factors, preparation for environmental decontamination is less important than in other similar attacks, such as with anthrax.^{7,8,10}

No vaccine is currently available. The U.S. manufactured vaccine (Greer) was discontinued in 1999 and was not protective for the pneumonic form of the plague. Research is under way, and a new vaccine protective against pneumonic plague is in advanced development.^{6,8} There are no early warning systems for the detection of *Y. pestis* if an aerosolized form were dispersed. In addition, there are no rapid diagnostic tests to detect *Y. pestis* in suspected patients.^{8,12}

POSTINCIDENT ACTIONS

All cases of pneumonic plague should be considered terrorism-related until proven otherwise. Hospital infection control officers and local and state, national health, and law enforcement officials should be notified immediately of any suspected cases of the plague.

The risk for reaerosolization of *Y. pestis* from the contaminated clothing of exposed persons is low. Under ideal conditions, *Y. pestis* can survive in the environment for about 1 hour, and since patients will present with symptoms after 24 hours, there is no need for routine decontamination. In situations where there may have been recent, gross exposure to *Y. pestis*, decontamination of skin and potentially contaminated fomites (e.g., clothing or environmental surfaces) may be considered to reduce the risk of cutaneous or bubonic forms of the disease.

The plan for decontaminating patients may include several steps. Patients should be instructed to remove contaminated clothing. Clothing should be stored in

labeled, plastic bags and gently handled to avoid dispersal of *Y. pestis*. Patients should be instructed to shower thoroughly with soap and water. Environmental surface decontamination may be performed using an Environmental Protection Agency-registered, facility-approved sporidical/germicidal agent or a 0.5% hypochlorite solution (one part household bleach added to nine parts water).^{1,13,14}

In its natural form, pneumonic plague is transmitted person to person via large droplets (not via fine-particle aerosol) and requires close personal contact (2 meters or less) for effective transmission.^{4,15,16} Patients with symptoms suggestive of pneumonic plague should be isolated using droplet precautions in addition to standard precautions. Patients with suspected pneumonic plague should be placed in a private room when possible. It is appropriate to cohort symptomatic patients with similar symptoms and the same presumptive diagnosis (i.e., pneumonic plague) when private rooms are not available. Maintain spatial separation of at least 3 feet between infected patients and others when cohorting is not possible. Avoid placement of patients requiring droplet precautions in the same room with an immunocompromised patient. Special air handling is not necessary, and doors may remain open. Patient transport should be limited to essential medical purposes. When transport is necessary, minimize dispersal of droplets by placing a surgical-type mask on the patient. Isolation precautions should be continued for 2 days after initiation of antibiotics and until some clinical improvement occurs in patients with pneumonic plague.⁸

MEDICAL TREATMENT OF CASUALTIES

Specific antibiotic treatment must be initiated within 24 hours after symptom onset, otherwise pneumonic plague is nearly uniformly fatal.^{6,8} Table 103-1 shows the Working Group on Civilian Biodefense's antibiotic recommendations for pneumonic plague.⁸ These consensus-based recommendations cover contained exposures, mass casualty exposures, and postexposure prophylaxis. They are based on the best available evidence. However, it should be noted that there is a lack of published trials in treating plague in humans and a limited number of studies in animals. A number of possible therapeutic regimens for treating plague have not been prospectively studied or approved by the Food and Drug Administration.

In a contained casualty setting, parenteral antibiotics are recommended for all symptomatic patients. In a mass casualty incident, local resources must be evaluated and if sufficient supplies of parenteral antibiotics are not available, oral antibiotics may be used. Oral antibiotics should also be given for 7 days as postexposure prophylaxis. Individuals refusing postexposure antibiotics should be observed for fever or cough for 1 week, although isolation is not recommended.^{6,8} Several antibiotics that should not be used for pneumonic plague include rifampin, aztreonam, ceftazidime, cefotetan, and ceftazolin.²⁰

Laboratory testing is needed to confirm pneumonic plague. A sputum Gram stain should be used emergently because it may reveal bipolar staining gram-negative bacilli or coccobacilli. *Y. pestis* is described as having a bipolar (also termed "safety pin") staining best seen with Giemsa or Wayson stains.²¹ The only gram-negative bacilli to cause rapidly progressing pulmonary symptoms are *Y. pestis* and *Bacillus anthracis*. Blood or sputum cultures should demonstrate growth within 24 to 48 hours, although some laboratory systems may misidentify *Y. pestis*.²² Laboratory personnel should be notified when *Y. pestis* is suspected to decrease the chance of laboratory exposure and to increase the diagnostic yield. Biosafety Level 2 conditions are acceptable for routine laboratory procedures.⁸ Serologic tests are useful for bubonic plague, but since patients do not seroconvert until between 5 and 20 days postexposure, they would be of little use in a pneumonic plague outbreak.⁴

Due to the severity of pneumonic plague, patients may require advanced supportive measures including mechanical ventilation, pressors, and invasive monitoring. Clinical deterioration despite appropriate antimicrobial treatment should raise the possibility of an antimicrobial-resistant strain of *Y. pestis*. This has been reported to occur naturally as well as via genetic engineering by Soviet scientists.²³

UNIQUE CONSIDERATIONS

Y. pestis must be considered one of the most likely bacteria to be used as a bioterrorism agent. *Y. pestis* has been used as a biowarfare agent throughout history, it is readily available worldwide in nature and biologic laboratories, and mass production is relatively simple. Although aerosolized *Y. pestis* is not known to have ever been used, it has been successfully weaponized by the former Soviet Union and could be effectively dispersed as an aerosol.^{8,23} Under proper conditions, such a release could lead to widespread epidemic pneumonic plague with continued human-to-human transmission. Cases would not present for at least 24 hours after exposure. Pneumonic plague is highly contagious and virulent, and antimicrobial treatment must be initiated within 24 hours to improve survival. Without appropriate antibiotic treatment and supportive care, numerous casualties would result.

PITFALLS

- Failure to notify appropriate public health and law enforcement agencies when an outbreak of pneumonic plague is suspected or confirmed
- Failure to consider pneumonic plague as the etiologic agent in major pneumonia endemics or pandemics
- Failure to use droplet precautions and standard precautions in potential cases of pneumonic plague
- Failure to initiate specific antibiotic therapy within 24 hours of symptom onset
- Failure to provide postexposure antibiotic prophylaxis

TABLE 103-1 RECOMMENDATIONS FOR ANTIMICROBIAL TREATMENT OF PNEUMONIC PLAGUE*

PATIENT CATEGORY	RECOMMENDED THERAPY
Contained Casualty Setting	
Adults	<p>Preferred choices</p> <ul style="list-style-type: none"> Streptomycin, 1 g IM twice daily Gentamicin, 5 mg/kg IM or IV once daily or 2 mg/kg loading dose followed by 1.7 mg/kg IM or IV 3 times daily[†] <p>Alternative choices</p> <ul style="list-style-type: none"> Doxycycline, 100 mg IV twice daily or 200 mg IV once daily Ciprofloxacin, 400 mg IV twice daily[‡] Chloramphenicol, 25 mg/kg IV 4 times daily[§]
Children	<p>Preferred choices</p> <ul style="list-style-type: none"> Streptomycin, 15 mg/kg IM twice daily (maximum daily dose, 2 g) Gentamicin, 2.5 mg/kg IM or IV 3 times daily[†] <p>Alternative choices</p> <ul style="list-style-type: none"> Doxycycline, <ul style="list-style-type: none"> If >45 kg, give adult dosage If <45 kg, give 2.2 mg/kg IV twice daily (maximum, 200 mg/d) Ciprofloxacin, 15 mg/kg IV twice daily[‡] Chloramphenicol, 25 mg/kg IV 4 times daily[§]
Pregnant women [¶]	<p>Preferred choice</p> <ul style="list-style-type: none"> Gentamicin, 5 mg/kg IM or IV once daily or 2 mg/kg loading dose followed by 1.7 mg/kg IM or IV 3 times daily[†] <p>Alternative choices</p> <ul style="list-style-type: none"> Doxycycline, 100 mg IV twice daily or 200 mg IV once daily Ciprofloxacin, 400 mg IV twice daily[‡]
Mass Casualty Setting and Postexposure Prophylaxis[#]	
Adults	<p>Preferred choices</p> <ul style="list-style-type: none"> Doxycycline, 100 mg orally twice daily^{††} Ciprofloxacin, 500 mg orally twice daily[‡] <p>Alternative choice</p> <ul style="list-style-type: none"> Chloramphenicol, 25 mg/kg orally 4 times daily^{§, **}
Children	<p>Preferred choice</p> <ul style="list-style-type: none"> Doxycycline,^{††} <ul style="list-style-type: none"> If <45 kg, give adult dosage If >45 kg, then give 2.2 mg/kg orally twice daily Ciprofloxacin, 20 mg/kg orally twice daily <p>Alternative choices</p> <ul style="list-style-type: none"> Chloramphenicol, 25 mg/kg orally 4 times daily^{§, **}
Pregnant women [¶]	<p>Preferred choices</p> <ul style="list-style-type: none"> Doxycycline, 100 mg orally twice daily^{††} Ciprofloxacin, 500 mg orally twice daily <p>Alternative choices</p> <ul style="list-style-type: none"> Chloramphenicol, 25 mg/kg orally 4 times daily^{§, **}

(From Inglesby TV, et al. Consensus Statement: Plague as a Biological Weapon: Medical & Public Health Management. *JAMA*. 2000;283[17]:2281-90.)

*These are consensus recommendations of the Working Group on Civilian Biodefense and are not necessarily approved by the Food and Drug Administration. One antimicrobial agent should be selected. Therapy should be continued for 10 days. Oral therapy should be substituted when patient's condition improves. IM indicates intramuscularly; IV, intravenously.

[†]Aminoglycosides must be adjusted according to renal function. Evidence suggests that gentamicin, 5 mg/kg IM or IV once daily, would be efficacious in children, although this is not yet widely accepted in clinical practice. Neonates up to 1 week of age and premature infants should receive gentamicin, 2.5 mg/kg IV twice daily.

[‡]Other fluoroquinolones can be substituted at doses appropriate for age. Ciprofloxacin dosage should not exceed 1 g/d in children.

[§]Concentration should be maintained between 5 and 20 µg/mL. Concentrations greater than 25 µg/mL can cause reversible bone marrow suppression.^{17,18}

^{||}Refer to "Management of Special Groups" for details. In children, ciprofloxacin dose should not exceed 1 g/d, chloramphenicol should not exceed 4 g/d. Children younger than 2 years should not receive chloramphenicol.

[¶]In neonates, gentamicin loading dose of 4 mg/kg should be given initially.¹⁹

[#]Duration of treatment of plague in mass casualty setting is 10 days. Duration of postexposure prophylaxis to prevent plague infection is 7 days.

^{**}Children younger than 2 years should not receive chloramphenicol. Oral formulation available only outside the United States.

^{††}Tetracycline could be substituted for doxycycline.

CASE PRESENTATION

It is a Tuesday afternoon in August in your emergency department, and you have just encountered your third patient with a history of high fever, cough, shortness of breath, nausea, vomiting, and chest pain. The first patient was a 24-year-old healthy male diagnosed with pneumonia. He was admitted for intravenous antibiotics and fluids secondary to persistent hypoxia, tachypnea, and dehydration. The second patient was a 40-year-old female with a similar story; however, she needed intubation and admission to the intensive care unit for respiratory distress and hypoxia. You see a few more patients in what appears to be a typical work day. As you read the next chart, you recall that the last name of the woman whom you admitted to the intensive care unit earlier in the morning is the same as this patient's last name; it is her husband. He is an ill-appearing 42-year-old male wearing a T-shirt from the air show that occurred over the weekend. You remember that he had been sweating and coughing while in the emergency department with his wife earlier in the morning. During your interview, he states that he and his wife had been at the air show. "It was a great show. I especially liked the stunt planes that were spraying the smoke!" You finish your evaluation and determine that he also has pneumonia. It is near the end of your shift and one of your colleagues arrives to relieve you. He states, "I'm here for work, but I don't feel that well. I think I may need to call the back-up person in to work. I have been getting this really bad cold, and this morning I had a fever. The kids are all sick, too, with the same thing." It crosses your mind that he was the medical director at the air show.

Francisella Tularensis (Tularemia) Attack

Irving Jacoby

DESCRIPTION OF EVENT

Tularemia, known also as rabbit fever, hare fever, deerfly fever, or lemming fever, is a zoonotic bacterial illness caused by a small, gram-negative coccobacillus, *Francisella tularensis*, that infects more than 150 animal species, can be transmitted to humans, and is associated with a wide variety of clinical presentations. Reservoirs for this disease include terrestrial and aquatic mammals, such as rabbits, hares, ground squirrels, voles, muskrats, water and other rats, and skunks. Most recently, it has been identified in prairie dogs.¹ Additionally, *F. tularensis* survives in amoebae, which may explain the association of this bacterium with swamps and waterways.² The primary vectors are ticks, mosquitoes, and biting flies, such as the deerfly.

Four subspecies are currently recognized by microbiologists, with somewhat different geographic distributions. *F. tularensis* subspecies *tularensis*, also known as Type A, is found almost exclusively in North America and is considered a more virulent strain in humans, whereas the *F. tularensis* subspecies *holarctica* (Type B) is found throughout the northern hemisphere, predominantly in Europe, and is associated with a milder disease state. *F. tularensis* subspecies *novicida* is also found in North America, and subspecies *mediasiatica* is found in Kazakhstan and Uzbekistan.² Transmission to humans occurs in a number of ways, including the handling of infected animal tissues or fluids; bites from infected arthropods, particularly ticks and mosquitoes that have fed on infected animals; direct contact or ingestion of contaminated water or food; and via the inhalation of infective aerosols. Examining an open culture plate has resulted in human infection in laboratory workers, and Biosafety Level 3 facilities must be used for work with the organism. Historic origins related to human infection have been presented elsewhere.³ No human-to-human transmission has ever been documented; hence, isolation is not required. Most naturally occurring cases in the United States are seen from May to August, although infection can occur at any time.

Tularemia is high on the list of dangerous weaponizable biologic agents due to its extreme infectivity once aerosolized, ease of dissemination, and substantial capacity to cause morbidity and mortality. One of the most

infectious pathogens known, as few as 10 to 50 inhaled organisms have been shown to be capable of producing disease.^{4,5} Tularemia has historically been a part of biologic weapons programs in the last century. It was one of the agents studied at Japanese germ warfare research units operating in Manchuria between 1932 and 1945. Ken Alibek suggests that the tularemia outbreak that infected thousands of Soviet and German soldiers before the Battle of Stalingrad in 1942 was related to weaponized tularemia developed by the Soviets, which spread out of control by wind changes,⁶ although this remains controversial.⁷ *F. tularensis* weapons were produced and stockpiled at the biologic warfare production facility of the U.S. Army at the Pine Bluff Arsenal, Ark., by 1954 to 1955, but were destroyed by 1973.⁸ Vaccine-immune and antibiotic-resistant strains of tularemia were prepared by Biopreparat, the covert Soviet biologic weapons effort, in the 1980s.⁶

Clinical manifestations of disease in humans are varied and often depend on the mode of transmission, site of infection, and the virulence and dose of the infecting organism. Presenting syndromes are glandular, ulceroglandular, oculoglandular, oropharyngeal, pneumonic, typhoidal, and septic.

The most common forms of naturally acquired disease are ulceroglandular and glandular. A cutaneous papule forms at the site of the bite or cutaneous inoculation from an infected animal hide or carcass, and involvement of regional lymph nodes occurs. The pustule suppurates and ulcerates within a few days. Lymph nodes can swell to a large size and resemble the buboes of bubonic plague or the adenopathy of cat scratch disease. An eschar may form and resemble anthrax. Symptoms include fever, chills, headache, and myalgia. Glandular tularemia is present when there is adenopathy without ulceration.

Oculoglandular disease occurs when inoculation takes place directly into the eye, often by a finger that has viable organisms on it, and ulceration of the conjunctiva may be seen. Pronounced chemosis and pre-auricular node enlargement are manifest.

Oropharyngeal tularemia occurs after ingestion of contaminated water or food. Stomatitis, exudative tonsillitis, or pharyngitis may occur with or without ulceration. Lymphadenopathy of cervical or retropharyngeal nodes can be marked.

Tularemia pneumonia follows either inhalation of contaminated aerosols or is secondary to bacterial spread from a local site and is a much more serious form of tularemia. Mortality rates of 30% are reported for this form. The pneumonia is accompanied by hilar adenopathy, dry cough, shortness of breath, and chest pain, either substernal or pleuritic. The term “lawnmower tularemia” was first used when two cases of pneumonic tularemia were reported to have occurred in adolescent males who mowed over a dead rabbit with presumptive aerosolization and inhalation of contaminated fomites. Both were treated with streptomycin and recovered.⁹ A larger outbreak was reported with patients who had mowed lawns and cut brush on Martha’s Vineyard in 2001.¹⁰ Adult respiratory distress syndrome has been reported in association with tularemic pneumonia.¹¹

Typhoidal tularemia refers to illness characterized by systemic infectious manifestations of fever and chills, but without cutaneous, ocular, lymphatic, or pulmonary findings. Diarrhea and abdominal pain may predominate.

Tularemic sepsis is severe and often fatal. The patient is toxic-appearing, confused, and may become comatose. Systemic inflammatory response syndrome (SIRS) may occur with shock and disseminated intravascular coagulation.¹¹

Standard blood, wound, and body fluid cultures should be sent for detection of *F. tularensis*. Because the organism may grow on conventional culture media, it is important to notify laboratory personnel of your suspicion for this organism because growth on a plate represents a significant contagion risk to the laboratory worker.¹² Notification in advance may also increase the likelihood of detecting the organism because use of special media can enhance growth and recovery. If organisms suggestive of *Francisella* are grown by a standard hospital laboratory, further steps in identification may need to be halted, with referral of the isolate to a Centers for Disease Control and Prevention (CDC) reference or national laboratory for definitive identification and sensitivity testing. Such laboratories would be part of the CDC’s Laboratory Response Network (LRN) where standardized, unpublished protocols are followed when dealing with such suspected agents of bioterrorism.

Other clinical tests for general use can be ordered, such as commercially available serologic tests for *F. tularensis* antibody, antigen capture enzyme-linked immunosorbent assay (cELISA), and polymerase chain reaction/TaqMan assays, for detecting antigen in inactivated clinical samples. If present, pleural fluid should be tapped and sent for staining, culture, and direct fluorescent antibody (DFA) testing.

PREINCIDENT ACTIONS

Tularemia is typically a rural disease, and, although urban and suburban exposures may occur, occurrence in the latter situations may signal the possibility of a terrorist attack, even when a link to an animal vector can be made, since known contaminated hides or fomites could be circulated as a terrorist act. Given the greater severity of Type A disease and the inhalational route, and the known

weaponization of *F. tularensis*, a terrorist attack is most likely to be perpetrated via the aerosolized route. However, identification of an index case is key in defending against a tularemic terrorist attack. An index case may represent autoinoculation by the perpetrator. Detecting an uncommon disease can be enhanced by ongoing public health communications of isolated occurrences or outbreaks in a real-time continuum.¹³ The similarity of many of the clinical manifestations of tularemia to other more common syndromic presentations would make it difficult to come up with tularemia as an immediate diagnosis because it is unlikely to be a leading cause of community-acquired pneumonia or conjunctivitis. The careful history of live or dead animal exposures would be an important source of clues to suggest the need for a diagnostic workup for tularemia. Familiarization with the different syndromic presentations of tularemia remains the most important tool in your armamentarium.

Vaccination before exposure is a way of preparing for an attack. The former Soviet Union used a live-attenuated vaccine strain (LVS) for decades, starting in the 1930s, to immunize millions of people living in endemic areas. In the United States, an investigational new drug is approved for clinical trials. A retrospective study of laboratory workers working with *F. tularensis* at a U.S. Army research facility found a decrease in risk of infection from 5.70 cases of typhoidal tularemia per 1000 person-years of risk with a killed vaccine to 0.27 cases per 1000 person-years of risk after introduction of an LVS vaccine.¹⁴ However, the incidence of ulceroglandular tularemia was unchanged, albeit cases were moderated. LVS vaccine is currently the only effective vaccine under investigation, but it is not available for clinical use at this time, since data required for licensing were not adequately documented during the manufacture of current lots, and the older method of growth using shaker culture no longer meets current good manufacturing processes. A new process for production must be devised to obtain licensure.¹⁵ Improved vaccines are needed since the LVS vaccine requires scarification, is cumbersome, and difficult to standardize. Current vaccine efforts are reviewed elsewhere.^{15,16}

POSTINCIDENT ACTIONS

The local or state health department should be alerted if tularemia is highly suspected, particularly if multiple patients present with a compatible illness.

If prompt recognition of an attack with a tularemia bioweapon occurs during the early incubation period, exposed persons should be treated prophylactically, with either doxycycline 100 mg p.o. twice daily or ciprofloxacin 500 mg p.o. bid for 14 days.

If an attack has been identified only after cases are occurring, it has been recommended by the Working Group on Civilian Biodefense that persons potentially exposed should begin a fever watch. Persons who develop an otherwise unexplained fever or flulike illness within 14 days should begin treatment as noted later in the chapter.¹⁷

If a laboratory worker has had a potentially high-risk infective exposure to *F. tularensis*, such as via a spill, centrifuge accident, needlestick exposure, or exposure

to an open culture plate, oral postexposure prophylaxis should be given. With low-risk events, the laboratory worker can be placed on a fever watch and treated if any symptoms develop within 14 days of exposure.

Laboratory spills of infectious *F. tularensis* broth or suspension should be decontaminated with 10% bleach solution; after 10 minutes, it is recommended that 70% solution of alcohol be used to further clean the area and reduce the corrosive effects of the bleach.¹⁷

Isolation is not recommended for infected patients, given lack of human-to-human transmission. Close contacts of patients with diagnosed disease thus do not require prophylaxis.

If the LVS vaccine were available, immunity would take 2 weeks to develop and hence has no role in protecting against inhalational exposure after the fact.

MEDICAL TREATMENT OF CASUALTIES

Treatment of tularemia is antibiotic-based. The preferred first-line choice of antibiotics for adults is streptomycin 1 g intramuscularly twice daily or gentamicin 5 mg/kg intramuscularly or intravenously once daily for 10 days.¹⁸

For patients allergic to aminoglycosides, alternatives are doxycycline 100 mg intravenously twice daily; chloramphenicol 15 mg/kg intravenously four times daily for 14 to 21 days. Ciprofloxacin 400 mg intravenously twice daily for 10 days; other fluoroquinolones have also been used.¹⁹

In pregnant women, preferred choices are gentamicin or streptomycin; alternative choices are ciprofloxacin or doxycycline.

Bioterrorist attacks using resistant strains are a possibility. Culturing to obtain isolates for sensitivity testing is essential. This should be suspected if patients fail to respond to first-line therapy.

Supportive care is critical for fluid management and the detection and treatment of the complications of sepsis, including shock, acute respiratory distress syndrome, disseminated intravascular coagulation, rhabdomyolysis, and organ failure.

UNIQUE CONSIDERATIONS

It would be expected that tularemia would have a slower progression of illness and a lower case fatality rate than inhalational anthrax or pneumonic plague. Presumptive laboratory diagnosis of anthrax or plague would likely be made more rapidly than tularemia, due to the need for referral to reference laboratories.

Outbreaks of tularemia in patients from an urban setting should trigger suspicion of a bioterrorist attack. A World Health Organization expert committee in 1970 gave an estimate that aerosol dispersal of 50 kg of virulent *F. tularensis* over a metropolitan area with 5 million inhabitants would result in 250,000 incapacitating casualties, including 19,000 deaths.²⁰

Painful pre-auricular lymphadenopathy is a hallmark of oculoglandular tularemia and distinguishes it from cat scratch disease, tuberculosis, sporotrichosis, and syphilis.

Epidemiologic workup may be needed to determine the reservoir in a given outbreak. The occurrence of an outbreak of tularemia in a war-torn area, although suggestive of possible bioterrorism, can be related to factors such as environmental disruption, as was recently shown in Kosovo.²¹

PITFALLS

Although intuitively one might think that only pneumonic tularemia would occur from an airborne attack with viable organisms, airborne transmission can result in an initial clinical illness without prominent respiratory symptoms.

Mild inhalational disease in a rural setting can be indistinguishable from Q fever.

Due to the many varied presentations of classical tularemia, the differential diagnosis is very broad. Add to

CASE PRESENTATION

You are on duty at an academic medical center emergency department. A 41-year-old male presents for fever, cough, and pleuritic chest pain. The patient reports he has been ill for 3 days. No one else is ill at home. His social history includes the following: No travel, no hunting, and the patient lives in a suburban area of a Midwestern metropolitan area. The review of his systems is positive for diffuse myalgia and shortness of breath. On examination, he is mildly ill-appearing. His pulse is 112; respiratory rate, 20 with splinting respirations; temperature, 103.0; and blood pressure, 114/68 mm Hg. His oxygen saturation is 94% on room air. The patient's skin examination is normal, and no insect or tick bites are found. The HEENT (head, ears, eyes, nose, throat) examination is normal, but some submandibular lymph nodes feel prominent. Lung sounds are decreased in the left base posteriorly, and a pleural friction rub is heard. Chest radiograph shows a widened mediastinum, with a left pleural effusion, but no obvious pulmonary infiltrates are seen. Your differential diagnosis includes viral pleurisy, bacterial empyema, and mediastinitis with its attendant differential. You start the workup by ordering blood and sputum cultures, a complete blood count, differential, electrolytes, liver function tests, and coagulation tests. You mention the case to your double-coverage colleague, who replies that he admitted a similar patient last night from the same suburban neighborhood and had heard about another case during the prior shift. You return to the patient and ask about any unusual occurrences over the past week involving animals or hides, and he reports that he was outdoors 5 days ago in a suburban shopping mall when a spray plane had passed overhead spraying what he had assumed was insecticide for mosquitoes. He wondered whether he might have gotten sprayed with insecticide, which he thought may have caused the illness. You had not heard of such spraying taking place. You call the local health department now, despite no definitive diagnosis, and relay your suspicions of a possible terrorist attack. You then contemplate the differential, adding bioterrorism-type agents; plan further workup and initial treatment; and call the hospitalist to admit the patient for a pleural tap and intravenous antibiotics.

that the unusual manifestations of tularemia, including pericarditis, lymphocytic meningitis, hepatitis, endocarditis, osteomyelitis, sepsis and septic shock, and rhabdomyolysis, and it is apparent that tularemia could be missed easily in the urban setting, until laboratory confirmation is made.

Brucella Species (Brucellosis) Attack

Teriggi J. Ciccone

DESCRIPTION OF EVENT

Brucellosis, also known as Mediterranean fever, undulant fever, and Malta fever, is a protean clinical syndrome caused by a number of species within the genus *Brucella*. *Brucellae* are small, gram-negative aerobic coccobacilli. Clinical cases of brucellosis are rare in North America, occurring almost exclusively in workers exposed to livestock; however, the syndrome is endemic throughout agrarian areas with poor food and sanitation standards, such as in the Middle East, India, and Latin America. Domesticated animals such as cattle, swine, sheep, and dogs comprise *Brucellae's* natural reservoir.

One of the first biologic agents to be weaponized by the United States,¹ *Brucella* is classified as a category B agent by the Centers for Disease Control and Prevention (CDC).² Several characteristics of *Brucellae* make them ideal candidates for production into biologic weapons. *Brucellae* can be manipulated in the laboratory and manufactured into particles measuring 1 to 5 μm in diameter. Particles of this size are ideally suited to enter into and remain in the alveolar spaces of the lung where they initiate the disease process described later in the chapter. Such weaponized particles are highly virulent, with only 10 to 100 organisms required to cause infection.³ Additionally, *Brucellae* species are very hardy organisms and can survive for prolonged periods in storage and under hostile conditions. In soil or water, these organisms may survive for up to 10 weeks.⁴ However, unlike the CDC category A agents (*Bacillus anthracis*, *Francisella tularensis*), the *Brucellae* have very low mortality among immunocompetent hosts, with only about a 2% mortality rate.^{5,6} Additionally, a prolonged incubation period on the scale of months between exposure and clinical illness limits the terrorist's ability to cause a large number of casualties in a short time period.

Due to the low mortality and prolonged incubation period, medical and public health officials may not recognize a *Brucella* attack for quite some time. The most likely scenario would involve a large number of otherwise healthy individuals presenting over weeks to months with vague, multisystem complaints. An attack would most likely occur in an urban area where airborne particles could be spread over a heavily populated area. Once a few cases of brucellosis are confirmed in an

urban area among persons without exposure to domesticated animals, the possibility of a bioattack should be highly considered.

In affected individuals, after respiratory, gastrointestinal, or mucous membrane inoculation, the bacteria spread hematogenously to various organ systems. Weeks to months later, clinical manifestations begin to arise. Patients experience intermittent and irregular fevers over weeks and possibly months. Other constitutional symptoms such as chills, fatigue, malaise, sweats, and headache may occur. Pulmonary manifestations are generally rare, even after inhalation.⁶ Patients may complain of cough in addition to constitutional symptoms. Interstitial pneumonitis, hilar lymphadenopathy, pleural effusions, and empyema may be found on chest x-ray. Gastrointestinal manifestations are more common, and involve nausea, vomiting, anorexia, diarrhea, and abdominal pain. Rarer gastrointestinal manifestations include hepatitis, pancreatitis, cholangitis, or hepatic and splenic abscesses. Musculoskeletal manifestations, such as arthralgias of the axial skeleton and larger joints, occur in up to 60% of patients⁴ and may offer the most specific clue to the diagnosis of brucellosis. Sacroiliitis is most commonly found, and may proceed to osteomyelitis. Central nervous system manifestations occur rarely and may range from depression to meningoencephalitis.⁷ Acute orchitis and epididymitis have been reported.⁸ Although rare, endocarditis is the most common cause of death from *Brucellae* infections.⁹

Laboratory data are generally low yield and nonspecific; however, anemia with thrombocytopenia may be found on complete blood count. Serum white blood cell count may reveal lymphocytic pleocytosis. Elevated liver transaminases may occur in cases of hepatic involvement. *Brucellae* species grow quite slow in culture media, and cultures should be maintained for 4 to 6 weeks if the diagnosis is suspected. Bone marrow cultures have been shown to provide a higher yield than blood cultures.⁶

PREINCIDENT ACTIONS

Hospital, emergency department, and outpatient facilities should all have general disaster plans in place in the event

of a bioterrorist attack. Mass casualty events require coordination of local, state, and federal public safety resources. Both emergency medical service and hospital-based triage systems may need to be altered in the event of a large number of patients seeking medical care within a brief time period. Isolation procedures should be in place in the event of an attack with known person-to-person transmission. However, transmission of *Brucellae* species between individuals is not believed to occur, and no specific isolation precautions are needed in patients suspected of having brucellosis. The possibility of contracting brucellosis by inhalation of particles in culture among laboratory workers is significant, and negative-pressure isolation measures and Biosafety Level 3 procedures should be used within laboratories. Healthcare providers should practice universal precautions.

Since a true mass casualty scenario after a *Brucella* attack is unlikely, physicians and other healthcare providers must remain vigilant in identifying trends that may correspond with an outbreak of brucellosis. These trends may only be noted over days to weeks with an increasing volume of otherwise healthy patients with fever and multiple systemic complaints that came on insidiously and have persisted for prolonged time periods.

POSTINCIDENT ACTIONS

Clinicians with a high level of suspicion of a possible *Brucella* attack or confirmatory data of a case of brucellosis should notify the appropriate local, state, and federal public health and law enforcement authorities. Materials and surfaces possibly contaminated by brucellosis patients should be disinfected with 0.5% hypochlorite solution.¹

MEDICAL TREATMENT OF CASUALTIES

Antibiotic treatment for brucellosis requires multiple agents. Prolonged antibiotic therapy is required to prevent relapse of disease. Most cases can be successfully treated with doxycycline 100 mg twice daily plus rifampin 600 to 900 mg daily for 6 weeks. In more severe cases, streptomycin 1 g intramuscularly daily should be substituted for rifampin during the first 3 weeks.¹⁰ In children, substituting doxycycline with trimethoprim-sulfamethoxazole has been used; however, relapse rates are high when compared with the doxycycline/rifampin regimen.¹¹

Although no formal recommendations exist for post-exposure prophylaxis, high-risk patients after a *Brucella* attack may be considered to receive a 3-week course of doxycycline and rifampin. Currently, no vaccine is available for brucellosis.

UNIQUE CONSIDERATIONS

Brucellae species are small, gram-negative bacteria that cause a wide spectrum of clinical symptoms and signs in

infected humans. Even though they are considered to be a possible bioweapon due to their high virulence when inhaled, *Brucellae* species have a disadvantage when compared with other inhaled bacteria due to their low mortality and prolonged incubation period. This makes the identification of a possible *Brucella* attack extremely difficult. In the event of a *Brucella* attack, the only clue may be the presentation of a large number of healthy individuals over days to weeks with prolonged fevers and a myriad of multisystem complaints. Additionally, providers should be aware that treatment for brucellosis requires multiple antibiotic agents and a prolonged treatment regimen to prevent relapse.

PITFALLS

- Failure to prepare adequate systems to respond to possible terrorist attacks before the attacks occur
- Failure to consider brucellosis as the etiologic factor for persistent fever in patients
- Failure to consider a *Brucella* attack in the setting of a large number of otherwise healthy people who present over days to weeks with a wide range of vague complaints
- Failure to treat cases of brucellosis with multiple agents over a prolonged time period to prevent relapse
- Failure to notify appropriate public health and law enforcement agencies when an outbreak of brucellosis is suspected or confirmed among persons with no exposure to domesticated animals

CASE PRESENTATION

During the past few weeks, both your own emergency department and other departments throughout the city have seen a 20% increase in patient volume. A large number of otherwise healthy individuals are presenting with a wide variety of complaints, most notably fevers and malaise that last for weeks. Public health officials are puzzled and have reluctantly announced that a “viral syndrome” is sweeping the city. On a busy Wednesday morning, you see a 30-year-old graduate student with no medical history who is complaining of fever, fatigue, vomiting, difficulty concentrating, and low back pain. He is unable to tolerate oral fluids, and as a result, he is admitted for dehydration. Persistent low back pain as an inpatient prompts his healthcare providers to perform a bone scan, which reveals evidence of osteomyelitis. Bone cultures taken during debridement have not shown any microorganism growth after 72 hours. Meanwhile, hospitals citywide are getting busier and busier with case of “viral syndromes.”

Coxiella burnetii (Q Fever) Attack

Teriggi J. Ciccone

DESCRIPTION OF EVENT

Q fever is a febrile illness caused by a gram-negative, intracellular rickettsia *Coxiella burnetii*. The name Q fever derives from “Query fever,” the original name given to the syndrome first noted among abattoir workers in Australia in the 1930s.¹ *C. burnetii* is maintained in a large natural reservoir within mammals, birds, and arthropods. Natural human infection occurs primarily in persons exposed to livestock including sheep, goats, and cattle. The organism is shed in urine, feces, milk, and birth products from infected livestock, after which aerosolized particles inhaled by the victim result in infection. Placental tissues contain especially high amounts of infectious particles, and persons exposed to parturient livestock are at particularly high risk. Infection can also occur via ingestion of unpasteurized milk from infected animals. Far less commonly, infection can occur through an arthropod vector, particularly ticks. Natural infections occur worldwide, with reports from all continents with the exception of Antarctica. Rarely, infection has occurred with blood transfusions, sexual contact, and transplacental transmission to newborns. Person-to-person transmission has been reported, but is believed to be extremely rare.

C. burnetii is classified as a category B agent by the Centers for Disease Control and Prevention.² Although its use in warfare has never been described, military personnel have become infected with *C. burnetii* in endemic areas.³ The U.S. military stockpiled *C. burnetii* in its biologic arsenal until 1971, when these agents were destroyed.^{3,4}

Multiple factors contribute to *C. burnetii*'s use as a biologic weapon. This agent is highly virulent, with inhalation of a single particle sufficient to cause disease in some patients.^{3,4} Additionally, the spore-like form of *C. burnetii* can survive for weeks to months in the natural environment, resistant to both heat and desiccation, and can spread over large distances while airborne.^{3,7} The release of infectious particles within or over a major population center would result in tens of thousands of infections.⁷ However, *C. burnetii* infection carries a relatively low fatality rate. In a large case series, Raoult and colleagues reported 13 deaths among 1383 cases of Q fever over 14 years, most frequently from myocarditis,⁸ somewhat limit-

ing *C. burnetii*'s ability to cause a mass-fatality disaster scenario. A biologic attack with *C. burnetii* would more likely cause a “temporarily incapacitating illness.”⁴

Infection with *C. burnetii* results in a wide spectrum of human disease. Identification of a biologic attack using aerosolized *C. burnetii* would be difficult for healthcare, public health, and law enforcement officials due to lack of a specific clinical syndrome and a variable incubation period. The most likely scenario for a *C. burnetii* outbreak would involve a cluster of previously healthy persons presenting with a nonspecific febrile illness over days to weeks. Once the diagnosis of *C. burnetii* infection was confirmed in patients without significant risk factors (e.g., exposure to livestock), the possibility of a biologic weapon attack must be considered.

Acute symptomatic infection occurs in 50% to 77% of victims, with asymptomatic seroconversion occurring in nearly all other victims.^{8,9} Disease severity is inversely proportional to the amount of inoculum to which the victim is exposed.^{3,4} Presumably, a biologic attack with aerosolized *C. burnetii* would expose victims to a relatively high level of inoculum, and thus a greater number of patients with acute disease. A nonspecific febrile illness with fever, chills, malaise, fatigue, anorexia, and headache occurs after an incubation period of 10 to 40 days.^{3,4,8} Patients frequently recover from this syndrome without treatment.

Q fever pneumonia occurs in 17% to 50% of cases.^{4,8} Patients may complain of cough and pleuritic chest pain. Chest radiographs are most often consistent with an atypical pneumonia, although consolidation and pleural effusion may be found.¹⁰ Frequently, patients will have positive chest radiographic findings without pulmonary symptoms.¹¹

Thirty to forty percent of victims will develop hepatitis^{4,8} with abdominal pain and tenderness, hepatomegaly, and elevated serum transaminases. Sonographic liver imaging or liver biopsy may reveal a granulomatous hepatitis. Jaundice is a rare finding.¹²

Rarely, endocarditis, myocarditis, meningioencephalitis, and osteomyelitis have been reported, each accounting for about 1% of acute cases of Q fever in a large series of patients.⁸ Fatalities from acute Q fever are most often the result of myocarditis. Infection in pregnant women is associated with spontaneous abortion.^{8,13}

Chronic Q fever affects up to 23% of patients with *C. burnetii* infection.⁸ The most prominent clinical manifestation is endocarditis, affecting 60% to 73% of patients with chronic infection.^{8,12} Patients with pre-existing valvular disease and prosthetic valves are at the highest risk.¹¹ Other chronic syndromes include arterial aneurysms, osteomyelitis, chronic hepatitis, and chronic fatigue syndrome.

Laboratory data are often nonspecific in acute Q fever. Total serum white blood cell count is usually normal. Thrombocytopenia is a common finding. Increased serum transaminase levels are found in a majority of patients. Elevations in erythrocyte sedimentation rate, smooth muscle antibodies, and antiphospholipase antibodies may be found.¹² In chronic Q fever, increases in serum transaminases, creatinine, and rheumatoid factor have been reported.¹²

Diagnosis of *C. burnetii* infection is confirmed by serologic testing. Laboratory methods include complement fixation, indirect fluorescent antibody assays, enzyme-linked immunosorbent assays (ELISA) and macroagglutination and microagglutination. ELISA is regarded as the most sensitive serologic test, with sensitivities greater than 90%.¹² Culture of *C. burnetii*, technically difficult and potentially hazardous to laboratory personnel, is rarely performed.

PREINCIDENT ACTIONS

General preparation for a possible biologic attack requires that hospitals, emergency departments, public health authorities, and law enforcement officials have disaster plans in place before any attack occurs. A clear chain of command should be established in the event of a disaster that coordinates the actions of these various groups. The volume of patients presenting after such an attack may overwhelm the standard resources of emergency medical services and healthcare facilities, and disaster-based methods of triage should be instituted. Isolation and decontamination procedures should be in place to prevent person-to-person transmission of hazardous substances. Local and regional supplies of critical antidotes and antibiotics should be maintained. Mass-casualty drills should be performed to test the multisystem response to potential biologic attacks and determine where improvements need to be made.

Because person-to-person transmission of *C. burnetii* is thought to be extremely rare, no specific isolation precautions are required. Healthcare workers should practice universal precautions at all times. Laboratory workers handling biologic samples possibly contaminated with *C. burnetii* should work under Biosafety Level 2 precautions, including limited lab access to trained personnel, working in safety hoods with potentially aerosolized materials, and strict protocols for disposal of sharps and autoclaving potentially hazardous materials.

POSTINCIDENT ACTIONS

Confirmation or suspicion of *C. burnetii* infection in an individual or group without significant exposure to

domesticated animals should alert the clinician to the possibility of a biologic attack. Hospital infection control personnel should be consulted. Local, regional, and federal public health and law enforcement officials should be notified. Material and surfaces contaminated with *C. burnetii* should be disinfected with a 0.05% hypochlorite solution.¹⁴

MEDICAL TREATMENT OF CASUALTIES

Although most cases of Q fever resolve spontaneously without treatment, antibiotic treatment should be started in confirmed or suspected cases to shorten the course of illness and to reduce the number of complications. Tetracyclines are considered the drug of choice for acute Q fever.^{3,4} A standard regimen with 100 mg of doxycycline given twice daily for 14 to 21 days provides adequate coverage for most adults.^{12,15} Macrolide and quinolone antibiotics have also been shown to have effect against *C. burnetii*.^{3,6} Patients with preexisting valvular heart disease or prosthetic heart valves require a prolonged course of treatment to prevent endocarditis. A combination of doxycycline and hydroxychloroquine (600 mg/d) should be given for 1 year.¹⁴ Treatment of known Q fever endocarditis requires 1 to 3 years of treatment with doxycycline and hydroxychloroquine.¹⁶ In pregnant women with Q fever, treatment with co-trimoxazole during the first two trimesters has

CASE PRESENTATION

For the past 3 days, emergency departments and emergency medical services throughout the city have been overloaded. A large number of otherwise healthy persons are presenting with complaints of fever, chills, and headache. Many patients have been diagnosed with viral syndromes and atypical pneumonias, then discharged home.

You are treating a young man with similar symptoms who had been seen 3 days before in another emergency department, where he was diagnosed with "viral pneumonia." He now complains of persistent fever, chills, cough, nausea, and mild abdominal pain. His liver is palpable 3 cm below the costal margin, and he has mild right upper quadrant pain. A chest radiograph demonstrates bilateral interstitial infiltrates. Routine blood testing reveals thrombocytopenia and elevated serum transaminases. He is admitted, and on hospital day 2 he begins complaining of mild chest pain. An electrocardiogram reveals nonspecific ST-segment and T-wave changes. Viral myocarditis is suspected. On hospital day 4, an astute infectious disease consultant recommends serologic testing for *C. burnetii* despite the fact that the patient has had no known high-risk exposures. ELISA test results are positive for antibodies to *C. burnetii*. Public health and law enforcement officials are notified, and testing on other patients reveals a large number of Q fever cases, prompting an investigation into a possible biologic attack.

been shown to reduce the incidence of spontaneous abortion,¹⁶ and treatment with macrolides in the third trimester would be appropriate to avoid kernicterus. In children, co-trimoxazole administered at a dosage of 4 mg/kg every 12 hours is a possible treatment regimen. Alternative regimens include doxycycline at 2.2 mg/kg every 12 hours, chloramphenicol 25 mg/kg/day divided every 6 hours, or erythromycin 50 mg/kg/day divided every 6 hours.

A formalin-killed vaccine to *C. burnetii* is available for high-risk personnel such as abattoir workers, veterinarians, and laboratory workers.^{3,4} A single vaccination is 95% effective against aerosolized *C. burnetii* and offers protection for up to 5 years.⁴

UNIQUE CONSIDERATIONS

Acute infection with *C. burnetii* causes a nonspecific febrile illness. The time of onset after exposure and the severity of disease are proportional to the amount of inoculum. The ability of *C. burnetii* to cause infection with as few as one infective particle, in addition to the spore-like form's ability to be spread as an aerosol over large distances, make this agent a possible biologic weapon. Release of *C. burnetii* particles over a large population center would result in a high number of casualties over days to weeks. As the clinical syndrome caused by *C. burnetii* infection is relatively nonspecific, healthcare, public health, and law enforcement officials should maintain a high index of suspicion for Q fever when a large number of previously healthy persons without exposure to livestock or other domesticated animals become ill with a febrile illness over a brief time period. The combination of pneumonia with hepatitis should alert the physician to the possibility of Q fever. Once cases of Q fever are confirmed in otherwise low-risk persons, the possibility of biologic attack should be highly considered.

PITFALLS

Several potential pitfalls in response to an attack exist. These include the following:

- Failure to establish disaster plans for a possible biologic attack. Healthcare, public health, and law enforcement systems should have a coordinated plan in place with a clear chain of command before any attack occurs.

- Failure to consider Q fever when a large number of persons present over a brief period of time with non-specific febrile illnesses.
- Failure to consider Q fever in patients with fever, pneumonia, and hepatitis.
- Failure to begin appropriate antibiotic treatment in cases of acute Q fever to prevent more severe chronic forms of disease such as endocarditis.
- Failure to notify appropriate infection control, public health, and law enforcement officials when cases of Q fever are diagnosed or suspected.

Rickettsia prowazekii Attack (Typhus Fever)

Vittorio J. Raho And Jonathan A. Edlow

DESCRIPTION OF EVENT

Historically, the most devastating disease caused by *Rickettsia* bacteria with respect to sheer numbers of human casualties and associated morbidity is epidemic (or louse-borne) typhus (ET). Often rampant during times of war and poverty, plaguing survivors of natural disasters, erupting among prison populations, and even described to be present aboard pirate ships of the eighteenth century, ET has played a significant role throughout recent history.^{1,2} Caused by the bacteria *Rickettsia prowazekii* and spread among humans by the body louse, it has been described as an illness that has determined the outcome of major wars. The primary vector of transmission—the body louse—lives in clothes and is supported by conditions of poor hygiene and crowding. As the louse takes a human blood meal, it defecates; as a consequence, it passes bacterial organisms onto the skin of the victim.³ The local irritation and pruritus stimulates scratching, causing minor trauma and allowing autoinoculation of the microbes. The disease is then spread rapidly from person to person via the infected lice. The illness has also been reported to spread in the form of dried louse feces in an aerosolized route by passing through mucous membranes of the eyes and oropharynx.³ Other than humans, the only known reservoir for *R. prowazekii* are flying squirrels of the eastern United States, with multiple documented human cases confirmed by the CDC, although the exact mechanism of transmission remains unclear.⁴

Clinical manifestations of ET occur after a 1- to 2-week incubation period and begin with the abrupt onset of extreme exhaustion, severe headache, and high fever. Approximately 5 days after the onset of fever, a maculopapular rash erupts, often beginning on the axillae and upper trunk and spreading to involve the entire body excluding the palms, soles, and face.⁵ The rash may evolve over time from macular to papular, and eventually petechial to frank purpura as the course of illness progresses. Also described are photophobia; neurologic manifestations including confusion, delirium, and coma; injected conjunctivae; “dry-brown tongue” changes; and extremity manifestations including gangrenous digits.³ If untreated, the illness can become severe with vascular collapse, hypotension, renal failure, disseminated

intravascular coagulation, pneumonia, and encephalitis, with reported mortality approaching 15% to 40%.^{1,6,7}

Early laboratory data are nonspecific and may include marked thrombocytopenia, elevated liver function test results, and normal or decreased white blood cell count.

PREINCIDENT ACTIONS

Currently, there is no established system for ET surveillance in the United States. Cases are so infrequent that commercial testing is generally unavailable. *R. prowazekii* infection can be confirmed through the use of polymerase chain reaction, serologic testing for immunoglobulin G and M titers, and culture.⁸ The most efficient means to identify collected specimens is usually through state public health laboratories for specific CDC molecular testing.

POSTINCIDENT ACTIONS

If a large-scale attack or outbreak of ET is suspected, several immediate actions may help prevent its spread and decrease mortality. First, proper communication channels must be established; hospitals and emergency departments must set up the proper triage system and isolation rooms necessary to deal with a transmissible infectious illness. Healthcare workers and first responders should take proper body substance isolation precautions. Cleansing of known exposed areas with cyfluthrin has been successfully used in prison outbreaks.⁹ Exposed persons who may contain infected lice or dried louse feces should be treated as potential sources of infection and should be decontaminated, isolated, and cleansed. Dusting of exposed persons with permethrin 0.5% powder, and more important, removal and incineration of all clothing and linen articles is required.⁹

MEDICAL TREATMENT OF CASUALTIES

In all *Rickettsial* infections, antibiotic choice is crucial because the organisms are naturally resistant to all

beta-lactams.¹⁰ According to practice guidelines, the current recommended treatment for suspected ET is a single oral 200-mg dose of doxycycline, although most clinicians extend this treatment until patients are afebrile for 72 hours.^{11,12} Some authorities recommend 100 mg of doxycycline twice a day for the same duration.¹³ Pregnant women and those unable to take tetracycline antibiotics may be treated with 500 mg of chloramphenicol four times a day for the same duration. The remainder of treatment consists of supportive medical care and management of the numerous possible complications of the illness. Postexposure prophylaxis has been successfully used among prison populations,⁹ but the decision to treat large numbers of low-risk persons should be made at a public health level. Vaccines have been used successfully by the U.S. military.¹⁴

UNIQUE CONSIDERATIONS

Most *Rickettsia* bacteria have life cycles that require a strict intracellular existence. They are therefore unable to survive the extracellular environment long enough to be freely transmissible and usually require some means of inoculation through the skin via an arthropod vector. *R. prowazekii*, however, has been reported to spread by the aerosol route and thus has the potential to be manufactured into a bioweapon.

CASE PRESENTATION

On a Thursday afternoon, two men in their 30s who are otherwise healthy and have no chronic medical conditions present from their office downtown to the emergency department after experiencing the rapid onset of high fevers to 104°F, severe exhaustion and weakness, severe headache, myalgias, and nausea and vomiting. The results of their initial workup are nonspecific and include a negative chest radiograph and a negative lumbar puncture, and only thrombocytopenia was noted on the CBC. They are started on empiric antibiotics and admitted to the hospital, as are numerous other people from the same building for similar presentations at other hospitals. The symptoms now include confusion and delirium, and rashes were described beginning on the chest and spreading with purpuric features.

Epidemiologic data months after the outbreak demonstrate a crude mortality rate around 12%, with a total of 196 patients ill—all from the same building complex. When their empiric antibiotic regimens are compared, a strong predictor of mortality appears to be the absence of tetracycline-class antibiotics. It is suspected that a ventilation system attack using an aerosol form of ET was carried out.

PITFALLS

Several potential pitfalls in response to an outbreak of ET exist. These include the following:

- Failure to consider ET as a potential cause of acute, febrile illness during such an outbreak
- Failure to ensure proper decontamination and isolation of suspected exposed persons
- Failure to initiate early empiric therapy when the disease is highly suspected
- Waiting for confirmatory blood test or biopsy results or the presence of a rash before beginning treatment in a suspected case
- Failure to report suspected cases to the state department of public health or affiliated authority for appropriate CDC notification and proper serologic testing
- Failure to alert local and state agencies to a suspected biologic attack when presented with a cluster of unusual and uncommon illnesses
- Failure to use doxycycline in adults and children unless absolutely contraindicated

Orientia tsutsugamushi (Scrub Typhus) Attack

Peter B. Smulowitz and Jonathan A. Edlow

DESCRIPTION OF EVENT

Scrub typhus is a febrile illness caused by *Orientia tsutsugamushi*, previously known as *Rickettsia tsutsugamushi*. This bacterial pathogen is a gram-negative coccobacillus, and like other rickettsiae, it is an obligate intracellular bacterium. This tiny parasite is transmitted via the bite of larval stage mites (also known as *chiggers*) of the genus *Leptotrombidium*.

Clinical cases of scrub typhus are exceedingly rare in the United States, limited to travelers returning from endemic areas in eastern and southeastern Asia, India, Pakistan, and northern Australia and its adjacent islands. Focal pockets of infection are created in endemic areas secondary to the chiggers' general ability to feed only once¹ and the mites' preference for certain habitats (e.g., scrub vegetation, forest clearings, riverbanks, grassy regions).² Although rodents are the main host for the mites, humans who enter these "mite islands" are at high risk of disease transmission. There may be no risk to humans in nearby areas because chiggers typically stay within several meters of where they hatch.¹

According to the Centers for Disease Control and Prevention (CDC), travelers and healthcare providers are generally not at risk of becoming infected via exposure to an ill person. Rickettsial species in general are usually not transmissible directly from person to person, although transmission has been documented to occur via blood transfusion.³ Rickettsial organisms have caused infection via inhalation of laboratory-derived aerosols, suggesting the potential threat of the organisms as an aerosolized bioweapon.⁴ The USSR successfully developed *Rickettsia prowazekii* as a biologic weapon during the 1930s and investigated a naturally occurring dormant, stable form that is infectious for long periods of time. During the 1930s and 1940s, the Japanese experimented with both *R. prowazekii* and typhus.^{4,5} To date, *O. tsutsugamushi* is not known to have been developed as a biologic weapon. Theoretically, the organism could be spread by aerosol if it were manipulated to enhance its ability to survive in the environment. It may also be spread via the rodent host or the chigger vector. Despite the propensity of the chigger to feed only once, dissemi-

nation into a crowded population could result in numerous infections.

Affected persons typically develop clinical symptoms between 6 and 18 days after inoculation by an infected chigger. Before the development of systemic symptoms, patients may develop a red papule at the site of the bite, which later forms a vesicle or ulcerates and forms a black eschar. The incidence of the eschar has been reported to occur in 36% to 88% of cases.² The lesion may be associated with regional lymphadenopathy at this time and generalized lymphadenopathy in the next 4 to 5 days. The finding of an eschar in a traveler should raise the possibility of scrub typhus. However, finding this lesion in a domestic patient should raise the possibility of cutaneous anthrax.

The onset of systemic symptoms in scrub typhus is usually sudden, with the most common findings being fever, myalgias, severe headache, and rash. Fever, in early stages up to 104° F to 105° F, is the most common symptom. The rash typically occurs after about 5 days of illness. A macular and papular or occasionally vesicular rash begins on the trunk and spreads to the extremities. Other symptoms occasionally encountered include nausea, vomiting, diarrhea, tremors, delirium, nervousness, slurred speech, deafness, and nuchal rigidity.¹ The disease has even been reported to present as an acute abdominal process.⁶

Serious complications occurring with untreated scrub typhus are predominantly pulmonary. Interstitial pneumonia and pulmonary edema may occur. Up to 22% of patients developed serious pneumonitis.⁷ Cardiac involvement is less common, but patients may develop myocarditis or congestive heart failure. Other serious complications include meningitis, encephalitis, disseminated intravascular coagulation (DIC), shock, acute respiratory distress syndrome, and acute renal failure.

No laboratory test is diagnostic in scrub typhus. Most patients have a normal white blood cell count, although both leukopenia and leukocytosis may occur. Patients with severe disease often develop thrombocytopenia. In one series of 47 patients from Taiwan, 77% of patients demonstrated abnormalities of hepatic enzymes, with 6 patients presenting with a picture similar to acute viral hepatitis.⁸ Lumbar puncture is also nondiagnostic, usually revealing a lymphocytic pleocytosis; in one series of

27 patients, the white blood cell count ranged from 0 to 110/mm³, with about half lymphocytes.¹

Diagnosis of scrub typhus is made via serologic studies. The indirect fluorescent antibody test, which detects antibodies to specific antigens of the bacteria, is used most often due to its simplicity, rapidity, and a specificity approaching 99%.⁹ The Weil-Felix test, based on cross reactivity between antirickettsial antibodies and *Proteus* antigens, lacks sensitivity and specificity and is not recommended. An enzyme-linked immunosorbent assay, passive hemagglutination assay, dot blot immunoassay dipstick, and polymerase chain reaction have been developed for the diagnosis of scrub typhus. Polymerase chain reaction shows promise in definitively establishing the diagnosis early in the course of infection, when serologic test results may still be negative. It is a relatively rapid test, yielding results in between 6 and 48 hours,¹⁰ but is currently only available in a few specialized centers.

PREINCIDENT ACTIONS

The magnitude of a bioattack using *O. tsutsugamusbi* depends on the mode of dissemination: aerosol versus the chigger vector. Populations of patients may present with the eschar or systemic symptoms described. At the phase of illness at which an eschar is present, cutaneous anthrax must be considered. Isolation may be initially required for patients with other symptoms of scrub typhus, which may be similar to the symptoms of bacterial meningitis. Other differential diagnoses to consider include malaria, dengue, leptospirosis, other rickettsial diseases, typhoid fever, endocarditis, tularemia, hemorrhagic fevers, meningococemia, measles, secondary syphilis, infectious mononucleosis, and rubella.

Transmission of *O. tsutsugamusbi* between persons is not believed to occur and poses little risk to healthcare workers.

POSTINCIDENT ACTIONS

Clinicians with a high level of suspicion for a possible scrub typhus attack or confirmatory data of a case of scrub typhus should notify the appropriate local, state, and federal public health and law enforcement authorities. Control of the disease depends on control of the trombiculid mites. Focal areas can be treated with chlorinated hydrocarbons such as lindane, dieldrin, or chlordane, although these may cause secondary environmental problems. Insect repellants and miticides such as *N,N*-diethyl-*m*-toluamide (DEET) are effective when applied to both clothing and skin, whereas permethrin and benzyl benzoate are effective when applied to clothing and bedding.¹¹

MEDICAL TREATMENT OF CASUALTIES

Doxycycline, tetracycline, and chloramphenicol have all been used clinically in treating patients with scrub

typhus. Ciprofloxacin and azithromycin have been used successfully with in vitro models, and ciprofloxacin (a rickettsicidal antibiotic with good intracellular penetration), 500 mg given twice a day, was successful in one case study.¹²⁻¹⁴ Azithromycin has been suggested as an alternative therapy in pregnant women and children. Doxycycline is the most commonly used treatment for scrub typhus. The regimen consists of 100 mg given orally or IV for 5 to 7 days. Some studies have advocated short-course therapy, consisting of anywhere from 1 to 3 days of treatment, although the 5- to 7-day course is still recommended to prevent relapse of the disease. Relapse may still occur despite proper antibiotic therapy. The two most likely reasons for relapse include treatment during the first 5 days of the disease and the emergence of doxycycline-resistant strains of *O. tsutsugamusbi*. In resistant strains, a collection of limited data has demonstrated the utility of adding rifampin to doxycycline.^{15,16}

Due to the serotypic heterogeneity of *O. tsutsugamusbi*, no effective vaccine has been developed. If an attack with the organism is highly suspected, chemoprophylaxis against potentially exposed persons might be successful with doxycycline 200 mg taken by mouth weekly.¹

CASE PRESENTATION

A 45-year-old male traveler from Africa presents with his 16-year-old son. Both patients report temperature as high as 103° F, headache, and myalgias. They had recently gone scuba diving in the Torres Strait Islands, off the coast of Northern Australia, and are now visiting the United States. The symptoms have been getting worse since they started about 3 days ago, and the father is worried that both he and his son might have meningitis.

As you are entertaining the possibility of malaria and other tropical diseases, you turn your attention to the son. You immediately notice his toxic appearance. On examination he has conjunctival injection, and his right upper quadrant is mildly tender to palpation. You also notice some tender right inguinal lymphadenopathy, and as you are palpating the lymph nodes you see a black lesion on the right thigh that appears to be an eschar. Wondering whether mosquito bites ever produce an eschar, or whether the father and son might have somehow been exposed to anthrax, you decide to review the possibilities by consulting the CDC.¹⁷

UNIQUE CONSIDERATIONS

Mass bioattack with the bacteria causing scrub typhus is difficult since the bacteria require the mite vector for dissemination. The larval mites rarely travel far from the place where they hatch, and they usually bite only once. However, focal islands of infection may be created in areas suitable to the mites, and cases have been reported in urban areas of Asia. Scrub typhus should be considered in patients presenting with an eschar or with fever and a rash because early treatment can prevent many of the serious complications of the disease.

Several potential pitfalls in response to an outbreak of scrub typhus exist. These include the following:

- Failure to consider scrub typhus in a patient with a cutaneous eschar
- Failure to realize that relapse of the disease can occur if treated early in the course or if doxycycline fails (or is not used) to treat resistant strains
- Failure to consider scrub typhus in the setting of high fever and a rash developing in patients within a focal geographic location
- Failure to avoid serious complications of the disease by delaying necessary antibiotic therapy
- Failure to report suspected cases of scrub typhus to the appropriate health and law enforcement agencies

Rickettsia rickettsii (Rocky Mountain Spotted Fever) Attack

Vittorio J. Raho and Jonathan A. Edlow

DESCRIPTION OF EVENT

Rocky Mountain spotted fever (RMSF), once known as “black measles” and “black fever” for its associated hemorrhagic rash, has been recognized as the most lethal tick-borne illness in the United States since 1896 when some of the earliest documented outbreaks in Idaho claimed numerous lives.^{1,2} Belonging to the group of bacteria called rickettsiae, the etiologic infectious agent of RMSF is *Rickettsia rickettsii*. It is an obligate intracellular bacterium that appears as a gram-negative coccobacillus under proper staining. RMSF is the most recognized and clinically significant rickettsiosis in the United States, with a range of several hundred to over a thousand cases reported annually to the Centers for Disease Control and Prevention (CDC).^{3,4} The rickettsiae have a wide distribution and exist naturally in a complex life cycle involving certain hard tick species and their warm-blooded hosts. RMSF-identical illnesses have been reported throughout North, Central, and South America, having local names such as Columbian and Tobia fever.⁵ Ticks act as both hosts and vectors by passing the organisms to their progeny transovarially. Wild mammals may become transiently infected when bitten, thus representing another host reservoir for the bacteria.⁵ Humans appear to be accidental hosts when bitten by infected ticks and the vast majority of human cases occur in spring and summer months, which represent the peak activity for the tick’s reproduction cycle.

The clinical syndrome known as RMSF is a well-described, acute, febrile illness with a reported mortality of up to 30% in the preantibiotic age. Even now, with specific antibiotics and improved supportive care, RMSF still carries a 5% mortality when properly treated. Mortality rises if proper antibiotics are started late in the patient’s course, and also in patients who present “out of tick season” or without a rash.^{6,7} After inoculation through the skin, the organisms enter the bloodstream via the lymphatics, infecting the vascular endothelium. This infectious vasculitis causes extravasation of plasma, edema, hypovolemia, and ischemia, with secondary thrombosis and platelet consumption. In this manner, multiple organ systems may be affected, and the clinical appearance is

either nonspecific or can appear to be focal, depending on what organ system is primarily involved. The classic triad of headache, fever, and rash after tick exposure should raise suspicion of the illness but is only found in, at most, 60% of cases. Severe myalgias are prominent. Gastrointestinal symptoms—nausea, vomiting, abdominal pain, diarrhea, and anorexia—may also predominate. The characteristic rash, which is absent in up to 15% of cases, appears by the third to sixth febrile day as pink macules on the wrists and ankles, progressing to papules and eventually petechiae that characteristically involve the palms and soles.⁸ Cardiac dysrhythmias suggesting myocarditis and pulmonary involvement with pneumonitis are a hallmark of higher morbidity.⁸ Renal insufficiency is thought to be mostly of prerenal origin caused by the hypovolemic state, although fulminant renal failure requiring hemodialysis is reported. Neurologic sequelae are protean, ranging from focal deficits to florid encephalitis and coma. Headache of varying severity remains by far the most common neurologic manifestation.⁹ Each of these various presentations may lead the clinician away from the diagnosis, especially when there is no history of tick bite, which occurs in one third of cases.

Laboratory and radiologic data are relatively unhelpful in aiding the diagnosis. Thrombocytopenia and anemia have been consistently reported in about one third to one half of all cases. Hyponatremia may be noted occasionally, and cerebrospinal fluid evaluation often shows elevated protein and mild pleocytosis. The current preferred method of diagnosing RMSF is through indirect immunofluorescence assay; however, this can only be used later in the course of the illness. The Weil-Felix test has fallen out of favor due to its lack of acceptable sensitivity and specificity compared with more modern testing. Ultimately, physicians must treat patients who may have RMSF based on clinical suspicion and epidemiologic context. Waiting for laboratory confirmation will lead to an increased mortality.

PREINCIDENT ACTIONS

A similar situation exists for all local and state agencies and disaster-management task forces when planning the

response to a potential biologic weapons attack. The state's department of public health or a similar organization should ensure the adequate supply of approved equipment for decontamination and isolation procedures. It should provide access to stockpiles of antidotes and antimicrobial agents as needed. Hospital emergency departments in conjunction with local fire and police departments should be conducting random citywide drills to provide feedback and test the integrity of the implemented system.

It is unknown whether RMSF has ever been used as a bioweapon. Considering the natural history of the disease and the relative frailty of the causative organism outside its normal host environment, it seems a daunting task to achieve. Therefore, a biologic attack using *R. rickettsii* is highly unlikely. If it were to occur, clinicians may notice an unusual seasonal or geographic pattern where the diagnosis of RMSF is made. Exposure to infected ticks is the only known risk factor for *R. rickettsii* among humans, and the strong seasonal occurrence is significant. Deviation from the normal pattern of illness may alert the astute clinician to the possibility of an unnatural cluster of cases during an unusual time of year. In this situation, the possibility of bioterrorism should be considered. It should be noted that several epidemiologic studies have shown that approximately 90% of U.S. RMSF cases have occurred between April 1 and September 30, and around 60% of patients had a history of tick exposure.⁴

POSTINCIDENT ACTIONS

Initial response to a bioterrorism event will be local. The success of the response will depend greatly on the efforts of preincident planning. After the event occurs, a number of successive reactions should occur: communication channels must be established, resources need to be activated, teams and leadership structure need to be assembled, and hospitals and emergency departments must initiate and construct proper triage and decontamination sites.

Fortunately, RMSF is not known to be contagious. In addition, there is an inexpensive and effective treatment available for both active disease and for chemoprophylaxis of patients who may have been exposed to a *R. rickettsii* biologic weapon. The difficulty arises in confirmatory diagnostic testing, which is unavailable during the acute phases of the illness. The exception to this is cutaneous tissue biopsy, which is at best about 70% sensitive and only useful in patients presenting with the characteristic rash.⁸ The diagnosis remains clinical, and treatment should be instituted early based on the clinician's index of suspicion. Such action might reduce overall mortality as a bioterrorism event unfolds.

In the event of a mass exposure to weaponized *R. rickettsii*, empiric treatment of actual cases with doxycycline should be implemented immediately. Chloramphenicol may be used as an alternative drug but should be used with caution since it may cause aplastic anemia. Prophylactic use of antibiotics should be considered in

exposed but asymptomatic patients, although no controlled human studies show whether this is beneficial. From a public health perspective, however, watchful waiting for symptoms would also be a reasonable alternative.

MEDICAL TREATMENT OF CASUALTIES

The current specific recommended treatment for suspected RMSF is 100 mg of doxycycline twice daily for 7 to 10 days or until the patient is afebrile for 48 hours. Although young children (younger than 9 years old) may be susceptible to the adverse bone and tooth-staining effects of the tetracyclines, the known morbidity and mortality of the illness mandates the use of doxycycline in all children unless absolutely contraindicated by allergy or similar reasons.¹⁰⁻¹² Pregnant women and those unable to take tetracycline antibiotics may be treated with chloramphenicol given 50 to 75 mg/kg/day in four divided doses for the same duration.¹³ Chloramphenicol carries its own uncommon risks of idiosyncratic aplastic anemia, and blood monitoring should be undertaken accordingly. The remainder of treatment consists of supportive medical care and management of the numerous possible complications of the illness. There are no formal postexposure prophylaxis recommendations, and the decision to treat high-risk persons should be made at a public health level. There is no current vaccine available for RMSF.

CASE PRESENTATION

It is the beginning of March and no influenza cases have been reported in more than 6 weeks. However, your hospital has reported a possible cluster of four young, healthy patients presenting to the emergency department with acute, febrile illness of uncertain etiology. The patients reported fever, headache, and myalgias very similar to influenza but lacking cough or sore throat symptoms. One case fatality from sepsis and apparent encephalitis has occurred among the cluster, and several other patients remain in the intensive care unit. Three of the patients demonstrated diffuse, maculopapular rashes involving the palms and soles that eventually progressed to purpuric lesions.

On further review, the patients had no history of tick exposure or camping trips, no recent travel, and no intravenous drug use. Laboratory cerebrospinal fluid and blood test results have been negative for meningococemia, HIV, streptococcus species, or other known pathogens to this date. It was determined during the inpatient course that cephalosporins, penicillins, aminoglycosides, and vancomycin were not improving the patients' clinical status. Eventual biopsy of an early skin lesion on the wrist of one of the patients demonstrates intracellular coccobacillary forms within vascular endothelial cells, and an anti-rickettsial antibody titer is 1:128.

UNIQUE CONSIDERATIONS

Rickettsiae, while virulent, are highly adapted to their intracellular environment and exist in a very delicate balance in nature. Their life cycle begins and ends almost entirely within other living organisms. Due to this delicate existence and the apparent need for parenteral inoculation for infection, they are far from the ideal candidate for any bioterrorist attack. A mass exposure would be very difficult to deploy and an unlikely choice for terrorists when other airborne and nonfastidious agents such as anthrax, tularemia, or Q fever exist. If *R. rickettsii* organisms could survive in an aerosolized form in the absence of a tick vector, it is not known whether RMSF could be transferred to exposed victims through inhalation.

PITFALLS

Several potential pitfalls in response to an attack exist. These include the following:

- Failure to consider RMSF as a potential cause of acute, febrile illness, regardless of whether a rash is present
 - Failure to initiate early empiric therapy when the disease is highly suspected
 - Waiting for confirmatory blood test or biopsy results or the presence of a rash before beginning treatment in a suspected case
 - Removing RMSF from the differential diagnosis if a rash is absent
 - Failure to report suspected cases to the state department of public health or affiliated authority for appropriate CDC notification
 - Failure to alert local and state agencies to a suspected biologic attack when presented with a cluster of unusual and uncommon illnesses such as RMSF
- Using geographic or seasonal exclusion criteria for the diagnosis²
 - Failure to use doxycycline in adults and children unless absolutely contraindicated

Vibrio cholerae (Cholera) Attack

Milana Boukhman

DESCRIPTION OF EVENT

Cholera is the name given to the severe diarrheal illness caused by the bacterium *Vibrio cholerae*. For purposes of this chapter, the term *cholera* will be used when referring to the symptomatic illness, whereas *Vibrio cholerae* will be used when referring to the organism.

V. cholerae, a Centers for Disease Control and Prevention (CDC) category B bioterrorism agent, is a motile, curved, gram-negative rod that exists in nature independent of a mammalian host and is a normal inhabitant of surface water. Over 99.9% of naturally occurring, waterborne *V. cholerae* organisms are associated with copepods (a zooplankton), a fact that has led to the effective filtering of water through low-tech filters (e.g., eight layers of “sari” cloth in Bangladesh). Although cholera is virtually nonexistent in North America (zero to five cases per year), it is endemic in agrarian areas with poor sanitation such as Asia and Africa. At least 5.5 million cases of cholera occur worldwide each year, with more than 100,000 deaths.

Transmission occurs via the fecal/oral route but also by ingestion of the normal environmental reservoir of *V. cholerae*. Undercooked food, especially shellfish in which the bacteria occur naturally, and “burial ceremonies requiring the handling of intestinal contents” have also been implicated in transmission.¹ Cholera can survive for 24 hours in sewage, about 6 weeks in water containing organic matter, and 16 days in soil. It can withstand freezing for 3 to 4 days but is readily killed by dry heat at 242.6° F (117° C) or boiling.² Of the 18 cholera investigations undertaken by the CDC between 1988 and 1998, 4 were in the United States and involved various factors including nursing home patients, imported food, raw fish, or contaminated food on an international flight. In addition to sporadic cases, epidemics sometimes occur, including several during the 1990s in South and Central America.⁴

Only two serotypes of *V. cholerae* cause epidemic disease: the O1 serotype (divided into two groups, El Tor and “classical”) and the O139 serotype. Other serotypes cause sporadic cases of gastroenteritis. Recently, the O139 serotype has spread from India and Asia to the Middle East.⁵ At this time, there is no known weaponized form of cholera. An attack would most likely occur among persons via a contaminated water or food source.

Infection can occur after the ingestion of as few as 1000 organisms. Infection is more likely in patients who are receiving acid suppression therapy since gastric acid at a pH of less than 2.5 will effectively kill *V. cholerae* organisms. After ingestion, the incubation period is 4 hours to 5 days, with most patients presenting within 2 to 3 days.^{2,6,7} Most *V. cholerae* infections are asymptomatic or present with only mild disease. Depending on the serotype, up to 75% of infected persons will remain asymptomatic. Of the other 25%, the majority have a mild diarrheal illness not requiring medical attention, 5% require hospitalization, and 2% develop classic cholera (also known as *cholera gravis*) with voluminous “rice water” stools. The symptoms of cholera gravis include gradual to sudden onset of vomiting, malaise, headache, and intestinal cramping with little or no fever, followed by painless and voluminous diarrhea of rice-water appearance; fluid losses may exceed 5 to 10 liters/day and up to 1 liter/hour of diarrhea is not uncommon. Patients with blood type O are more likely to develop severe disease. The mortality rate in the 2% with cholera gravis is 50% to 75%, giving an overall mortality in infected persons of 1% to 1.5%. Patients can die within 2 to 3 hours of the first signs of illness, although death in untreated patients usually occurs after several days.⁸ The mortality risk is increased in children (10 times greater than in adults), the elderly, and pregnant women. There is also an increased risk of fetal death.⁹

Definitive testing for *V. cholerae* is performed relatively easily in the laboratory. Stool cultures should be sent and plated on thiosulfate-citrate-bile salts-sucrose (TCBS) agar or tellurite, taurocholate, and gelatin agar (TTGA). Gram stains of stool may show sheets of curved gram-negative rods. Other rapid diagnostic methods primarily used in epidemiologic studies include the detection of *V. cholerae* organisms in stool specimens by polymerase chain reaction and monoclonal antibody-based stool tests.¹⁰

The most likely scenario for an outbreak would involve a large number of otherwise healthy persons presenting over several days with severe diarrhea/gastroenteritis symptoms and dehydration. Once a few cases of cholera are confirmed, the possibility of biologic terrorism should be considered.

Cholera should be included in the differential diagnosis of all cases of severe watery diarrhea and vomiting,

especially those producing severe and rapid dehydration. The possibility of one or more cholera epidemics is a powerful stimulus to the development of needed infrastructure for sanitation and for public health in general, including improvements in sanitation, safer water handling, and public health capacity for surveillance and response to epidemics.

PREINCIDENT ACTIONS

Transmission of cholera-causing species between persons is rare, and no additional precautions beyond universal precautions are needed in patients suspected of having cholera. The possibility of contracting cholera by inhalation is extremely unlikely, and personal protective equipment is not needed.

POSTINCIDENT ACTIONS

If cholera is diagnosed either clinically or by laboratory testing, notify the appropriate local, state, and federal public health and law enforcement authorities. Steps should be taken to identify the source of the contamination and to prevent further spread of infection.

Simple soap-and-water bathing/skin-washing will remove nearly all *V.cholerae* from the skin surface; washing should be performed immediately and often. Chlorine and other antibacterial solutions would provide adequate decontamination of the surfaces of potentially contaminated objects.

Cholera is almost unknown where water supplies are properly disinfected (~100 ppm of chlorine). However, it is tolerant to residual (<2 ppm) chlorine. Water should be boiled if an event warrants necessity of this precaution (e.g., in the event of a water purification infrastructure failure), and all food should be well cooked. Reverse osmosis of water, iodine, chlorine (e.g., chlorine bleach added to drinking water: 2 drops household bleach [5.25%] per liter) or micropore filters can also be used. It is not likely that simple filtering procedures (e.g., sari cloth) would be effective in the event of an epidemic because organisms in purposefully contaminated water would not be associated copepods.

MEDICAL TREATMENT OF CASUALTIES

The course of treatment is decided by the degree of dehydration. Oral rehydration solutions have reduced the mortality rate associated with cholera from over 50% to less than 1%.⁵ These solutions take advantage of the fact that sodium and water absorption in the small intestine is facilitated by glucose and occurs even in the presence of cholera toxin. World Health Organization (WHO) recommends a solution containing, per liter of water,¹¹ 3.5 g of sodium chloride, 2.9 g of trisodium citrate or 2.5 g of sodium bicarbonate, 1.5 g of potassium chloride, and 20 g of glucose or 40 g of sucrose. A number of studies have investigated alternatives to WHO-Oral

Rehydration Solution (ORS). ORSs containing rice or cereal as the carbohydrate source may be even more effective than glucose-based solutions in shortening the duration of diarrhea and reducing stool volume.^{8,11}

Patients who have lost more than 10% of their body weight from dehydration or who are unable to drink because of vomiting or mental status changes should be started on intravenous rehydration. The ideal solution is lactated Ringer's solution. Normal saline can be used with the realization that bicarbonate and potassium losses are not being replaced. Five percent dextrose in water does not replace sodium, bicarbonate, or potassium losses.

Antimicrobial therapy can also be used in the treatment of cholera but should be viewed as an adjunct to appropriate hydration. Antibiotics reduce the volume of diarrhea by 50% and the duration of *V.cholera* excretion by about 1 day. Thus, antibiotics are cost-effective and generally recommended for severely ill patients (i.e., those with cholera gravis). Antibiotics are given orally when vomiting stops and when initial rehydration is accomplished. Antibiotic susceptibility patterns should guide treatment. Tetracycline and doxycycline are the most commonly prescribed antibiotics. Ciprofloxacin has also been used with equal or greater effectiveness than doxycycline. Risks and benefits need to be weighed when determining treatment in pregnant women and children. Options in children and pregnant women include erythromycin or azithromycin. It is of note that many strains are tetracycline resistant. It is also likely that any organism used as a weapon would be multidrug resistant.

A parenteral killed whole-cell vaccine is available in the United States but provides less than 50% protection for only 3 to 6 months and is not effective for all types of cholera (such as O139).¹² A number of new vaccines are under investigation. In 1999, the WHO recommended that the oral whole-cell/recombinant B subunit (WC/rBS) oral cholera vaccine should be considered for use in preventing cholera in populations at risk of an epidemic within 6 months and not experiencing a current epidemic.¹³ Vaccine use during an epidemic is not recommended. Another intuitive option is antibiotic prophylaxis for entire populations. However, this has been shown to be ineffective and should not be used. Since person-to-person transmission does not occur, treating family members is unnecessary. However, if the family is using the same contaminated water source (e.g., in third-world countries or with a breakdown of water treatment in the United States), consider prophylactic use of antibiotics if more than one person in a family becomes infected.

UNIQUE CONSIDERATIONS

The main considerations/problems in the treatment of cholera are (1) ensuring an adequate supply of intravenous fluids if a large population of persons becomes symptomatic and (2) adequately measuring stool output in order to calculate replacement. The first problem can be addressed by using oral rehydration solution in the least sick patients and in all patients who can keep up with fluid output orally. The second problem has been

solved in third-world countries using “cholera beds.” Cholera beds are stretchers with a hole in them through which the patient stools. The stool is collected in a bucket so that fluid loss can be measured. Cholera beds can be improvised by cutting holes in simple canvas or nylon stretchers or military cots without too much difficulty. Repulsive as it may seem, this setup is very practical and reduces staff time substantially (e.g., time spent getting patients to the commode). Clearly, these would only be used during an epidemic when hospital resources are stretched thin.

PITFALLS

Several potential pitfalls in response to a cholera epidemic exist. These include the following:

- Failure to prepare adequate systems (e.g., hospital beds, personnel, local, state, and federal resources) to respond to possible terrorism attacks before the attacks occur
- Failure to have adequate supplies of the oral and intravenous rehydration solutions and supplies
- Failure to adequately rehydrate patients, instead relying on antibiotic treatment
- Failure to notify appropriate public health and law enforcement agencies when an outbreak of cholera is suspected or confirmed
- Failure to treat patients with oral rehydration solution instead of intravenous hydration, when possible. (An excessive amount of intravenously treated patients will unnecessarily tie up resources needed by sicker patients in the event of a mass-casualty event related to cholera attack.)

Shigella dysenteriae (Shigellosis) Attack

Suzanne M. Shepherd, Stephen O. Cunnion, and William H. Shoff

DESCRIPTION OF EVENT

Recognized since ancient times, shigellosis encompasses a broad spectrum of acute bacterial infectious diseases of the intestinal tract, caused by species of the genus *Shigella*. Shigellae are nonmotile, gram-negative, rod-shaped bacteria. Four groups of shigellae are recognized based on serologic and biochemical differentiation: group A (*S. dysenteriae*), group B (*S. flexneri*), group C (*S. boydii*), and group D (*S. sonnei*). Groups A, B, and C possess multiple serotypes and subtypes. *S. dysenteriae*, type 1, also known as Shiga's bacillus, produces Shiga's toxin and causes the most severe clinical illness, including hemolytic uremic syndrome and toxic megacolon; can harbor R-factor plasmids, conferring resistance to multiple antibiotics; and can produce pandemics with severe clinical illness and a high case-fatality rate in all age groups.

Shigellosis is endemic throughout the world and hyperendemic in developing countries. *S. sonnei* is the predominant isolate in industrialized nations, whereas *S. dysenteriae* and *S. flexneri* are most common in developing countries. The annual worldwide incidence of shigellosis is 200 million cases, most commonly in children 2 to 3 years of age, with an approximate mortality of 650,000.¹ Ten thousand cases of shigellosis are reported in the United States yearly, with particularly high rates of disease noted in daycare centers and custodial centers for the mentally ill and physically challenged.² Except for captive primates, humans serve as the only natural host and reservoir for shigellae. Disease incidence is seasonal, peaking in summer. Shigellosis is transmitted via the fecal/hand/oral route under conditions of poor sanitation, crowding, and limited personal hygiene. Less frequently, shigellosis is transmitted via contaminated food and water, including swimming pools, and seasonally via some insects such as houseflies.³ *Shigella* transmission, primarily *S. flexneri*, is increasingly reported via anal/oral contact in men having sex with men.^{4,5}

Both its virulence and short incubation period make *Shigella* a good candidate for use as a bioweapon. Foodborne diseases are a major public health problem in the United States, with a yearly incidence of 60 to 80 million and 500 to 9000 deaths.⁶⁻⁸ Consequently, identifying an outbreak of shigellosis as an incident of bioterrorism

may initially escape local public health and medical community awareness and surveillance modalities due to the following: (1) the large baseline noise produced by the relatively common occurrence of foodborne and waterborne illness; and (2) the large, often multistate nature of current outbreaks of foodborne disease.

Shigellae are also interesting bioweapon candidates due to their relatively low infectious dose; as few as 10 shigellae may cause disease in humans. This finding supports the clinical observations of the ease with which shigellosis can be transmitted among people via the fecal/hand/oral route during epidemics, particularly in the midst of conditions of crowding and poor sanitation and when poor personal hygiene is practiced among infected victims.⁹ The low infectious dose coupled with the short incubation period for *Shigella* infection (1 to 4 days; 1 to 8 days for *S. dysenteriae* type 1) sets the stage for a widespread outbreak in a short period of time when conditions are appropriate. Additionally, since many persons are only mildly ill, they remain in contact with others and can further transmit the infection.¹⁰ Shigellae can infect both immunocompetent and immunosuppressed persons. Finally, shigellae are hardy organisms and may survive for weeks or months in untreated water.¹¹

Shigellae are more acid resistant than other bacterial enteropathogens and therefore have higher rates of survival during passage through the stomach, which explains in part their relatively low infectious dose. After a 1- to 4-day incubation period, the spectrum of illness includes asymptomatic infection; mild, watery diarrheal illness similar to that caused by many other bacterial, viral, and protozoal organisms; and classic, severe dysentery, with frequent, small, bloody, mucus-containing stools, tenesmus, significant abdominal cramping, vomiting, high fevers, rigors, and toxemia. Typically, illness progresses through several distinct phases. Initial toxemia, malaise and high fever, and less commonly, seizure activity in children are followed by several hours of watery diarrhea and then dysentery. The terminal ileum and colon serve as the most significant sites of pathology, demonstrating shigellae's ability to invade and reproduce within intestinal epithelial cells, ultimately leading to cell death, with resultant ileal, colonic, and rectal edema and ulceration, hemor-

rhages, microabscess formation, and a significant inflammatory infiltrate in the lamina propria. Bacteremia is not common, except in patients with AIDS and in malnourished children infected with *S. dysenteriae* type 1. Although all serotypes can cause any type of illness, the *S. flexneri* and *S. dysenteriae* serotypes tend to be associated with more severe illness and *S. sonnei* with more mild illness. Shigellosis may be complicated by severe dehydration in young children. Other complications include the hemolytic uremic syndrome; severe hypoproteinemia in young children, producing an acute kwashiorkor syndrome with edematous extremities¹²; leukemoid reactions (polymorphonuclear leukocyte counts may reach more than 100,000/mm³); toxic megacolon and rectal prolapse in young children; and rarely, Reiter's syndrome.

No characteristic features suggest shigellosis on clinical examination. Laboratory data are also nonspecific. The white blood cell count is often elevated, with a left shift on the differential. Stool microscopy for fecal leukocytes usually yields positive results. Patients may develop complications to include the hemolytic uremic syndrome with significant proteinuria and Reiter's syndrome. A specific diagnosis can usually be made within 48 hours by culture of two fresh stool samples on selective and differential media. Of note, *S. dysenteriae* type 1 can be very difficult to culture. In an outbreak investigation, serodiagnosis of serum antibodies to O antigen of specific *Shigella* serotypes can be performed by enzyme-linked immunosorbent assay or passive hemagglutination.

PREINCIDENT ACTIONS

Preincident actions should focus on public health preparedness, healthcare provider education, and medical surveillance. The Centers for Disease Control and Prevention (CDC) maintain passive national laboratory-based surveillance for shigellae and other foodborne and waterborne pathogens. Rapid statistical analysis of this electronically transmitted information can detect unusual disease clusters by geographic area or time. A passive, physician-based reporting system also provides data to monitor trends. These systems are, however, prone to significant underreporting and lack of timeliness.⁷ Realizing this, the CDC designed the Foodborne Diseases Active Surveillance Network (FoodNet) to more precisely determine the incidence of foodborne illness in the United States and to provide a network to identify and respond to new and emerging foodborne diseases.¹³ Healthcare providers should remain vigilant in identifying case trends suggestive of a *Shigella* outbreak. Ongoing CDC and World Health Organization funding has focused on the development of a vaccine that is well tolerated, has a broad spectrum, and possesses long-lived immunity.¹⁴

Emergency department, hospital, and outpatient facilities should all have general disaster plans in place that address bioterrorist attacks and major infectious disease outbreaks, and the plans should be regularly tested.

The importance of staff implementing universal precautions and handwashing procedures should be stressed. Measures should be delineated in these plans for changes in triage guidelines to accommodate a rapid increase in patient census, patient isolation, and procedures to obtain increased antibiotic supplies. These plans should be developed in coordination with those of local, state, and federal emergency medical services and public health and governmental agencies, carefully specifying leadership and decision-making roles.¹⁵

Ongoing measures to reduce the availability of shigellae for malicious purposes are under development. Congress enacted the Public Health Security and Bioterrorism Preparedness and Response Act of 2002, requiring the U.S. Food and Drug Administration to develop regulations regarding food safety and tracking measures.¹⁶ National collections and hospital and research laboratories are increasingly developing guidelines for the control of access to areas storing microbiologic agents. Freezers and incubators are increasingly secured, with access limited to designated personnel and continuous written records/surveillance maintained of persons entering these areas or handling these materials.¹⁷

POSTINCIDENT ACTIONS

Healthcare providers with a high level of suspicion that a possible *Shigella* outbreak is the result of a deliberate action should notify their hospital infection control personnel and their local public health officer and law enforcement authorities. Prepositioning of drug and medical equipment stockpiles may prove critical in responding during very large outbreaks. Appropriate infection control procedures should be strictly enforced. Depending on the nature of the purported attack, materials and surfaces possibly contaminated by *Shigella* should be decontaminated with an appropriate disinfectant solution. During naturally occurring outbreaks of shigellosis, mass antibiotic prophylaxis has not been shown to be useful.¹²

MEDICAL TREATMENT OF CASUALTIES

The treatment of patients with shigellosis should initially focus on the emergency management of life-threatening complications, supportive measures, and provision of specific antimicrobial therapy. Rapid intravenous access and infusion of crystalloid should be instituted in patients exhibiting signs and symptoms of shock and acidosis. In less critically ill persons, oral rehydration with oral glucose-electrolyte solutions is preferred. Seizure activity in children necessitates monitoring for airway compromise, head and neck trauma, and aspiration. Intravenous benzodiazepine administration can be used for initial seizure control. Accompanying fever can be controlled with antipyretics and ice baths, if needed. Agents that suppress intestinal motility should be used only in conjunction with antibiotic therapy.

Appropriate antibiotics significantly decrease the duration of diarrheal illness, fever, and shigellae excretion. Only a few antibiotics have been proved to be clinically useful, and widespread use of these agents has led to the emergence of resistance to the sulfonamides, tetracycline, and ampicillin. Current treatment options include the use of parenteral ceftriaxone in severely ill children and oral quinolones or trimethoprim sulfamethoxazole. Currently no vaccine is available for shigellosis.

- Failure to notify appropriate public health agencies when an outbreak of diarrheal illness is suspected
- Failure to consider *Shigella* as a bioweapon
- Failure to consider *Shigella* in the setting of nondysentery illness
- Failure to monitor *Shigella* for antibiotic resistance.
- Failure to adequately instruct patients on appropriate infection control precautions

CASE PRESENTATION

Over the past week, your emergency department, which is the major medical center near a large state college, has experienced a significant increase in the number of patients presenting with diarrheal illness. You see a 20-year-old biology student without medical or travel history who presents with malaise, fever, and significant watery diarrhea. She states that most of her friends and others in the biology department have experienced diarrheal illness over the last week. She notes that several persons have been quite ill with fever, cramps, and bloody diarrhea, and some of these students were taken home by their parents. She remembers the onset of illness because it occurred at about the same time that the new biology teaching assistant arrived to replace one who had suddenly departed. . . .

UNIQUE CONSIDERATIONS

Shigella species have an advantage over other potential enteropathogenic bioweapons due to their low infective dose, their short incubation period, and their variety of potential disease presentations. Healthcare providers should be aware of shigellae's ability, especially in those organisms producing Shiga's toxin, to develop resistance to commonly used antibiotics. Furthermore, as relatively common causes of intestinal illness worldwide, the only clue to their use as a bioweapon may be the presentation of a large number of persons with an unusual strain, at an unusual time of year, or in an uncommon setting.

PITFALLS

Several potential pitfalls in response to an attack exist. These include the following:

- Failure to develop, implement, and test emergency response plans that include plans to respond to acts of bioterrorism

Salmonella Species (Salmonellosis) Attack

Sumeru Mehta and C. Crawford Mechem

DESCRIPTION OF EVENT

Salmonella organisms are non-spore-forming gram-negative rods of the family Enterobacteriaceae. Salmonellae are primarily pathogens of lower animals. The reservoir of infection in animals constitutes the principal source of nontyphoidal *Salmonella* organisms that infect humans, although transmission may occur from person to person. Salmonellae have been isolated from many animal species including poultry, cows, pigs, turtles, dogs, cats, and many birds.¹

Salmonella species are classified as category B biologic agents according to the Centers for Disease Control and Prevention (CDC). Criteria for this category include moderate ease of dissemination, a lower mortality rate than category A agents such as anthrax, and the requirement for enhancement of the CDC's diagnostic capacity as well as enhanced disease surveillance. Several category B agents pose a threat to the food supply. *Salmonella's* potential as a bioterrorism weapon is well established. The most prominent example of the use of *Salmonella* as a bioterrorism agent occurred in 1984 in the Dalles, Oregon, when followers of the cult leader Bhagwan Shree Rajneesh attempted to influence a local election by contaminating salad bars in several local restaurants with *Salmonella* cultures. No deaths resulted, but 751 people were sickened.²

In the vast majority of cases, humans acquire salmonellae through the ingestion of contaminated food, milk, or water. Infection has also resulted from the ingestion of contaminated medications, through the administration of intravenous platelet transfusions, and via direct transmission through inadequately sterilized fiber-optic instruments that have been used on patients undergoing upper gastrointestinal endoscopy.¹ Direct fecal/oral spread can also occur, particularly in children.

Salmonella infections occur with greatest frequency in the United States from July through November. A seasonal variation is also seen worldwide, with peak incidence corresponding to warm weather. The majority of reported isolations of *Salmonella* from humans come from sporadic cases; however, epidemiologic investigations of these apparently random events often identify unrecognized outbreaks in larger groups. The largest proportion of *Salmonella* outbreaks occur in the home,

with institutional outbreaks (e.g., those affecting hospitals) ranking second.

The development of disease after ingestion of *Salmonella* is influenced by the number and virulence of the organisms ingested as well as individual host factors. In most cases, a large number of bacteria, in the range of 1 million to 1 billion, must be ingested to cause symptomatic infection.³ In the case of unusually virulent strains or in patients with reduced resistance, symptomatic infection may result from smaller inocula. Factors that predispose persons to infection include underlying immunocompromising diseases, inflammatory bowel disease, malignancy, or use of antacids or histamine-2 blockers.¹ After ingestion of a sufficient number of bacteria, one or more of several clinical syndromes may manifest individually or concurrently. These clinical syndromes include enterocolitis (gastroenteritis), enteric (typhoid) fever, bacteremia, extraintestinal infection, and the chronic enteric or urinary carrier state.

Acute enterocolitis is the most common clinical manifestation of *Salmonella* infection. Nausea and vomiting are the earliest symptoms and develop 6 to 48 hours after ingestion of contaminated food, milk, or water. These are followed by diarrhea, which can range in severity from a few loose stools to fulminant, bloody diarrhea. Diarrhea usually persists less than 7 days but rare cases may continue for several weeks. Fever, when present, usually lasts less than 2 days. Prolonged fever combined with diarrhea should suggest a complication or another diagnosis. Electrolyte and water depletion may be severe, leading to hypovolemic shock in some cases.

Enteric fever produced by *Salmonella* serotypes other than *S. typhi* is called paratyphoid fever. The clinical features of paratyphoid fever are essentially the same as typhoid (see Chapter 113) but with milder symptoms. Signs and symptoms of enteric fever develop after an incubation period of 1 to 2 weeks and include fever, bradycardia out of proportion to the fever, myalgias, arthralgias, headache, hepatosplenomegaly, and rose spots, typically on the anterior chest wall. If the patient is not treated, altered mental status may develop.¹

Salmonella infection can produce an illness characterized by fever and sustained bacteremia without manifestations of enterocolitis or enteric fever. The clinical syndrome of *Salmonella* bacteremia is characterized

by a febrile course lasting for days or weeks. In bacteremia, the organism is isolated from blood, but stool cultures often have negative results. Bacteremia has also been shown to occur in 8% to 16% of infants and children younger than 3 years of age who require hospitalization.⁴ The median duration of persistence of *Salmonella* in stool is 7 weeks for patients younger than 5 years and 3 to 4 weeks for older children and adults.

Extraintestinal manifestations of *Salmonella* infection include meningitis, pleuropulmonary disease, endocarditis, pericarditis, arteritis, osteomyelitis, arthritis, hepatosplenic abscess, urogenital tract infections, and soft tissue abscesses. Chronic carriers (i.e., persons who continue to excrete the organism for more than a year after infection) are asymptomatic and unusual in nontyphoidal salmonellosis. Chronic enteric carriers tend to be older and have a much higher incidence of biliary tract disease than the general population.

PREINCIDENT ACTIONS

Foodborne diseases present a major challenge to public health authorities. Surveillance for acts of terrorism involving the intentional contamination of food or water with a biologic agent is dependent on close cooperation between community clinicians, public health officials, and law enforcement agencies. Clinicians must be able to recognize the unusual disease or disease pattern, order the appropriate laboratory tests and cultures, and report their suspicions or positive culture results to public health officials. The public health officials must then perform an appropriate epidemiologic investigation to identify the source. If a bioterrorism incident is suspected or confirmed, the appropriate law enforcement agencies must be notified. Methods to enhance surveillance include promoting awareness of bioterrorism among the medical community and general public, performing appropriate microbiologic testing in suspected cases, developing a clearly defined reporting system that facilitates early recognition of outbreaks, and promoting interagency cooperation and communication on local, regional, and national levels.⁵

POSTINCIDENT ACTIONS

Bioterrorism will often resemble a point-source outbreak, with all cases clustering around a single time period. An unusually high incidence may suggest deliberate infection, particularly if several point-source outbreaks occur simultaneously. Several features may suggest that a *Salmonella* outbreak is the result of an act of bioterrorism. These include the following: (1) large numbers of patients seeking care for similar signs and symptoms; (2) unusually high morbidity or mortality, or failure of the infection to respond to standard therapy; (3) multiple clusters of cases of salmonellae in areas that are not geographically contiguous; and (4) a tight cluster of cases with a common point source.⁶ If an act of bioterrorism is suspected, the proper authorities should be notified immediately. Information on salmonellosis should also

be disseminated to the general public to prevent further transmission of disease, to identify and treat those affected, and to initiate a disease prevention program.

MEDICAL TREATMENT OF CASUALTIES

The type of syndrome produced by *Salmonella* species influences selection and duration of antimicrobial therapy. Antimicrobial therapy is not indicated in transient intestinal carriers nor in the vast majority of patients with enterocolitis. The most important therapeutic consideration in enterocolitis is fluid and electrolyte replacement. Patients with bacteremia or enteric fever should be treated with appropriate antibiotics, which include ampicillin, trimethoprim-sulfamethoxazole, or chloramphenicol. Recently, the selection of antimicrobial agents has been complicated by the emergence of *Salmonella* strains resistant to multiple antimicrobials.⁷ Fluoroquinolones and the third-generation cephalosporins are recommended for use in areas where resistance is common. In 1997, the first recognized outbreak of fluoroquinolone-resistant *Salmonella* infection occurred in the United States.⁸ The development of widespread fluoroquinolone resistance among serotypes that commonly cause infection would have serious implications for public health and pose a major obstacle in the response to a bioterrorism incident.

CASE PRESENTATION

As a local emergency medicine physician in a small rural town, you notice that there has been an unusually high incidence of gastroenteritis among the local high school students in the past few days. You even had to admit an otherwise healthy 17-year-old on your last shift for severe dehydration. You were off yesterday, and this is your first shift since you admitted the young student. On follow-up, you note the patient is still requiring intravenous fluids and is receiving broad-spectrum antibiotics for fever and severe gastroenteritis.

When you begin your shift, three of your first five patients are all young students from the same high school. They present with the same symptoms, including diarrhea, nausea, vomiting, and abdominal pain with cramps, as the young man who was admitted. Along with intravenous fluids and select blood tests, you also decide to request stool cultures because you suspect a foodborne outbreak.

While taking a short dinner break, you overhear on the radio that a recently fired high school cafeteria employee was just arrested for assaulting the high school principal who had fired him. Suddenly, the nurse interrupts your meal because the waiting room is filling up with more high school students and family members, all of whom are afflicted with severe gastroenteritis.

A coordinated investigation involving medical, public health, and law enforcement personnel lead to the arrest of this employee for deliberately contaminating cafeteria food with *Salmonella*.

UNIQUE CONSIDERATIONS

Salmonellosis is in most cases a disease of morbidity, with an overall mortality rate of 0.4%. However, its appeal as a potential bioterrorism weapon derives from its ability to produce a large number of victims whose care could overwhelm local medical resources. In addition, *Salmonella* is a common pathogen that clinicians encounter routinely, with an estimated 1.4 million cases occurring annually in the United States.^{1,9} Therefore, an outbreak of salmonellosis would be less likely to raise concern over an act of bioterrorism than would a rare pathogen such as anthrax. As a consequence, recognition of a deliberate release of *Salmonella* organisms would most likely be delayed, increasing the number of victims and decreasing the likelihood that the perpetrators would be apprehended.

PITFALLS

Several potential pitfalls in response to an outbreak exist. These include the following:

- Failure to educate healthcare providers and the general public on the signs and symptoms of salmonellosis
- Failure of healthcare providers to maintain a high index of suspicion for intentional salmonellosis infection
- Failure to order appropriate laboratory tests, delaying diagnosis
- Failure to treat with appropriate antibiotics and follow up on stool cultures to verify antimicrobial sensitivity
- Administration of antibiotics when they are not indicated, a practice that can lead to the development of antibiotic-resistant strains
- Failure to notify the proper authorities when an outbreak of salmonellosis is suspected or confirmed

Salmonella typhi (Typhoid Fever) Attack

Lawrence Proano

DESCRIPTION OF EVENT

Typhoid fever is a clinical syndrome caused by the bacterium *Salmonella typhi*. These anaerobic, gram-negative, flagellated bacilli possess an antigenic structure comprised of a lipopolysaccharide somatic surface antigen (O) and a flagellar antigen (H). *S. typhi* organisms usually possess a polysaccharide surface antigen (Vi) that coats the O antigen, protecting it from antibody attack.

Salmonella are classified as category B agents by the Centers for Disease Control and Prevention (CDC).¹ This category includes viruses, bacteria, fungi, and toxins that are relatively easy to disseminate, cause moderate morbidity and in most cases low mortality, and require specific enhancement of diagnostic and surveillance capacities for the laboratory to effectively respond during an outbreak. However, unlike the CDC category A agents, typhoid fever has a relatively low mortality rate among immunocompetent hosts, with only about a 10% mortality rate if untreated.¹

The disease is not the most attractive weapon from a bioterrorism standpoint in that it is difficult to spread efficiently on a wide-scale basis compared with some other organisms, which can be transmitted via the aerosol route. Nevertheless, one should not underestimate the ability to intentionally cause a large outbreak of disease by using the foodborne route of infection.

The potential results of such an attack on the food supply can be inferred from some historic examples of unintentional foodborne disease outbreaks. In 1994, an estimated 224,000 people in the United States were infected during an outbreak of *Salmonella enteritidis*, caused by contamination of pasteurized liquid ice cream that was transported nationally in tanker trucks, resulting in one of the largest foodborne disease outbreaks in U.S. history.² In 1985, contamination of pasteurized milk from a dairy plant in northern Illinois resulted in over 170,000 people being infected with an outbreak of *Salmonella typhimurium* that was multidrug resistant.³

Due to the lower incidence in the United States, medical and public health officials may not recognize a foodborne attack such as typhoid fever for some time. From 1975 to 1984, the average number of cases of typhoid fever reported annually in the United States was 464. In

that period, 57% of cases were in patients aged 20 years or older and 67% of cases were acquired while traveling internationally.⁴ The most likely foodborne attack scenario would involve a large number of otherwise healthy persons presenting over days to weeks with vague, multisystem complaints, with some of the cases progressing to more toxic syndromes.

The incubation period of typhoid fever varies from several days to longer than 3 weeks, averaging around 14 days. During the first week there are often nonspecific symptoms such as malaise, anorexia, gradually worsening fever, occasional chills, headache, upper respiratory symptoms, cough, and hearing loss. Patients are often constipated during the first week.

In the second week there is a continuation of fever, often accompanied by a relative bradycardia, diarrhea, vomiting, and a more toxic appearance of the patient. Rose spots, 2- to 4-mm pink papules visible on the torso of fair-skinned persons, are seen in about 50% of patients. Abdominal pain and distension with hepatosplenomegaly may be present.

During the third week the patient becomes increasingly toxic with high fever, delirium, or coma; the so-called typhoid state. Diarrhea may have a “pea-soup” appearance. Multiplication of *S. typhi* in Peyer’s patches of the small bowel may result in small bowel hemorrhage or perforation and peritonitis. Sepsis, anemia, leukopenia, pneumonia, and myocarditis may also occur. Death may occur in untreated patients in the third week of illness, usually from gastrointestinal perforation, anemia, toxemia, or occasionally, meningitis. If the patient survives through the fourth week of illness and gastrointestinal complications do not occur, fever, toxemia, and abdominal symptoms abate over a few days.

Complications of typhoid fever are numerous and can occur at any time during the illness, even after a seemingly benign course.¹ Complications may be the presenting symptom or sign rather than the picture of typhoid fever. Complications include small bowel perforation, gastrointestinal hemorrhage, hemolytic anemia (common in patients with G6PD deficiency), typhoidal pneumonia, meningitis, glomerulonephritis, acute renal failure, nephrotic syndrome, arthritis, osteomyelitis, orchitis, hepatitis, acute cholecystitis, and parotitis. Abscesses may occur virtually anywhere in the body as

a late complication, most commonly in the liver, spleen, brain, breast, and bone. Deep venous thrombosis and Guillain-Barré syndrome have been reported in association with typhoid fever.

PREINCIDENT ACTIONS

Adequate preparation for and response to bioterrorism events require coordination of local, state, and federal public safety resources in the United States. Several agencies are involved in detection and epidemiologic investigation of foodborne disease outbreaks, whether intentional or unintentional. These include local and state health epidemiology departments, public health laboratories at the local and state levels, the Council of State and Territorial Epidemiologists, the Association of Public Health Laboratories, and the CDC. The U.S. Food and Drug Administration and the U.S. Department of Agriculture have the primary regulatory authority over food safety, in coordination with state departments of agriculture.⁵

A mass-casualty event resulting from an outbreak of typhoid, or most other foodborne illnesses, is less likely to occur compared with what would be expected from the intentional dissemination of a category A bioterrorism agent. However, smaller-scale attacks are well within the realm of possibility. Therefore, physicians, healthcare workers, and health agency personnel must remain vigilant in identifying trends that may correspond with an outbreak of typhoid, or any foodborne or waterborne illness, whether terrorist related or not. With some diseases, including typhoid fever, these trends may take days or even weeks to develop, and they may involve somewhat non-specific systemic complaints that evolve over time.

Numerous unintentional foodborne outbreaks are reported every year. Epidemiologic clues to a deliberate, covert act of contamination include the following:

1. The presence of a large epidemic with unexplained morbidity and mortality
2. More severe disease than is usually expected for a specific pathogen or failure to respond to specific therapy
3. Multiple simultaneous or serial epidemics
4. A disease that is unusual for a particular age group
5. Unusual strains or variants of organisms or antimicrobial resistance patterns different from those circulating in the population
6. A similar genetic type among agents isolated from distinct sources at different times or locations

Features that would be suggestive of deliberate contamination might also arise in unintentional outbreaks as well. Confusing matters further, these epidemiologic clues might not necessarily be evident in an outbreak due to deliberate contamination.¹

POSTINCIDENT ACTIONS

Clinicians suspicious that an outbreak may represent typhoid fever, even before bioterrorism is suspected,

should notify the appropriate local, state, and federal public health and law enforcement authorities. This is the proper course of action, even from a public health perspective, because occasional outbreaks of typhoid fever can occur.

Both state and federal regulatory agencies participate in food-specific aspects of outbreak investigation, especially those related to the tracking of suspected foods and their recall. A trace-back investigation locates the origin of the food vehicle to establish the source of contamination, often by review of the records of vendors, shippers, producers, and processors, and by inspection of their facilities.

Integration of data from the epidemiologic and trace-back investigations is crucial to properly identify the contaminated food and the mode of contamination, underscoring the need for the closest collaboration between epidemiologists, microbiologists, and food-safety officials.⁵

MEDICAL TREATMENT OF CASUALTIES

Successful treatment of typhoid fever requires rapid diagnosis, antibiotic administration, and supportive care. With prompt treatment, mortality rates have been reduced from between 10% and 15% to between 1% and 4%.¹

Chloramphenicol is the antibiotic most widely used worldwide for treating typhoid fever. Tetracyclines and aminoglycosides are not effective against *S. typhi*, although they may demonstrate in vitro activity. Ampicillin, amoxicillin, and trimethoprim-sulfamethoxazole have been successfully used to treat this entity. However, in the past decade, fluoroquinolones and third-generation cephalosporins have been shown to be as effective as chloramphenicol, and in the developed world have largely become the antibiotics of choice. Thus, fluoroquinolones would be the recommended agent to treat victims diagnosed with typhoid fever.

Aside from antibiotic administration, general supportive care, hydration, and electrolyte management are important in treating this disease. This is especially important because patients with severe typhoid fever have a limited ability to maintain their nutritional and fluid status.

In addition to antibiotic therapy, studies have clearly demonstrated that corticosteroid administration reduces mortality in patients with severe typhoid fever. It does not appear to increase the incidence of complications, relapse rate, or induction of a carrier state among those treated.

UNIQUE CONSIDERATIONS

The features of typhoid fever tend to be nonspecific, and a number of other causes need to be considered when encountering febrile illnesses including malaria. Malaria would be the most likely consideration in the tropics but would be far less likely in developed countries such

CASE PRESENTATION

A notice is posted inviting all 50 workers from the hospital laboratory to the break room to enjoy some free muffins, doughnuts, and coffee. Twenty of the workers respond to the invitation and consume the pastries. Over the next week to 10 days, 17 of the 20 workers become ill with what they initially attribute to a viral illness. Their supervisor notes the cluster of illness among the staff and reports it to the hospital's infection control department.

By the end of the first week, six of the staff members who were ill have visited the hospital's emergency department with fevers, constipation, abdominal pain, and lethargy. Four of these patients require admission and are evaluated for a fever of unknown origin. After admission, two of the four rapidly develop profuse "pea-soup" like diarrhea and become toxic. Three of the four are noted to have hepatosplenomegaly. Blood cultures of all four of these persons are positive for *S. typhi*. The remainder of the staff with similar symptoms is called in for evaluation, cultured, and treated empirically for typhoid fever.

Subsequent investigation of the incident leads to the discovery that a coworker had engaged in an act of foodborne terrorism by intentionally contaminating the pastries with stored bacteria from the laboratory. She subsequently pleads guilty to the charge.

This case presentation may sound apocryphal; however, it is based on a real incident of domestic foodborne terrorism that occurred in 1996 in Dallas, Texas.⁶ Although the organism in the actual event was *Shigella dysenteriae*, the consequences could have been much more severe if the agent had been *S. typhi*.

as the United States. Tuberculosis and brucellosis can also mimic typhoid fever. Other illnesses to consider in the differential diagnosis of typhoid fever include dengue fever, endocarditis, typhus, and lymphoproliferative disorders. The tests for typhoid fever do not have a high degree of sensitivity or specificity, and because of the relatively low prevalence of this disease in the United States, it would not likely be an early consideration in the minds of most clinicians.

Nonspecific hematologic and biochemical findings can lend support for the diagnosis of typhoid fever. Leukopenia is common. There is often a modest degree of hyponatremia, as well as a mild transaminitis.

PITFALLS

Several potential pitfalls in response to an outbreak of typhoid fever exist. These include the following:

- Failure to prepare adequate state or local systems to respond to possible terrorist attacks before the attacks occur
- Failure to consider typhoid fever as the etiology for patients who present without diarrheal illness. Early typhoid fever often presents initially with constipation, not diarrhea!
- Failure to consider typhoid fever as a bioterrorism attack in the setting of a large number of people who present over days to weeks with symptoms consistent with this or any foodborne illness
- Failure to notify appropriate public health and law enforcement agencies when an outbreak of foodborne illness is suspected or confirmed

Burkholderia mallei (Glanders) Attack

Mark A. Graber

DESCRIPTION OF EVENT

Burkholderia mallei is a Centers for Disease Control and Prevention category B biologic agent and causes the disease known as glanders. *Burkholderia mallei* was previously called *Pseudomonas mallei*. It is a non-motile, nonsporulating, obligate aerobic, gram-negative bacillus.¹

In its natural state, glanders is primarily a disease of horses and other equids (e.g., donkeys, mules), with humans becoming secondarily infected. Because of its impact on equids, glanders has had significant historic, economic, and military effects. In modern times, *B. mallei* was used as a biologic warfare agent in World War I (WWI) with particularly devastating effects on troop and artillery movement on the eastern front. During WWII, civilians and prisoners of war in China were purposefully infected with glanders by the Japanese. Finally, *B. mallei* was used by the former Soviet Union on a limited basis in Afghanistan in the 1980s. Glanders has been all but eradicated in the United States and most developed countries but continues to be a problem in countries still dependent on equids, mainly in Africa and Asia. It is thought likely that antibiotic-resistant strains are being developed as a biologic warfare agent.¹

The transmission of glanders from equids to humans generally occurs by direct contact with broken skin and mucous membranes, although transmission through intact skin has been reported. The effectiveness of percutaneous transmission is not well documented. Historically, 30% of horses in China were infected with *B. mallei* after WWII but few human cases were reported, suggesting poor transmission. However, the low rate of human cases may reflect reporting problems or a less virulent strain of the bacteria and not the low infectivity of the organism. A second mode of transmission is by inhalation of droplets, either directly from infected patients or equids, or by inhalation of aerosolized laboratory samples. Transmission by droplet is quite efficient, with 46% of those exposed to *B. mallei* in laboratory accidents developing the illness.² The number of organisms required for an infectious inoculum in humans is not known. However, in hamsters, inhalation of 1 to 10 aerosolized *B. mallei* organisms is fatal. Rats require a larger inhaled inoculum.^{1,3,4} It is the inhalation mode, cou-

pled with the ability of *B. mallei* organisms to survive up to a couple of months in favorable conditions, that makes *B. mallei* a potential agent for biologic terrorism.⁵

There are no reported cases of naturally occurring human glanders in English literature since 1949. However, several laboratory-related cases have been reported. Sporadic cases have been reported in Asia and Africa, generally among veterinarians, abattoir workers, or those working closely with horses. Equids (and an occasional infected carnivore) are the only natural reservoir of *B. mallei*. There is no natural occurrence in soil or water. This point is demonstrated by the fact that no isolates of *B. mallei* have been found in Great Britain since WWII. For this reason, *any case of glanders should be considered a bioterrorism event until proven otherwise.*

There are four unique presentations of *B. mallei*: an acute form localized to the skin, a chronic form localized to the skin (also known as “farcy”), a pulmonary form, and a rapidly fatal septic form (Table 114-1). Persons with diabetes and immunosuppressed persons are particularly susceptible to systemic spread. The incubation period for glanders is between 1 and 14 days, with 10 to 14 days being the norm. However, cases have been reported up to 10 years after exposure. The hallmark of systemic glanders (pulmonary and acute sepsis syndromes) is widespread erythroderma or widespread skin pustules and abscesses. Because of the predominance of skin findings, glanders may be mistakenly identified as a systemic staphylococcal infection, etc.⁶ *The leukocyte count is often normal or only mildly elevated.* Liver enzymes may be elevated, reflecting hepatic abscess formation.⁷

Historically, a mallein-antigen purified protein derivative (PPD) was used to identify early infection in animals. However, given that the mallein PPD must be injected into the infected organism’s palpebral fissure, this method of testing is limited to animals. *B. mallei* can be cultured at 37.5°C using medium containing 1% to 5% glucose, or 5% glycerol, or both. Meat-infusion nutrient media can also be used. Using these ideal media, the organism can generally be recovered in 48 hours. *Automated bacterial identification systems will often misdiagnose B. mallei as a pseudomonas organism (e.g., Pseudomonas fluorescens or Pseudomonas putida).* Gene sequencing can reliably identify *B. mallei*.⁸ Enzyme-linked immunosorbent assay and polymerase

TABLE 114-1 PRESENTATIONS OF *B. MALLEI* INFECTION

DISEASE	USUAL INCUBATION	PRESENTATION	LABORATORY/X-RAY	SIGNS	MORTALITY
Pulmonary	10-14 days	Cough, fever, sweats, chest pain, photophobia	Miliary granulomas in lung progressing to consolidation and abscesses, liver and spleen abscesses, and granulomas	Photophobia, lacrimation, hepatosplenomegaly, generalized erythroderma or granulomatous/necrotic lesions of the skin, adenopathy	90% to 95% if untreated, 40% if treated
Fulminant sepsis	Likely 10-14 days	Sudden-onset fever, rigors, sweats, myalgias, pleuritic chest pain, jaundice, diarrhea	Granulomas in liver and spleen, pulmonary consolidation, nodules and abscesses, mild leukocytosis with left shift or leukopenia	As above	>95% if untreated, 50% if treated
Acute cutaneous	1-5 days	Skin ulceration, swollen lymph nodes, mucopurulent drainage if mucous membrane	Possible systemic dissemination in 2-4 weeks after infection of lymph nodes (possibly sooner)	Nodules, abscesses, ulcers of skin and along lymphatic vessels and subcutaneous tissues	After systemic dissemination: 95% if untreated, 50% if treated
Chronic cutaneous (aka farcy)	Variable	Induration, lymphedema of skin, ulcerations, ropey looking lymphatic vessels with lymphadenopathy	As above	As above	May rarely progress to meningitis; 50% eventual mortality despite treatment

chain reaction tests exist to identify *B. mallei*. However, neither test is widely available. Latex agglutination tests are too nonspecific to be of much use. Finally, a complement fixation test for antibody to *B. mallei* is available. It is considered positive at 1:20 or with a fourfold increase in titer. However, a negative test result does not rule out the disease.⁹

There is no vaccine available for glanders and no prophylactic antibiotic regimens are currently recommended, although this might change in the face of an epidemic. Although person-to-person spread is considered unlikely, isolation is the crux of prevention. Isolation rooms are recommended, if available. At the least, patients should be masked to prevent droplet spread. Standard precautions are recommended for persons caring for patients. These include the use of surgical masks, gloves, face shields, and gowns. Level 3 precautions are recommended for those working with *B. mallei* in the laboratory, and hospital laboratory personnel should be made aware that a potentially dangerous organism is being cultured. The organism is susceptible to heat (55°C), drying, and various disinfectants including benzalkonium chloride, 1% sodium hypochlorite, 70% ethanol, and iodine preparations.⁹

PREINCIDENT ACTIONS

Preparation should be the same as for any possible bioterrorism event. Additionally, equids should be continuously and closely monitored for the development of glanders. Monitoring, and the destruction of any infected equids, is mandated by law. However, surveillance has likely lapsed given the rareness of the illness. The inclusion of veterinarians in preparation for biologic

emergencies can facilitate early identification of possible outbreaks of this and other diseases (e.g., brucellosis and anthrax).

POSTINCIDENT ACTIONS

The most important point here is to remove the natural reservoir of *B. mallei* from the population. For this reason, any equids in the area should be tested using the mallein PPD, and those animals testing positive, along with any showing symptoms or signs of *B. mallei*, should be euthanized and disposed of properly. As evidenced by the lack of *B. mallei* infection in developed countries, this approach has been shown to be very effective at removing *B. mallei* from the population and saving animals in the long term.¹⁰ Continued monitoring of the human population is also important given the latency period for developing glanders of up to several years that has been seen after *B. mallei* exposure.

MEDICAL TREATMENT OF CASUALTIES

Presumed cases should be isolated if possible. There are no trials of antibiotics for glanders in humans; these recommendations reflect those of the *European Union Commission on Preparedness and Response to Biological and Chemical Agent Attacks* as well as other sources. *These recommendations may not apply to the drug-resistant glanders that will likely be used in a bioterrorism event.*

First-line therapy for systemic glanders is imipenem, ceftazidime, or meropenem plus either doxycycline or ciprofloxacin in severe cases. Another option is trimetho-

prim/sulfamethoxazole (TMP/SMX), 5 to 10 mg/kg (given intravenously or orally) based on the trimethoprim component given every 8 hours. In mild cases of glanders, oral therapy can be tried with TMP/SMX, doxycycline, or amoxicillin/clavulanate. The duration of intravenous therapy should be 2 to 3 weeks. *B. mallei* can reactivate and requires prolonged treatment. For this reason, treatment should be continued with an oral agent. Ciprofloxacin, doxycycline, TMP/SMX, or amoxicillin/clavulanate administered for 60 to 150 days are all good choices. Although there is no consensus, most authors suggest treating for about 24 weeks.¹¹⁻¹⁴

- Failure to treat infected persons in the long term
- Treatment with inappropriate antibiotics; several antibiotics should be administered when treating glanders since it is likely that organisms released in a bioterrorism event will be multi-drug resistant. Sensitivity testing should always be performed
- Use of inappropriate media for growing the organism
- Misidentification of the organism as a pseudomonal species
- Failure to use proper isolation precautions in the laboratory and clinical settings

CASE PRESENTATION

Two likely scenarios are possible:

1. A 45-year-old man presents with tender lymphadenopathy, fever, chills, and a pustule on the left lower extremity. A presumptive diagnosis of staphylococcal infection with secondary lymphadenitis is made, and the patient is administered a first-generation cephalosporin. Initially the patient appears stable, but 2 weeks later he develops diffuse erythroderma with pustules and an enlarged and tender liver and spleen. Computed tomography reveals granulomas in the liver and spleen.
2. You see multiple patients in your emergency department complaining of cough, fever, and chills during the month of November. A diagnosis of influenza is made. Because influenza A is predominant this season, you administer rimantadine to the patients. The patients become progressively ill, and chest radiographs performed on the second visit reveal evidence of a military pattern of granulomas in the lungs. A course of doxycycline and imipenem is begun, the patients are hospitalized, and they do well.

UNIQUE CONSIDERATIONS

Special considerations are noted above and include long-term monitoring of the human population for reactivated or initial disease, removal of any reservoir of *B. mallei* (e.g., culling of equids), and long-term treatment (12 to 24 weeks) with an oral agent to prevent relapse in infected persons.

PITFALLS

Several potential pitfalls in response to an outbreak exist. These include the following:

- Failure to recognize the presentation of glanders
- Failure to monitor equids on an ongoing basis to facilitate prevention and early detection

Burkholderia pseudomallei (Meloidosis) Attack

Sean Montgomery

DESCRIPTION OF EVENT

Melioidosis, also known as *Whitmore's disease*, is caused by the bacterium *Burkholderia* (formerly *Pseudomonas*) *pseudomallei*, a motile, aerobic, non-spore-forming, facultative intracellular gram-negative bacillus.¹ People acquire the illness by inhaling dust or droplets contaminated by the bacteria or when contaminated soil or surface waters come in contact with abraded skin. Clinical cases of melioidosis are uncommon in North America because melioidosis is a disease of tropical climates; it is endemic in Southeast Asia and Northern Australia. In addition, it has been found in the South Pacific, Africa, India, and the Middle East. In the United States, cases range from zero to five each year, predominantly occurring among travelers and immigrants. Melioidosis predominantly occurs during the rainy season in endemic areas.² Peak incidence of melioidosis occurs in the fourth to fifth decades of life. It primarily affects people who have an underlying chronic disease, such as diabetes mellitus, renal disease, cirrhosis, chronic lung disease, or those who are otherwise immunocompromised.³

Illness from melioidosis can lead to a broad range of manifestations, including acute localized infection, pneumonia, bacteremia, and chronic suppurative infection. Asymptomatic infections are also possible. Melioidosis is highly virulent and has up to a 40% mortality rate in Thailand.³ The incubation period of melioidosis is not clearly defined but may range from 2 days to many years.

Melioidosis is similar to glanders disease (see Chapter 114) in many respects, but the epidemiology and natural reservoirs of melioidosis are distinct from glanders. The bacteria causing melioidosis can be found in contaminated soil and water and are spread through direct contact. Glanders is typically acquired through contact with infected domestic animals. Both melioidosis and glanders disease have been investigated by the United States and other countries as potential biologic weapons and are classified as category B agents by the Centers for Disease Control and Prevention (CDC). The United States studied these agents as possible biologic warfare weapons in 1943–1944 but did not weaponize them. The former Soviet Union is believed to have been interested in glan-

ders as a potential biologic weapon as well. During World War I, glanders was allegedly used to infect horses and mules destined for delivery to France by German agents.⁴ The Japanese are believed to have infected civilians, prisoners of war, and horses during World War II.

Several characteristics make *B. pseudomallei* a potential biologic weapon. The organism can be fairly easily recovered from water and wet soil in rice paddy fields in endemic areas. In northeast Thailand, the organism can be cultured from more than 50% of rice paddies.⁵ *B. pseudomallei* grows aerobically on most agar media and produces colonies within 24 hours at 37°C. Biosafety level 3 containment practices are required for laboratory staff when working with these organisms. In addition to being somewhat easily obtained and cultured, *B. pseudomallei* organisms are fairly resilient. They can survive in triple-distilled water for years.⁶ If aerosolized and distributed into a densely populated area, the consequences could be potentially devastating. The high mortality of *B. pseudomallei* infections is related to a tendency to develop high bacteremias (>50 cfu/mL).⁷ In addition, no effective vaccine currently exists, and successful treatment requires broad-spectrum, potent antibiotics.

Because of the variable presentations of melioidosis, the unpredictable incubation period, and the possibility that many carriers will remain asymptomatic, the medical and public health community may not recognize a bioterrorist attack involving *B. pseudomallei* until the organism is cultured from acutely septic persons. The attack would likely involve aerosolization of media containing *B. pseudomallei* and distributing it over a heavily populated, urban area. Over a period of days to weeks, affected persons would visit healthcare facilities with symptoms ranging from fevers, chills, and cough to fulminant multi-system organ failure. The diagnosis of melioidosis in the absence of travel to an endemic area should be presumed to be evidence of bioterrorism until proven otherwise, and appropriate authorities should be notified.

The outcome of infection with *B. pseudomallei* depends on a balance between the virulence of the organism, the size of inoculum, the point of entry, and the underlying immunologic status of the host. During a bioterrorist event, immunologically compromised hosts

and those who received the largest inoculum would likely be the first to manifest symptoms and would develop the most severe illness. Long periods of latency (up to 29 years) have been reported before the disease becomes clinically apparent.⁸

Melioidosis septicemia typically presents with high fever and rigors, although some patients will present with a recurrent fever. About half of patients will have a primary focus of infection, typically in the lung or skin. Patients may develop confusion, jaundice, and diarrhea. They often develop diffuse metastatic foci, acidosis, and shock, and many die within 48 hours. Poor prognostic features include absence of fever, leukopenia, azotemia, and abnormal liver function test results.³ The disease is characterized by abscess formation.⁹ The lung is the most commonly affected organ, and lung abscesses may rupture into the pleural space to cause empyema. The liver, spleen, kidney, and prostate are also common sites for abscess formation. In one third of children with melioidosis in Thailand, the infection was found to present with acute suppurative parotitis.¹⁰ Melioidosis presents as brainstem encephalitis or flaccid paraparesis in 4% of cases from Northern Australia.¹¹

Laboratory data may reveal anemia, leukocytosis with neutrophilic predominance, evidence of hepatic and renal impairment, and coagulopathy. An abnormal chest x-ray is found in up to 80% of patients, most commonly with widespread, nodular shadowing.⁸ *B. pseudomallei* can be readily cultured from infected sites or the blood.¹² Cultures should be grown on routine blood agar and Ashdown's selective medium. The median time taken to obtain a positive blood culture result is 48 hours. Latex agglutination tests based on monoclonal antibodies to lipopolysaccharide can then be undertaken for definitive identification.¹³

PREINCIDENT ACTIONS

Preparation for a mass-casualty event requires coordination of local, state, and federal officials and resources. Cities, hospitals, and emergency departments should have disaster plans developed and tested before the advent of a terrorist attack. The diagnosis of melioidosis in the absence of travel to an endemic area should be presumed to be evidence of bioterrorism until proven otherwise, and appropriate authorities should be notified. In the event of large numbers of people presenting with symptoms suspicious for a bioterrorist attack, symptomatic persons should be isolated pending further investigation, and the CDC must be rapidly notified.

Healthcare workers must remain vigilant in identifying trends that may correspond with an outbreak of melioidosis. These trends may become apparent over weeks to months, initially involving those with underlying, chronic illness and then possibly spreading to involve otherwise healthy persons presenting with skin infections, pneumonia, and multisystem organ failure. Mechanisms to detect progressively increased emergency department volume and symptom trends should continue to be developed and implemented, and further research into the development of a vaccine against melioidosis is warranted.

POSTINCIDENT ACTIONS

Appropriate federal, state, and local healthcare authorities and the CDC must be notified if any clinician has a high level of suspicion of a melioidosis outbreak or if a confirmed case of melioidosis is diagnosed in an individual without a known history of travel to an endemic area. Implementation of disaster plans may be warranted if several cases are simultaneously reported or emergency department volume is noted to be significantly increased. Mobilization of resources including expansion of intensive care units and release of antibiotic stockpiles may be required.

MEDICAL TREATMENT OF CASUALTIES

Patients presenting with melioidosis septicemia require aggressive supportive care, including hemodynamic and respiratory support and correction of volume depletion and shock. Abscesses should be drained whenever possible. The antibiotics of choice are ceftazidime, imipenem-cilastatin, or meropenem with or without trimethoprim-sulfamethoxazole.¹⁴⁻¹⁷ These should be given in full doses (1 g every 8 hours, or a dose appropriately adjusted for renal function or size) for 2 to 4 weeks, according to the clinical response. This should be followed by a 20-week course of doxycycline (100 mg twice a day) and trimethoprim-sulfamethoxazole (160 mg trimethoprim plus 800 mg sulfamethoxazole twice per day), which has been associated with a lower relapse rate than amoxicillin-clavulanic acid (500 mg amoxicillin/125 mg clavulanic acid three times a day). Prolonged oral antibiotics are needed to prevent relapse, which occurs in up to 23% of patients and is more common in patients who have more severe disease.¹⁷ Other agents with activity against *B. pseudomallei* include

CASE PRESENTATION

Over the past week you have noted an increased volume of patients visiting your emergency department. You see a 28-year-old female with fever and cough. Her examination is notable for a temperature of 40°C, heart rate of 140, respiratory rate of 28, blood pressure of 95/60, and oxygen saturation of 88% on room air. She has diffuse bibasilar crackles on her pulmonary examination and a diffuse pustular rash. Her laboratory results reveal a hematocrit of 24, a white blood cell count of 23 with a neutrophilic predominance, a creatinine level of 2.0, a glucose level of 433, and an international normalized ratio of 2.0. Her chest x-ray reveals widespread, nodular shadowing. Blood cultures are sent for evaluation; the patient is treated with oxygen, insulin, intravenous fluids, and antibiotics; and she is admitted to the intensive care unit. Meanwhile, intensive care units throughout the city are becoming overwhelmed.

ceftriaxone, aztreonam, doxycycline, and ticarcillin-sulbactam. The role of granulocyte colony-stimulating factor, which has also been used as adjunctive treatment in Australia, remains to be determined. Currently, no vaccine exists for melioidosis.

UNIQUE CONSIDERATIONS

During a bioterrorist event, affected persons would present to healthcare facilities over a period of days to weeks with symptoms ranging from fevers, chills, and cough to fulminant multisystem organ failure. Because of the variable presentations of melioidosis, the medical and public health community may not recognize a bioterrorist attack involving *B. pseudomallei* organisms until the organism is successfully cultured. In addition, *B. pseudomallei* pneumonia could be confused with plague given a similar appearance of stained organisms, and the diffuse, pustular eruption could be confused with smallpox or varicella.¹⁸ Healthcare providers need to be aware that melioidosis should be treated with either ceftazidime, imipenem-cilastatin, or meropenem in the acute phase, and a prolonged antibiotic course is also required to prevent relapse.

PITFALLS

Several potential pitfalls in response to an attack involving melioidosis exist. These include the following:

- Failure to prepare for potential bioterrorist attacks prior to the event
- Failure to consider melioidosis attack in the context of multiple persons presenting to healthcare facilities over a period of days to weeks with symptoms ranging from fevers, chills, and cough to fulminant multisystem organ failure
- Failure to treat melioidosis with ceftazidime, imipenem-cilastatin, or meropenem in the acute phase, and a prolonged antibiotic course to prevent relapse
- Failure to notify appropriate law enforcement and public health officials in the event of a suspected melioidosis attack or outbreak, or in the event of a con-

firmed case of melioidosis in a person without a known history of travel to an endemic area

Chlamydia psittaci (Psittacosis) Attack

Hans R. House

DESCRIPTION OF EVENT

Psittacosis, also known as parrot fever, is caused by *Chlamydia psittaci*, an obligate intracellular bacterium. Clinical cases of psittacosis are sporadic and have a worldwide distribution. Approximately 100 to 200 cases are reported annually in the United States.¹ The true incidence, however, is likely higher. Since psittacosis carries a nonspecific presentation and is difficult to culture, many cases go unnoticed or are simply attributed to “atypical pneumonia.”

The association of bird ownership or bird exposure with psittacosis is well known. Parrots, parakeets, cockatiels, and canaries are the species most commonly associated with *C. psittaci* infection. More than 130 avian species have been documented as hosts of *C. psittaci*, including pigeons, sparrows, ducks, egrets, chickens, and turkeys.² Not all cases of human psittacosis derive from avians; case reports describe transmission from infected sheep, cattle, cats, and dogs.^{3,4} Human-to-human transmission has been described, but it is rare.⁵

C. psittaci is categorized as a Centers for Disease Control and Prevention (CDC) class B biologic warfare agent for its potential to spread via aerosol and infect victims with a relatively low mortality rate.⁶ The United States, the former Soviet Union, and Egypt have all conducted research into its use as a weapon, but none is known to have deployed it. To date, no known incidents of intentional infection by *C. psittaci* have occurred.⁷

The few incidents of large-scale outbreaks of psittacosis involved the distribution or industrial processing of birds. The largest outbreak, from 1929–1930, involved 750 to 800 cases and was linked to the importation of exotic birds from Argentina to Europe and the United States. Epidemiologic data from the 1970s and 1980s in the United Kingdom, the United States, and Sweden show a direct relationship between increased importation of exotic birds and rising numbers of cases of psittacosis.^{8,9} More recent outbreaks occurred in workers at a duck farm and at turkey processing facilities.^{10–12}

C. psittaci is usually acquired by inhalation or direct contact with the infectious discharges from infected animals. Infected birds may transmit the disease while asymptomatic, but the greatest number of organisms is expressed during periods of obvious illness (shivering, emaciation, anorexia,

dyspnea, and diarrhea). Since the discharge from the beaks and eyes, feces, and urine are all infectious, feathers and dust in and around the birds' cages become infectious.¹³ Aerosolization of infectious material, such as bird excreta, is one possible route of infection that might be attempted in a biologic attack. However, a weaponized agent could also be used. According to Bill Patrick, who headed a component of the U.S. biologic weapons program at Fort Detrick, Md., in the 1950s and 1960s, *C. psittaci* was high on the list to be produced and stockpiled as a biologic weapon just before President Richard Nixon terminated the program in 1969 (Bill Patrick, personal communication, July 30, 2004). The organism, measuring 300 nm in its infectious form (or elementary body), is resistant to drying and may be viable for up to 1 week at room temperature.¹⁴

After inhalation of *C. psittaci* and establishment of an infection in the epithelial cells of the lower respiratory tract, psittacosis may follow one of two routes of pathogenesis. Direct local invasion of the pulmonary parenchyma results in a disease with a relatively short incubation period (1 to 3 days). More commonly, a primary bacteremia leads to infection of the reticuloendothelial cells of the liver and spleen. This results in an incubation period of 1 week to 15 days.

Based on this bimodal pathogenesis, it can be presumed that a biologic attack on a large population would lead to an epidemic with two spikes in cases. The first, smaller peak would occur only days after the attack, and a second, larger peak may be seen 1 to 2 weeks after the release of the agent.

Cases would probably go unnoticed initially. Although there may be clues on history and physical examination, psittacosis does not have a distinctive presentation; it usually presents as an atypical pneumonia with varying degrees of severity—from an unapparent mild disease to a severe, life-threatening systemic illness and respiratory failure. Untreated, up to 20% of cases may be fatal. With proper treatment, however, the mortality rate is around 1%.

The most common symptoms of psittacosis are cough, fever, headache, and vomiting. Most patients (about two thirds) describe a dry cough with scant sputum. Malaise, anorexia, and diarrhea are also common symptoms. Many other symptoms have been associated with cases of *C. psittaci* infection, including photophobia, tinnitus, ataxia, deafness, sore throat, hemoptysis, epistaxis, and rash.

Typical findings on physical examination include fever, rales, consolidation, and tachypnea.^{15,16} Two unusual findings that may alert the examiner to the possibility of psittacosis are splenomegaly and relative bradycardia (a normal heart rate in the presence of a high fever). Many other signs have also been described in reviews of psittacosis cases. These include somnolence, confusion, pleural rub, adenopathy, palatal petechiae, herpes labialis, and Horder's spots. Horder's spots are pink, blanching maculopapular eruptions similar to the rose spots seen in typhoid fever. As the disease progresses, multiple systemic complications may develop (see Postincident Actions).

The most important laboratory finding involves the chest x-ray, which usually demonstrates a variable degree of consolidation. Most often, this consolidation exceeds the clinical severity of the patient. The white blood cell count is usually normal, but often demonstrates a left shift. More than one-half of patients have moderately elevated transaminases levels, and many demonstrate mild hyponatremia.

Although isolation of the organism from the blood in cell culture is possible, it can be difficult and is dangerous for laboratory personnel. The preferred method of diagnosis is by serology; antibodies are measured by complement-fixation (CF) or microimmunofluorescence (MIF) during the acute illness and after recovery. A single convalescent titer of 1:32 in a patient with a compatible clinical picture is considered by the CDC to be a presumptive case. A four-fold rise in titer between acute and convalescent specimens in a consistent clinical setting is defined as a confirmed case. The presence of IgM antibody to *C. psittaci* in either specimen is also considered to be a confirmed case.¹⁷

PREINCIDENT ACTIONS

A biologic attack with psittacosis does not necessarily call for unique preparations. As with any potential incident, the emergency department, hospital, and local emergency services should have an integrated disaster response plan. This plan should provide for security and isolation of the treating facility; the triage of potential patients; a mechanism for liberating hospital beds and other treatment space; and the rapid recruitment of local police, fire, and healthcare personnel. Above all, the plan should provide for redundancy in communication methods—the element most commonly deficient in disaster scenarios. This plan should be reviewed and practiced annually.

Person-to-person transmission of psittacosis has been documented, but no specific isolation beyond universal precautions is indicated. The treating hospital should have a sufficient supply of antibiotics (tetracycline or doxycycline [see Medical Treatment of Casualties]) available to initiate therapy in suspected cases. The disaster plan should then include a mechanism for recruiting more doses from local and state suppliers within 1 day. After 48 to 72 hours, the federal stockpiles should be mobilized to the affected area.

The most significant challenge in addressing a *C. psittaci* attack is recognizing the event at all. A large

number of patients presenting with a nonspecific, febrile, respiratory illness would present over 1 to 2 weeks. Such a scenario would probably be interpreted as an influenza outbreak. Establishing a local or statewide syndromic surveillance system might assist in identifying psittacosis and other subtle biologic attacks using nonspecific diseases. A syndromic surveillance system that depends on observed rates of certain symptoms, such as cough, fever, or shortness of breath, would more rapidly detect a psittacosis attack than the conventional public health reporting system. A surveillance system that monitors pharmaceutical sales (such as the National Retail Data Monitor) may also be helpful. It may detect a spike in sales of antipyretics/analgesics or antitussives.

The hospital laboratory should not be expected to culture *C. psittaci*. The CF or MIF test for *C. psittaci* should be readily available. If the local facility cannot provide these tests, it must provide for rapid referral of specimens to the next level in the Laboratory Response Network (LRN). The LRN laboratories are a defined hierarchy of increasingly specialized and sophisticated testing institutions available for the confirmation of suspicious agents.¹⁸ The earlier the outbreak is identified, the sooner specific treatment can be initiated. Early therapy of psittacosis is important to minimize mortality, prevent secondary and recurrent cases, and reduce the rates of systemic complications.

POSTINCIDENT ACTIONS

If a case of psittacosis has been confirmed, the appropriate local public health authority should be notified (psittacosis is considered a reportable disease). In the event that multiple cases from different households are diagnosed, the possibility of a biologic attack must be considered. Alerting the disaster chain of command up to the federal level would be indicated.

Isolation of patients is not necessary, but decontamination of the affected area may help prevent additional cases. Patients' clothing should be discarded in a safe manner. Any surface possibly contaminated by infectious particles should be disinfected with 70% isopropyl alcohol or a 1:100 dilution of household bleach. Note that *C. psittaci* is susceptible to heat and most detergents, but it is resistant to acid and alkali. Avoid using a vacuum cleaner because it can aerosolize particles; sweep or wet mop the floor after spraying it with a disinfectant. The use of a N95 respirator and disposable protective clothing (gown, gloves, and mask) is advisable for those cleaning infectious dust.

If the outbreak is associated with a known bird population, isolate or cull the birds. Infected avians can be successfully treated with medicated water or feed or can be administered antibiotics. Wash and disinfect all cages or other containment areas.

After the initial acute cases have presented, the affected population can expect sporadic complications of systemic *C. psittaci* infection. In addition to the expected respiratory illness, psittacosis has been known to cause pericarditis, myocarditis, and "culture-negative" endocarditis. Unless the diagnosis is specifically sought,

a patient with *C. psittaci* endocarditis might be subjected to repeatedly negative evaluations, delaying definitive therapy and risking valve destruction.

Psittacosis has also been associated with hepatitis and jaundice, glomerulonephritis, hemolytic anemia, pancytopenia, and disseminated intravascular coagulation. A reactive, polyarticular arthritis is seen 1 to 4 weeks after the initial illness. Neurologic complications are common and diverse. Cranial nerve palsies, cerebellar dysfunction, transverse myelitis, confusion, meningitis, encephalitis, and seizures have all been described. The lumbar puncture is usually normal, but the protein level may be greatly elevated.

MEDICAL TREATMENT OF CASUALTIES

Tetracyclines are the treatment of choice for psittacosis. Satisfactory response is seen with oral therapy and doxycycline 100 mg twice per day or tetracycline 500 mg four times per day. Intravenous treatment can be initiated in the severely ill with doxycycline 2.2 mg/kg (up to 100 mg) twice per day. Defervescence is expected after 24 to 48 hours of therapy. Treatment should continue for 10 to 14 days after the fever resolves. Relapses can occur, so adequate duration of therapy is essential. Although in vivo data are lacking, erythromycin is presumed to be the best alternative agent for patients with a contraindication to tetracyclines, such as children and pregnant women. Antibiotic prophylaxis is not specifically addressed by psittacosis infection control guidelines, but preventative therapy for exposed persons (doxycycline 100 mg by mouth once per day) was demonstrated to be effective in at least one outbreak.¹⁹ There is no vaccine for psittacosis in either humans or animals.

UNIQUE CONSIDERATIONS

Psittacosis is an unusual disease that is rarely seen. Every medical student recognizes it as the “pneumonia caused by living with a parrot.” But would this disease be considered in a large number of patients who lack a history of exposure to birds? Very little has been written about the use of *C. psittaci* as a biologic weapon, so most would probably consider other agents before testing for psittacosis. Clinical clues to the possibility of psittacosis include a respiratory illness with unusual systemic symptoms and signs. Severe headache, neurologic abnormalities or complications, splenomegaly, or elevated transaminases levels in a patient with x-ray findings consistent with atypical pneumonia should suggest psittacosis as a possible diagnosis.

PITFALLS

- Failure to identify that a biologic attack has occurred; dismissing a spike in respiratory illnesses as a routine influenza outbreak

- Failure to consider psittacosis as a possible diagnosis in a patient who does not have contact with birds
- Failure to directly test for *C. psittaci* by serology in a patient with a history of bird contact or in a group of patients with similar, unexplained cases of “atypical pneumonia”
- Failure to design, practice, and implement a disaster plan to cope with the increase in patient load seen during a biologic attack
- Failure to stock adequate supplies of antibiotics or to request early mobilization of state and federal stockpiles
- Failure to treat infected patients with a sufficient duration of therapy to prevent relapses

CASE PRESENTATION

“Another Z PAK (azithromycin)?” you think, as you write yet another prescription for yet another case of atypical pneumonia. That makes three today alone. Add that to the four from the previous shift and the 12 cases last week, and this is starting to be the worst winter flu season in years. The only problem is that the calendar still reads September. The latest case is a 24-year-old female student complaining of a severe headache, fever, dry cough, sweats, and nausea for 5 days. On physical examination, you find bilateral crackles, splenomegaly, and photophobia, but no meningismus. Her chest x-ray reveals the same bilateral interstitial infiltrates that were seen in the other patients, and her laboratory results include moderately elevated transaminases levels. This prompts you to ask for further history; she denies smoking and alcohol or drug use. She also denies any recent travel, except to the state capital last week for a rock concert. By a strange coincidence, the last patient with pneumonia you treated also mentioned he had been at that particular concert.

Escherichia coli O157:H7 (Hemorrhagic *E. Coli*) Attack

Roy Karl Werner

DESCRIPTION OF EVENT

Escherichia coli is a ubiquitous, gram-negative, rod-shaped bacterium that can be located throughout the environment, including water and soil. It is most commonly found as normal flora of the intestinal tract of most mammals, including humans, where it lives to suppress growth of more harmful bacteria. In addition to the enterohemorrhagic *E. coli*, which is of concern as potential biologic weapons, there are four other types of *E. coli* that cause gastrointestinal disease.¹ A detailed discussion of these is beyond the scope of this chapter. However, their characteristics are summarized in Table 117-1.

E. coli O157:H7, an enterohemorrhagic strain, is considered a category B threat by the Centers for Disease Control and Prevention (CDC)² since it is easily spread via the fecal-oral route³ and has moderate morbidity but low mortality. The O157:H7 serotype produces a Shiga-like toxin that can cause a significant inflammatory response within the intestines without direct invasion of cells. The toxin is encoded on a plasmid and can be readily passed from one bacterium to another.¹ This bacterium is quite facile in its ability to obtain new genetic information and incorporate it into its arsenal for defense and infectivity in its hosts. *E. coli* O157:H7 can persist for significant lengths of time in hostile environments and may even require a slightly acidic environment to grow.⁴⁻⁶ Most *E. coli* O157:H7 outbreaks are linked to fecal-oral transmission due to poor handwashing techniques and unhygienic food handling. Sources of human infection have included, among others, poorly cooked meat (especially hamburger), apple juice, water (including water parks), vegetables and fruit from salad bars, and milk products such as yogurt and unpasteurized milk.⁷⁻¹¹ There are reported cases of aerosolized spread of *E. coli*, usually in sewage, but only under very specific circumstances and conditions.

E. coli O157:H7 can infect anyone, but more severe symptoms are found among patients at the extremes of age or in immunocompromised individuals.¹² The endotheliocidal properties of *E. coli* O157:H7 affect the intestinal endothelium as well as the renal and vascular endothelium, leading to the development of hemolytic uremic syndrome (HUS)

and thrombotic thrombocytopenic purpura (TTP).^{1,2,7,12-14} *It is noteworthy that other enterohemorrhagic E. coli exist with different serotypes. Thus, a bioterrorism attack need not be of the O157:H7 serotype.* For purposes of this chapter, the term *E. coli* O157:H7 will be used since it is the most common serotype, but the reader should understand that the clinical syndrome could be caused by other enterohemorrhagic serotypes as well.

Symptomatic *E. coli* O157:H7 infection affects approximately 75,000 individuals in the United States yearly and was first identified as a human pathogen in 1982 when it was isolated in the stool of individuals who had eaten raw or undercooked meat. In 1993 there was an outbreak from hamburgers served at a regional fast food chain, causing HUS and several deaths.^{8,15,16}

The incubation period of *E. coli* O157:H7 is between 3 and 9 days.^{6,14} Patients initially complain of symptoms similar to viral gastroenteritis: abdominal cramping with significant abdominal pain and tenderness; flatulence; elevated temperatures; and voluminous, watery diarrhea. The diarrhea eventually becomes bloody; 91% of patients report bloody stools at some time during the course of the disease. This likely overestimates the prevalence of bloody diarrhea since patients with less severe disease likely don't present to physicians. Approximately 30% of symptomatic patients require hospitalization, and the mortality rate is approximately 1%. *Shigella*, *Vibrio parahaemolyticus*, *Campylobacter*, and *Salmonella* species; cancerous lesions; ulcerative colitis; incomplete obstruction; gastrointestinal bleeding; and recent antibiotic usage (e.g., for *Clostridium difficile*)¹³ should all be included in the differential diagnosis of hemorrhagic diarrhea.

Treatment for *E. coli* O157:H7 infection is limited to supportive measures to prevent dehydration and other complications. The use of antibiotics is contraindicated and has been associated with increased incidence of hemolytic complications.^{2,7,13,14,17,18} Antimotility medications are appropriate in afebrile patients *without* bloody diarrhea. Early re-feeding of patients with a lactose-free diet can reduce the duration of diarrhea. The disease is generally self-limited and resolves approximately 1 week after the onset of symptoms.

TABLE 117-1 *E. COLI* CAUSING GASTROINTESTINAL SYMPTOMS

TYPE OF GI DISORDER	SOURCE / GEOGRAPHY	TOXIN	INVASIVENESS	CLINICAL	DIARRHEA
Enterotoxigenic					
Traveler's diarrhea (children and travelers)	Water sources	Cytotoxic heat stabile and/or heat labile	None; no cellular changes or bacteremia	No fever, mild dehydration, self-limited illness	Watery, voluminous; originates in proximal small bowel
Enteroinvasive					
Dysentery syndrome (children and adults)	Asia	Shigella-like	Epithelial cells of intestine	Fever, tenesmus, dehydration, abdominal cramps	Blood-tinged with many polymorpho-nuclear lymphocytes
Enteroggregative					
Children	Less developed countries	Some have a heat stabile	Aggregative adherence	No fever, mild dehydration, self-limited illness	Watery, nonbloody, and persistent
Enteropathogenic					
Children and newborns	Nurseries	None	Adherence, causing effacement	No fever, acute-onset diarrhea in neonates, dehydration	Nonbloody
Enterohemorrhagic					
Children and adults	Foods, raw beef	Shiga-like	Effacement of intestinal mucosa	Vomiting, no fever, nausea, chills, HUS, TTP	First nonbloody, then grossly bloody

HUS, Hemolytic uremic syndrome; TTP, thrombotic thrombocytopenic purpura

The most feared sequela of enterohemorrhagic *E. coli* is HUS, a triad of acute renal failure, thrombocytopenia, and microangiopathic hemolytic anemia. This is especially common in infants and children. Patients with the additional findings of fluctuating neurologic symptoms and fever are classified as having TTP. This may be more common in geriatric or infirm populations.¹⁹ Blood urea nitrogen (BUN) should be monitored because an increase may signal extraintestinal endothelial involvement and potential progression to TTP or HUS. Urine should also be monitored for hematuria and/or proteinuria, again suggesting progression to TTP or HUS. Discussion of the treatment of TTP and HUS is beyond the scope of this chapter.

All *E. coli* is easily cultured on sorbitol-MacConkey agar. Laboratory analysis will seldom identify the causative organism unless *E. coli* O157:H7 is specifically sought. However, the CDC recommends that all stools from patients with bloody diarrhea be screened for the O157:H7 serotype. Antisera to the O157:H7 antigen can be used to screen isolates. Any isolates that screen positive should be sent to a reference laboratory for further characterization. Isolation of the bacteria is most likely during the first 6 days of diarrhea. Many times the O157:H7 serotype cannot be isolated from even bloody diarrheal stools that commonly have high concentrations of this pathogen.^{20,21} Obtaining stool samples from multiple patients will increase isolation yield and assist with characterization of *E. coli* O157:H7 when present. Stool studies should include a search for other etiologic factors of the diarrheal disease, including those previously noted. Multiplex PCR (polymerase chain reaction using multiple primers) studies, fingerprinting, and rapid identification^{22,23} studies should be used to assist in determining the specific cause. If *E. coli* O157:H7 is identified, it is

mandatory that it be reported to the CDC; this allows centralized monitoring of outbreaks.

PREINCIDENT ACTIONS

The greatest potential for limiting the impact of a terrorist attack involving the dissemination of *E. coli* O157:H7 is the readiness of the “front-line fighters” of the health-care system—emergency medical personnel, outpatient clinics, and emergency departments. The presentation of an escalating number of patients with severe diarrheal disease along with similarities in medical, travel, or exposure history should alert medical and public health personnel to the possibility of a nonaccidental exposure.²⁴

Continuous water and food production monitoring by the appropriate local, state, and federal agencies as well as routine testing and retesting of in-place barriers to terrorism by Homeland Security task forces^{25,26} will also contribute to the safety of citizens.

Computer-aided programs, passive surveillance of foodstuffs, random testing of food processing areas, irradiation and filtration of airborne particles, and tighter control of treatment areas for national food and water supplies are all methods currently in place to decrease the impact of bioterrorism.^{24,26} Handwashing and glove use at patient points of contact or before handling foodstuffs are ways spread can be minimized.

POSTINCIDENT ACTIONS

When an outbreak of *E. coli* O157:H7 infection is suspected, hospital laboratories should be alerted, and

agent-specific cultures of stool samples should be obtained. Stool samples can also be tested for fecal leukocytes,^{13,28} although results are not particularly sensitive or specific. Fecal lactoferrin assays have the potential to be beneficial but their utility is also debated; fecal lactoferrin is considered more specific for bacterial causes of diarrhea²⁹ but cannot help with determining the specific etiologic factor. If the source of the outbreak can be readily identified, it should be contained and eliminated immediately. Foodstuffs in the area should be incinerated to decrease perpetuation of the infection.^{30,31} Surface areas can be decontaminated with a 5% to 10% bleach solution.

MEDICAL TREATMENT OF CASUALTIES

Oral rehydration solutions are helpful in patients with *E. coli* O157:H7 infection since most patients have minimal vomiting. The World Health Organization recommends solutions containing: 2.6 g sodium chloride, 2.9 g trisodium citrate dihydrate, 1.5 g potassium chloride, and 13.5 g anhydrous glucose, all dissolved in 1 L of clean water for a total osmolarity of 245 mOsm/L solution.^{13,28,32-34} Appropriate infection control practices should be instituted for *E. coli* and include body substance isolation and handwashing. Masks are optional for *E. coli* because airborne spread is inconsequential (unless contaminated feces are aerosolized). Rehydration should include intravenous solutions if oral intake is poorly tolerated or if the patient fails to improve.

UNIQUE CONSIDERATIONS

The relatively benign symptoms of fevers, abdominal cramping, and diarrhea are commonly minimized; therefore, *E. coli* O157:H7 infection is not suspected and thus fecal-oral spread continues before hemorrhagic diarrhea commences or *E. coli* O157:H7 infection is considered. Identification of *E. coli* O157:H7 requires specialized testing that may not be readily available at the local laboratory. Harbingers of a possible bioterrorism event with *E. coli* O157:H7 include a clustering of infectious diarrhea in a previously healthy population, all of whom have similar exposures (e.g., water, food). Travel to an area with a known outbreak of disease should also raise the clinician's level of suspicion.^{24,35}

CASE PRESENTATION

A carnival is in town for a July 4th celebration being held at an old farm that was recently converted into a recreational area. There are rides for all ages, games of skill, a large variety foods and fresh vegetables, and tents containing many attractions. Many of the town's people attend the festivities, including significant numbers of the hospital staff. The carnival ends without incident. One week later a number of children seek care at their doctors' offices with complaints of diarrhea and abdominal cramping. Most are sent home with antimotility drugs and prescribed a "BRAT" (bananas, rice, applesauce, toast) diet, and some are given oral antibiotics. There is also an increase in the number of geriatric visits for similar complaints. Three days later, these same people begin presenting to the emergency department due to bloody diarrhea and lethargy. Laboratory analysis is unremarkable, other than for mild leukocytosis and borderline electrolyte abnormalities. Some patients have elevated levels of protein and casts present on urinalysis. Many patients presenting to the emergency department with children or elderly family members are complaining of similar symptoms and easy bruisability. Laboratory studies on these otherwise healthy young adults show renal insufficiency and mild hemolytic anemia. Patients presenting with confusion or weakness are sent for computed tomography of the brain. An emergency medical technician in a town the carnival visited died approximately 2 weeks after the carnival left. She died from complications from treatment of severe dehydration and cerebral vascular accident. A husband and wife, both emergency medical technicians, who worked at a previous site the carnival visited also died after an infant son of theirs died. They all had a similar disease course as described above and had no predisposing factors.

Individuals of a terrorist group obtained part-time employment with the carnival company cleaning animals or common areas. These areas all contained a pressurized watering system used to clean these sections. These areas were theorized to have enormous concentrations of the aerosolized (36) *Escherichia coli* O157:H7 for periods of time throughout the day, usually at times of patron egress through causeways of the carnival. Small Petri dishes were found at the encampment containing genetically identical *E. coli* O157:H7 by multiplex PCR evaluation. After a thorough investigation, the CDC strongly suspects that the carnival was the site of a bioterrorism attack where the perpetrators disseminated *E. coli* O157:H7 via food and water contamination.

Viral Encephalitides (Alphaviruses) Attack

Matthew Berkman and Kelly J. Corrigan

DESCRIPTION OF EVENT

The Alphaviruses are one of the three families of the arthropod-borne viruses (arboviruses) that can cause encephalitis. Three Alphaviruses currently cause human disease in the United States: the Eastern equine encephalitis (EEE), Western equine encephalitis (WEE), and Venezuelan equine encephalitis (VEE) viruses. All three are transmitted through mosquitoes and can initially present as a flulike illness. The EEE virus is maintained through a bird-mosquito-bird lifecycle. The most important vector is the mosquito *Culiseta melanura*.¹ These mosquitoes are often found in coastal areas and near freshwater swamps. Hence, most U.S. cases have been reported in Florida, Georgia, Massachusetts, and New Jersey. EEE has a high case fatality rate—35% reported by the Centers for Disease Control and Prevention (CDC). Of those who survive, an estimated 35% will have permanent mild to severe neurologic deficits. There have been approximately 200 human cases in the United States since 1964, with two fatalities in August 2004 in Massachusetts.²

The closely related WEE has a reported 10% case fatality rate. Like EEE, it is a summertime disease but is found in states west of the Mississippi River and in some western Canadian provinces. It is also maintained by a bird-mosquito-bird lifecycle, with its primary vector the mosquito *Culex tarsalis*. The worst outbreak recorded was 3336 human cases in 1941. Since 1955, a varied range of 0 to 200 cases per year have been reported, with no human cases reported since 1994.^{1,2}

VEE is found in South and Central America. It is maintained by a rodent-mosquito lifecycle and claims at least 10 mosquito species as its vector. The fatality rates have been approximately 0.6% in reported outbreaks. Past epidemics include 32,000 human cases in Venezuela from 1962-64, and in 1971, more than 10,000 horses died from a VEE epidemic. Human cases have been sporadic since then.^{1,2}

All three of these Alphaviruses can present clinically with nonspecific flulike symptoms, but many may include high fever, headache, photophobia, stiff neck, nausea, and vomiting. In cases of encephalitic invasion, symptoms can progress to confusion, obtundation, seizures, and focal neurologic deficits.

PREINCIDENT ACTIONS

Humans who live in high-risk areas or work or play outside frequently in these areas should be sure to wear mosquito repellent that contains DEET and wear long-sleeved shirts and pants. During outbreaks, outdoor activity should be limited. Widely available vaccines are being developed and are undergoing validity testing.

In preparation for potential biologic terrorist attacks, the Institute of Medicine Committee on Research and Development to Improve Civilian Medical Response recommends that major hospitals conduct mass casualty planning and training and that they have isolation rooms available for infectious diseases; have decontamination capacity; and be fully supplied with drugs, ventilators, and personal protective equipment. The committee also encourages the CDC to keep medical care providers up-to-date on current dangerous biologic materials.³

POSTINCIDENT ACTIONS

All cases are to be reported to the CDC. Public health warnings are then issued, and prevention measures are initiated. Eradicating potential arthropod vectors and vaccinating equine reservoirs may help to prevent the spread of encephalitis in the event of a biologic attack.⁴

Since no person-to-person spread is known to be possible, only universal precautions must be maintained in patients infected with one of the arboviruses.^{4,5}

MEDICAL TREATMENT OF CASUALTIES

As in the case of most viral illnesses, treatment of the Alphavirus encephalitides consists primarily of supportive care.^{2,6-9} Patients suspected of having viral encephalitis should undergo a workup for concomitant meningitis with computed tomography of the head and lumbar puncture and be admitted to the hospital for further serologic testing. The airway should be protected; nutrition, fluids, and electrolytes should be optimized; pyrexia should be aggressively treated; and vigilance in preventing secondary infections should be maintained.^{7,9} In the

setting of increased intracranial pressure, patients should be managed in the intensive care setting with hyperventilation, head elevation, diuresis, and possibly steroids or intravenous immunoglobulin.⁹ Prevention of seizures is important, and consideration for administering temporary anticonvulsant therapy should be given.²

Consultation with a neurologist and infectious disease specialist is recommended. Neurosurgical consultation may be necessary if a brain biopsy is considered.⁸ Although there is no specific medical treatment available for the arboviruses, the use of ribavirin and recombinant interferon alpha is being assessed.^{2,8}

Prognosis depends not only on the particular type of arbovirus responsible for the encephalitis, but also on the age and prior health of the individual infected. Children 1 year old or younger and adults 55 years old or older are at increased risk of life-threatening complications.

UNIQUE CONSIDERATIONS

Although the effects of Alphavirus encephalitis can be devastating with persistent neurologic sequela or death, the vast majority of patients exposed to these viruses will be asymptomatic or present with nonspecific flulike symptoms.⁴ An early Alphaviral attack will be difficult to identify and distinguish from routine “viral syndrome” due to the similarity of illness presentation and lack of routine laboratory testing for the viruses.

The viral encephalitides are CDC category B biologic agents, which are moderately easy to disseminate and have low mortality rates. In their natural state, these viruses require arthropod vectors for transmission and have a variable seasonality dependent on the geography, local climate, and virus-specific lifecycle. These qualities make the use of the Alphaviruses as a terrorist agent more difficult to control and disseminate to the general public. That being said, aerosol transmission of a weaponized (manufactured) form of the virus has been demonstrated and would represent the most likely route of mass infection if terrorists were able to produce large amounts of aerosolized virus.^{4,9} Other characteristics of the Alphaviruses that lend themselves to weaponization include the ability to inexpensively produce large amounts of stable virus and the potential for genetic manipulation of native viruses.⁷

One possible clue to an Alphavirus attack is a large number of sick or dying equine animals in the vicinity,⁹ thus arthropod vector control and vaccinating equine reservoirs may help to prevent the spread of encephalitis during an outbreak.⁴

PITFALLS

- Failure to notify appropriate public health officials of a diagnosis of viral encephalitis
- Failure to prepare local emergency departments and clinics to respond appropriately in case of an outbreak

- Failure to disseminate medical instructions and training for local communities, as appropriate
- Failure to recognize that reports of sick or dying equine animals in the area may be related to a vector-borne disease

CASE PRESENTATION

The last few weeks have been hot and rainy, and there has been a moderate increase in the number of otherwise healthy individuals presenting to emergency departments with vague “viral syndrome” complaints. There are also news reports of a large number of equine illnesses in nearby communities. Many patients who were originally sent home with supportive care have returned with worsening mental status, lethargy, and seizures. An elderly patient, who has had a seizure, presents to the emergency department. He was reportedly seen at another hospital 3 days ago for nausea, vomiting, fatigue, low-grade fever, confusion, and headache. Since then his symptoms have become worse, with an inability to tolerate fluids by mouth and increasing agitation and confusion. He has a fever of 101° F, with mild tachycardia and a stable blood pressure.

Tick-Borne Encephalitis Virus Attack

Vittorio J. Raho

DESCRIPTION OF EVENT

Tick-borne encephalitis (TBE) is classically caused by infection with one of two flaviviruses: Russian spring-summer encephalitis virus (RSSEV) or Central European encephalitis virus (CEEV).¹ However, the TBE virus-complex is sometimes extended to include other entities such as Omsk hemorrhagic fever and Kyasanur Forest disease, which are closely related viruses with associated tick vectors.² The geographic distribution of TBE includes the former Soviet Union, Central and Eastern Europe, and Asia. TBE viruses are associated with hard-bodied Ixodid ticks, such as *Ixodes persulcatus*, which act as reservoirs for the virus as well as vectors when they infect their hosts, usually small woodland mammals. Humans are accidental hosts and do not participate in the virus's normal reproductive cycle.

In Russia, 5000 to 10,000 cases of TBE are reported annually, with fatalities in the low hundreds.³ When comparing the two closest subtypes of TBE viruses, RSSEV has a much more virulent clinical course, with reported mortality rates between 20% to 30%.^{4,5} RSSEV is sometimes referred to as Far Eastern encephalitis. A recent report of a severe hemorrhagic syndrome not previously described has now been associated with TBE infections in Russia, suggesting that more virulent strains may yet be discovered.⁵ Natural outbreaks of TBE coincide with the well-defined periods of tick activity, usually from April to October. Cases have also been documented from human ingestion of raw milk from infected goats.^{2,5}

TBE infection manifests clinically across a spectrum of severity, from mild aseptic meningitis to florid meningoencephalitis. After a 1- to 2-week incubation period, patients may experience a biphasic illness with initial symptoms of fever, malaise, myalgia, headaches, nausea, and vomiting that last around 2 to 4 days. After a brief remission of symptoms, between one fourth and one third of patients will develop the manifestations of severe meningoencephalitis, with symptoms of central nervous system dysfunction, including severe headache and meningismus, confusion, lethargy, delirium, convulsions, paralysis, coma, and death.⁶ Survivors have a significant rate of neurologic sequelae, including limb paralysis and cognitive deficits.⁷ A more rapid and severe course of illness is associated with RSSEV.

Nonspecific laboratory data include leukopenia, thrombocytopenia, and elevated liver function tests and sedimentation rate. During the meningoencephalitis phase, cerebrospinal fluid studies will show lymphocytosis and an elevated protein level.⁸ Magnetic resonance imaging has been shown to be superior to computed tomography in identifying tissue inflammation in other forms of viral encephalitis.⁹

PREINCIDENT ACTIONS

Surveillance systems, which acquire data from government sources, hospital emergency room discharge summaries, and state public health networks, can effectively identify unusual clusters of viral syndromes in certain geographic distributions. Epidemiologic analysis may be the only way to detect such an attack, especially since symptoms are so nonspecific and may resemble a myriad of other domestic illnesses.

POSTINCIDENT ACTIONS

Laboratory diagnosis of TBE is usually made using serologic testing, such as IgM enzyme-linked immunosorbent assay or reverse transcriptase PCR (polymerase chain reaction), for detection of viral ribonucleic acid. Laboratory workers should take biosafety precautions to prevent exposure to infectious aerosols.¹⁰ Fortunately, no person-to-person transmission of TBE has been reported. If the attack is via the natural tick-borne route, vector control using repellents such as permethrin may be the most efficient way to thwart an attack once it has been identified. Reports indicate that the TBE virus is neutralized by common disinfectants such as 1% sodium hypochlorite and formaldehyde.⁷

MEDICAL TREATMENT OF CASUALTIES

No specific medical treatment is available for any of these viruses. The management of such patients is dictated by their neurologic and cardiovascular sequelae

and may include respiratory support including mechanical ventilation, hemodynamic monitoring, treatment of secondary bacterial infections such as pneumonia, or possible steroid administration to suppress cerebral or spinal edema.

A formalin-inactivated vaccine was introduced in Austria in the late 1970s that confers some degree of immunity to TBE viruses, although it is not currently licensed in the United States.¹¹ However, researchers have shown promise with naked-DNA (deoxyribonucleic acid) vaccine trials in mice that confer immunity to both the CEEV and RSSEV strains.¹² Postexposure prophylaxis should be considered in high-risk groups.

UNIQUE CONSIDERATIONS

Flaviviruses are a large group of heterogeneous viruses known for their ability to infect humans through various arthropod vectors. Yellow fever, Japanese encephalitis, and dengue hemorrhagic fever, among others, are well known to the international medical community. TBE has become a significant public health problem in many parts of Europe, as civilization encroaches on wilderness and people engage in more recreational activity in rural areas. TBE may not be as internationally recognized as other flaviviruses and therefore not screened for as often, making it more desirable as a bioweapon. The ability of TBE to infect humans through ingestion is also of concern.

PITFALLS

- Failure to consider viral encephalitis as a potential cause of acute, febrile illness during such an outbreak
- Failure to properly isolate and inspect patients who may have infected ticks on their body
- Failure to collect blood, cerebrospinal fluid, or tick specimens and send appropriate samples to state public health laboratories
- Failure to take proper respiratory precautions when handling body fluid samples from suspected cases
- Failure to report suspected cases to the state department of public health or affiliated authority for appropriate Centers for Disease Control and Prevention notification and proper serologic testing
- Failure to alert local and state agencies to a suspected biologic attack when presented with a cluster of unusual and uncommon illnesses

CASE PRESENTATION

A 46-year-old man with no significant past medical history and up-to-date vaccinations presents to the emergency department with fevers, chills, myalgia, nausea, and vomiting of 3 days duration. He has had no recent exposures to sick persons, no insect bites, no recent travel, and owns no pets. Other than a fever of 101 °F, his vital signs are within normal limits. His physical examination is unremarkable, including a supple neck, clear lungs, and a normal neurologic examination. He is treated with acetaminophen and ibuprofen, tolerates oral fluids, and is sent home with a presumptive viral syndrome. After remaining afebrile and feeling better for several days, his fever recurs to 104 °F, and he develops a severe headache, neck stiffness, confusion, and vertigo. He is brought back to the emergency department by ambulance and is noted to be severely lethargic and confused, and he experiences a generalized tonic-clonic seizure. He is given antibiotics for presumed meningitis, and cerebrospinal fluid studies show a lymphocytic pleocytosis and a negative Gram stain. Herpesvirus tests, meningococcus serologies, and blood smears for malaria are negative, and computed tomography of the brain shows no bleeding or abscess. The patient remains unresponsive and intubated in the intensive care unit several days later. Records indicate that in the last month, 142 cases of severe acute viral syndromes of unclear etiology have been reported, with an associated mortality approaching 10%.

Viral Hemorrhagic Fever Virus Attack—Arenaviruses

Sandra S. Yoon

DESCRIPTION OF EVENT

The arenaviruses that cause viral hemorrhagic fevers (VHFs) include the Lassa, Junin, Machupo, Guanarito, and Sabia viruses. The latter four are also known as the New World arenaviruses. They are enveloped, single-stranded ribonucleic acid (RNA) viruses, whose natural host reservoir is the rodent. The rodent species has been identified for each virus except for the Sabia virus. Although its reservoir is unknown, it has caused several natural and laboratory infections. Because these viruses are highly species specific, they determine their endemic geographic distribution—West Africa, Argentina, Bolivia, Venezuela, and Brazil, respectively. Naturally occurring cases are transmitted by infected rodent blood, urine, or feces via aerosol, direct contact, or food contamination. Person-to-person transmission then may occur by direct contact with infected bodily fluids.

The arenaviruses have been classified as category A biologic agents by the Centers for Disease Control and Prevention (CDC).¹ A mortality rate as high as 30%, the relative ease of obtaining and propagating the viruses in cell culture, potential for transmission via the respiratory system, demonstrated person-to-person transmission, and the potential for inducing widespread panic in an affected population all contribute to this classification. Furthermore, these viruses have been produced in large quantities by other countries in the past. Even though person-to-person transmission via the aerosol route has not been proven, it has been suspected in several cases of nosocomial outbreaks involving the Lassa and Machupo viruses.²

After initial exposure, the incubation period is typically 3 to 19 days, but it may be as short as 2 to 6 days after parenteral exposure. There have not been any reports of disease transmission during the incubation period. The clinical syndrome of arenavirus hemorrhagic fevers may be difficult, if not impossible, to distinguish from other hemorrhagic fevers or even viral syndromes. The severity of the disease and prognosis are related to the degree of viremia. The virus, in addition to infecting endothelial cells, is thought to induce the release of inflammatory mediators from macrophages, contributing to capillary

leak, the hallmark of the disease. Typically, fever, headache, malaise, and myalgia are not sudden in onset as they are for other VHFs. Relative bradycardia and hyperesthesia of the skin may be clues to the diagnosis.

Lassa fever is characterized by the gradual onset of fever, nausea, abdominal pain, severe sore throat, cough, conjunctivitis, ulcerations of buccal mucosa, exudative pharyngitis, and cervical lymphadenopathy, followed by severe swelling of the head and neck, pleural and pericardial effusions, hypotension, and shock. Additional symptoms include retrosternal chest pain, back pain, vomiting, diarrhea, and proteinuria. Deafness may occur, usually in the second to third week of illness.²⁻⁴ The New World hemorrhagic fevers are characterized by gradual onset of fever, myalgia, nausea, abdominal pain, conjunctivitis, flushing of the face and trunk, generalized lymphadenopathy, hypotension, and shock. Epigastric pain, retro-orbital pain, dizziness, photophobia, constipation, and proteinuria may also be present. Hemorrhagic manifestations, such as petechiae, especially in the axilla, and mucous membrane hemorrhages, as well as central nervous system manifestations, such as dysarthria, hyporeflexia, tremors, myoclonic movements, and seizures, are more common than in Lassa fever.^{2,3,5,6} Severe manifestations of the disease usually occur during the second week of illness.

Routine laboratory analysis is typically unhelpful in making the diagnosis of VHFs. Laboratory studies may reveal leukopenia, thrombocytopenia, and hemoconcentration. Renal function is generally preserved until late in the course, although proteinuria is commonly present. Liver enzymes may be elevated, and in Lassa fever, aspartate transaminase levels greater than 150 IU/L are associated with higher mortality.³ Definitive diagnosis requires specialized laboratory studies available at the CDC or the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID) and include antigen detection by reverse transcriptase polymerase chain reaction (PCR) or enzyme-linked immunosorbent assays (ELISA), IgM and IgG antibody detection by ELISA, and viral isolation. Viral isolation requires a Biosafety Level 4 laboratory and may take several days.⁷ The presence of IgM antibody or a four-fold rise in IgG antibody titers is diagnostic;

however, antibodies may not be present until the second week of illness.

PREINCIDENT ACTIONS

Hospitals should have disaster plans in place and should exercise them frequently. The plans should include methods for coordinating with local, state, and federal authorities and emergency medical services and a method to protect the hospital environment from contamination. Given the constellation of vague symptoms and the challenge of making a diagnosis of VHF, health-care workers must maintain a high index of suspicion and consider this diagnosis in appropriate patients. Particular attention should be given to patients who have traveled to an endemic region, who have had direct contact with blood or other bodily fluids of a known infected person, or who work in a laboratory that handles the specific viruses.⁷ In the event of a bioterrorism attack, these risk factors would be absent. However, one would expect multiple victims with similar symptoms presenting within days of each other.

POSTINCIDENT ACTIONS

As with any suspected biologic attack, the appropriate local and state public health authorities should be notified.⁸ The state authorities are then required to notify the Federal Bureau of Investigation, local law enforcement authorities, and the CDC. Decontamination of patients may be necessary, although this is unlikely in the case of VHFs because symptom presentation lags days to weeks after exposure. Person-to-person transmission via infected bodily fluids is a common and known method of transmission; therefore, specific barrier precautions should be instituted immediately. These include hand-washing; double gloving; and the use of gowns, face shields, eye protection, and leg and shoe coverings. Although person-to-person airborne transmission is rare, given the difficulty of differentiating the VHFs, the high mortality, the unknown consequences of massive inoculation that may occur during a bioterrorism attack, and the potential for possible high viral loads, airborne precautions should be instituted as well.^{5,7} These include the use of negative air pressure rooms and either an N95 mask or a powered air-purifying respirator.

The hospital's clinical laboratory should be notified as a precaution before sending a potentially infectious specimen. These viruses must be handled in a Biosafety Level 3 laboratory with viral isolations attempts occurring only in Biosafety Level 4 laboratories.² Specimens should be hand delivered, not placed in pneumatic tubes. Surfaces or objects contaminated with blood or other bodily fluids, including laboratory equipment, should be disinfected with either 1:100 dilution of household bleach or a U.S. Environmental Protection Agency-registered hospital disinfectant. Bulk bodily fluids can also be treated with bleach before disposal; however, this may damage septic tanks, and the virus is unlikely to survive standard sewage treatment. Linens should be autoclaved, inciner-

ated, or may be washed in hot water with bleach. Laboratory samples of patients with known VHF virus should be pretreated with polyethylene glycol p-tert-octylphenyl ether (Triton X-100) for 5 minutes to reduce the titers of hemorrhagic fever viruses in serum.⁶

MEDICAL TREATMENT OF CASUALTIES

Medical management of VHF patients consists primarily of supportive care. The antiviral drug ribavirin and, in some cases, convalescent plasma, may be available as a treatment option via an investigational new drug (IND) protocol. Patients should have their fluid balance and electrolytes monitored and corrected, receive adequate analgesia, and have secondary infections aggressively treated. Indwelling lines should be kept to a minimum to prevent damage to already fragile vessels. Aspirin, nonsteroidal antiinflammatory, and other anticoagulant medications, as well as intramuscular injections, should be avoided.

If a VHF is suspected, ribavirin should be given while waiting for diagnostic tests. The dose is 30 mg/kg intravenously once (maximum of 2 g) followed by 16 mg/kg intravenously (maximum 1 g per dose) every 6 hours for 4 days, then 8 mg/kg intravenously (maximum 500 mg per dose) every 8 hours for 6 days. In the event of mass casualties, oral ribavirin may be given at the dose of 2000 mg loading; this is followed for the next 10 days by 600 mg twice a day if the patient weighs more than 75 kg, or 400 mg in the morning and 600 mg in the evening if the patient weighs less than 75 kg. Follow the same dosing guidelines for children, with the exception that for mass casualty settings, oral ribavirin is given at 30 mg/kg loading, followed by 15mg/kg/day divided into twice-daily dosing for 10 days.² Ribavirin may be effective in the treatment of Lassa, Junin, and Machupo infections, especially if given within 7 days of disease onset, and it has been suggested for Guanarito and Sabia viruses. The main toxicity of ribavirin therapy is dose-related anemia.⁹ Passive immunity using convalescent plasma has been used in the treatment of Junin and Machupo infections, and is suggested in Guanarito infection; however, there have been mixed clinical results.⁶

An effective live attenuated vaccine exists for the Junin virus and has been used in endemic regions of Argentina. Laboratory data suggest that this vaccine may also be effective for the Machupo virus.³ Postexposure prophylaxis with ribavirin has not been studied in humans. The current recommendations consist of medical surveillance, twice-daily temperature monitoring, and reporting of temperatures greater than 101° F or any symptoms. This should continue for 21 days past the potential exposure.²

UNIQUE CONSIDERATIONS

The arenavirus hemorrhagic fevers are difficult to diagnose. The diagnosis should be considered in patients with temperatures greater than 101° F for less than 3 weeks, who present with severe illness, and who have

experienced at least two hemorrhagic manifestations without a known predisposition. If there is any suspicion, ribavirin therapy should be considered and the CDC should be consulted for IND protocol approval. The effect of massive exposure to aerosolized virus has not been studied. In the event of a mass casualty incident, airborne and universal precautions should be followed. Higher levels of viremia are likely to result in greater person-to-person transmission rates. Multiple patients presenting with possible VHF should be clustered in the same part of the hospital.

PITFALLS

- Failure to have appropriate disaster plans in place
- Failure to consider VHF in the differential of an acutely ill patient with vague complaints

CASE PRESENTATION

A previously healthy 30-year-old man presents to an emergency department with a 6-day history of fever, headache, myalgia, epistaxis, and diarrhea. His examination is significant for a temperature of 102° F, heart rate of 70, blood pressure of 110/80 mm Hg, dehydration, hyperemic conjunctivae, and an exudative pharyngitis. Laboratory results are significant only for leukopenia (white blood cell count of 4.0), thrombocytopenia (platelet count of 74), and 2+ proteinuria. On further questioning, the patient stated that he recently returned from Venezuela, where he remembered hearing that there was a problem with the growing rodent population.

- Failure to consider ribavirin therapy in a timely manner
- Failure to notify the appropriate authorities and the laboratory
- Failure to practice strict barrier and airborne precautions

Viral Hemorrhagic Fever Attack—Bunya Virus

Sean Michael Siler

DESCRIPTION OF EVENT

In general, the hemorrhagic fever viruses, which consist of four families—Filoviridae, Arenaviridae, Bunyaviridae, and Flaviviridae—are seen as emerging pathogens because of the continued intrusion of man into areas where these viruses have developed an ecologic niche. With the increase in international travel, outbreaks caused by these viruses are more widely spread, and it would not be unexpected to see infections in cities with international travelers.

Only the Arenaviridae, which include the etiologic agents of the Argentine, Bolivian, and Venezuelan hemorrhagic fevers and Lassa fever, and the Filoviridae, which consist of the Ebola and Marburg viruses, are classified as Centers for Disease Control and Prevention (CDC) category A biologic agents.¹ Crimean-Congo hemorrhagic fever (CCHF) and Rift Valley fever (RVF) are a subset of the Bunyaviridae viruses that cause hemorrhagic fevers, and although not technically classified as category A agents, they do have the potential to be weaponized and delivered as fine-particle biologic aerosols. Both are a single-stranded ribonucleic acid (RNA) virus, spherical in shape, range from 70 to 120 nm in diameter, and possess a lipid envelope. Bunyaviridae are distributed endemically throughout the world, including Crimea, much of Africa, Iraq, Pakistan, Egypt, Korea, Eastern Europe, Russia, and Scandinavia.² CCHF virus is spread by the species of Ixodid ticks, primarily the tick *Hyalomma marginatum*, and occurs widely across Africa, south-eastern Europe, the Middle East, and Asia. CCHF also represents a growing threat as bioterrorists seek to weaponize natural pathogens for delivery in populated areas outside the pathogens' endemic regions. The CCHF virus possesses some characteristics that a bioterrorist might find desirable, including the potential for aerosolization and human-to-human transmission; however, it has proven difficult to weaponize.² In aerosol form, CCHF is highly contagious, and as technology improves, this agent may become a greater threat. Mortality for Korean and Seoul subspecies is around 15%, and mortality from the Crimean-Congo subspecies ranges from 13% to 50%. Both the young and the old are

at increased risk, as are those who have increased opportunity for exposure in the workplace, such as workers in healthcare and agriculture.^{2,3}

RVF virus is mosquito-borne illness that causes an acute-onset illness in livestock and wild animals as well as in humans, with an incubation period of 2 to 6 days.³ Despite high levels of viremia, there have been no reported person-to-person transmissions of RVF. Humans are infected by the bite of an infected mosquito or by direct specimen exposure. Livestock are readily infected and produce high viral titers, which provides a reservoir for mosquitoes to infect humans.³ RVF has the potential to be used as a bioweapon; it was studied by the U.S. Army in the 1960s but was never weaponized.³ Mortality is 1%, and there is no sex predilection. High-risk patients include the young and old, farm workers, travelers to endemic areas, and exposure to sick animals or people in the last 21 days. Healthcare workers who treat infected patients are at risk from bodily fluid exposure. Infections from percutaneous exposures have the shortest incubation times and the greatest mortality.³

In general, Bunya viruses damage the vascular beds throughout the body, causing increased permeability. CCHF is an influenza-like virus that has a 2- to 12-day incubation period. Initial symptoms include an abrupt onset of fever and chills, headache, myalgia, abdominal pain, nausea, and vomiting. Facial flushing and conjunctival injection are also prominent. A petechial rash starting on the back may extend over the trunk and then to the rest of the body. A hemorrhagic exanthem may begin on the soft palate and uvula. As many as 75% of patients will have hemorrhagic symptoms that begin between days 3 and 7 and include ecchymosis, bleeding from the gums, nose, mouth, uterus, gastrointestinal tract, pulmonary tract, and venipuncture sites. One-half of patients will have hepatomegaly and central nervous system involvement, such as agitation, depression, nuchal rigidity, or coma; central nervous system involvement is associated with a poor prognosis. Multiple organ system failure, severe hemorrhage, and shock can develop, and secondary infections often lead to concomitant sepsis. Death usually occurs between days 5 and 14.¹⁻⁶

RVF leads to the destruction of the infected cell, and patients will have varying degrees of vasculitis and hepatic necrosis. Reduced levels of anticoagulation factors are seen also secondary to disseminated intravascular coagulation (DIC) and hepatic dysfunction. Symptoms include fever, headache, jaundice, retro-orbital pain, and photophobia. RVF may cause retinitis in as many as 10% of individuals, with a rate of blindness of approximately 1%. Fewer than 1% of patients will develop hemorrhagic fever or encephalitis, but the mortality rate is as high as 50% in patients who do.^{3,7}

Patients will often have leukopenia and thrombocytopenia, which result in focal inflammatory reactions that produce thrombocytosis. Partial thromboplastin times may be prolonged, but prothrombin times are relatively unaffected. A common pathway for the systemic effects of CCHF is DIC.⁸ Transaminase levels are elevated, and hepatic damage is common. Aspartate aminotransferase (AST) is usually raised, and virtually all VHF distinguish themselves from viral hepatitis because the AST is disproportionately high compared with alanine aminotransferase (ALT). Ratios of AST to ALT may be as high as 11 to 1; the higher the ratio of AST/ALT, the poorer the prognosis. Patients are rarely jaundiced (except in yellow fever), and the bilirubin level is usually normal.⁵

An enzyme-linked immunosorbent assay is available to identify IgM, IgG, or viral antigens in the serum of acutely ill patients. Immunofluorescence assay, complement fixation, and neutralization assays may also be used. These tests are not widely available and often require sending samples to reference laboratory facilities. Isolation and identification often require 3 to 10 days. Electron microscopy of infected tissue also may be helpful in identification. Specimens should be transported only after consultation with the CDC or U.S. Army Medical Research Institute of Infectious Diseases and under very specific biosafety precautions.⁶

PREINCIDENT ACTIONS

Hospitals should have disaster plans in place and run routine drills. The plans should include coordination of local and state authorities and emergency medical services and a method to protect the hospital environment from contamination and exposure to others.

POSTINCIDENT ACTIONS

Report all suspected or confirmed cases to your hospital infection control personnel; laboratory personnel; your public health agency; and, if appropriate, law enforcement personnel. Patients may present as an isolated case or in clusters to one or more hospitals. The clinical situation will dictate when to initiate decontamination procedures. Persons with known or suspected exposures to CCHF or RVF should take a soap-and-water shower and irrigate any potentially exposed mucous membranes.

Extreme heat, detergents, chlorine, formalin, or ultraviolet radiation, including prolonged sunlight, can inactivate viruses. Equipment may be decontaminated with

an Environmental Protection Agency-registered hospital disinfectant, or a dilution of household bleach. Care should be taken to ensure solutions are freshly made and correctly applied to allow the disinfectant to completely sterilize the area.⁵ Potentially exposed persons should be instructed to check themselves for fever twice daily and to report any temperature of 101°F (38.3°C) or greater or any new symptoms to their physician or public health authority. Surveillance should continue for 21 days, and ribavirin therapy should be considered if either a fever of more than 101°F (38.3°C) or appropriate symptoms are noted. Consultation with the CDC is required since ribavirin would have to be administered under an investigational new drug (IND) protocol.

MEDICAL TREATMENT OF CASUALTIES

Treatment of most viral hemorrhagic fevers is supportive. Patients should be admitted or transferred to facilities capable of providing intensive care for patients in isolation. The early use of vasopressors is often necessary with the goal of minimizing end-organ dysfunction. The most commonly affected areas include the hematologic, pulmonary, and neurologic systems. Extreme care should be used when replacing fluids because the increased vascular permeability often leads to third spacing of fluids.³ Pulmonary edema is common after aggressive fluid replacement, and patients may require mechanical ventilation. Massive electrolyte shifts are common with aggressive fluid replacement and will need to be closely monitored. Blood component transfusions may be required. Pain and anxiety are also common and should be aggressively managed. Intramuscular injections, venipuncture, and central line placement should be minimized; they carry the same risks as when used with a massively anticoagulated patient. Secondary infections are common, and aggressive antibiotic therapy is often required. Antibiotic selection and dosing should be directed toward the source of the infection, with special consideration being given to any end-organ dysfunction.³

Ribavirin is an inhibitor of viral RNA and deoxyribonucleic acid synthesis, and it has been shown to benefit CCHF infections in vitro, in animal studies, and in human case reports.^{9,10} The Food and Drug Administration, however, has not officially approved the use of ribavirin for use in viral hemorrhagic fevers, and any use should be administered under an IND protocol. The CDC has recommended the use of ribavirin in suspected or confirmed cases of arenavirus or bunyavirus infection. The initial loading dose is 30 mg/kg (maximum 2 g) IV, followed by 16 mg/kg (maximum 1 g/dose) IV every 6 hours for 4 days, followed by 8 mg/kg intravenously (maximum 500 mg/dose) every 8 hours for 6 days. In a mass casualty setting the CDC recommends a loading dose of 2000 mg orally. This is followed by a 10-day treatment with 600 mg orally twice a day for patients with a body weight greater than 75 kg, or 400 mg every morning and 600 mg every evening for patients with a body weight less than 75 kg. Ribavirin is a category X

drug for pregnant women, but the treatment benefit for the mother may outweigh any risk to the fetus.³ Dosing in pregnancy is the same as for adults. For mass casualty settings, the pediatric dosing recommendations are a loading dose of 30 mg/kg orally, followed by 15 mg/kg per day in two divided doses for 10 days. A pediatric syrup is available for use under an IND application from the manufacturer, Schering-Plough Corp.³ Steroids have not been shown to improve outcomes.¹¹ Both live and attenuated vaccines for RVF are under investigation, but none has been approved.⁷

Interferon-alpha given before or just after exposure to RVF has been shown to protect monkeys from viremia and hepatocellular damage, but no human trials have been published to date.³ After aggressive and early supportive care, most patients will do well and recover, although convalescence may be prolonged.

UNIQUE CONSIDERATIONS

Diagnosis of RVF and CCHF may be quite challenging. The differential diagnosis is quite broad and may include malaria, typhoid fever, leptospirosis, rickettsial infections, relapsing fever, fulminant hepatitis, shigellosis, and meningococemia. Other noninfectious conditions include acute leukemia, lupus erythematosus, idiopathic or thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, and the multiple causes of DIC. Treatment of RVF and CCHF is largely supportive, but if either is strongly suspected, ribavirin therapy should be considered.

PITFALLS

- Failure to prevent nosocomial spread of infectious material due to a lack of adequate safety precautions or procedures
- Failure to recognize a patient with symptoms consistent with CCHF or RVF with known travel to an endemic area or exposure to persons who have recently traveled to such an area
- Failure to consider the use of a VHF agent in an attack when multiple patients present with symptoms of VHF
- Failure to aggressively treat hypotension with vasopressors
- Failure to use caution with fluid replacement, resulting in third spacing of fluids

- Failure to notify public health and law enforcement officials of suspected or confirmed cases of CCHF or VHF

CASE PRESENTATION

A 39-year-old man presents to an emergency department with 2 days of malaise, nausea, and vomiting and an abrupt onset of fever and chills the previous day. This morning he had two episodes of epistaxis that resolved with direct pressure. The patient also noticed a petechial rash that started this morning. He has a frontal headache and photophobia. He denies any recent illnesses or travel, but notes that several animals in the neighborhood have fallen ill over the past week. On admission and further evaluation, the patient is noted to be in massive hepatic failure. Meanwhile, local surveillance in the emergency department throughout the day notes an increased incidence of patients presenting with “viral syndrome,” with several others also commenting that pets and livestock were “not acting right.”

Viral Hemorrhagic Fever Attack—Filo Viruses

William Porcaro

DESCRIPTION OF EVENT

The Ebola and Marburg viruses are members of the Filoviridae family of viral hemorrhagic fevers, which have the ability to produce a high degree of morbidity and mortality, making them enticing candidates to be used as biologic weapons. The Centers for Disease Control and Prevention (CDC) has classified filoviruses as category A biologic agents because of their high degree of virulence, demonstrated aerosol infectivity, and ability to instill fear and anxiety in the population.¹ Concern exists about terrorist groups obtaining samples of filoviruses from existing laboratory stocks, rogue government agents, or from natural outbreaks. Some researchers have suggested that the Japanese cult group Aum Shinri Kyo, which was responsible for the Sarin subway attack in Tokyo in 1995, sent members to Zaire in the 1990s to obtain samples of the Ebola virus.² Viral hemorrhagic fevers are clinical syndromes characterized by acute onset of fevers and generalized symptoms such as malaise, headache, myalgia, and diarrhea. In the majority of victims the syndrome progresses to a bleeding diathesis, septic shock, and multiple organ failure. Russia and the former Soviet Union have produced and stockpiled large quantities of weaponized Marburg and possibly Ebola as recently as the 1990s.³

Marburg virus was first discovered in 1967 in Germany and Yugoslavia. African green monkeys, originating from Uganda, were determined to be the source animals that infected laboratory workers. Thirty-two cases were reported, with a 23% mortality rate. The Ebola virus, whose genome is remarkably homologous with the Marburg virus, was first identified in 1976 in Zaire and Sudan when simultaneous outbreaks occurred. In part, because of poor infection control practices, the human impact was devastating, with rapid spread to patients, family members, and healthcare workers. The Ebola-Zaire outbreak involved 318 patients with an 88% mortality rate, and the Ebola-Sudan outbreak affected 284 people with a 53% mortality rate.⁴ During the past quarter of a century, there have been numerous outbreaks of Ebola. Different strains of the virus have been identified, and several have been named according to the location of the outbreak.

The filoviruses are enveloped, negative-sense ribonucleic acid (RNA) viruses. They are generally grouped into “Marburg-like” or “Ebola-like” families. Several strains have been characterized in the Ebola family, including Ebola-Zaire, Ebola-Sudan, Ebola-Reston, and Ebola-Cote d’Ivoire. Microscopically, these viruses appear as thread-like filaments that have linear, circular, and U-shaped forms. Each of the viral genomes encodes nine protein products. Some demonstrate immunomodulatory properties, and others cause vascular cell toxicity.⁵ To date, the natural reservoirs for the filoviruses have not been discovered.

Both Ebola and Marburg viruses produce similar clinical syndromes. Current epidemiologic evidence suggests that these viruses are spread through direct contact with blood, secretions, or infected tissues. The viruses may also be transmitted via mucosal contact; thus, there is risk of human finger-to-mouth or conjunctiva spread. Although there is no conclusive documented evidence, several human and animal cases have raised some concern for airborne spread of the virus via droplet nuclei.^{3,6} Of note, Ebola and Marburg are relatively stable and may retain infectivity for some time at room temperature when exposed to the environment. Previous biologic weapons programs have also succeeded in aerosolizing these viruses and proving aerosol transmission in animal models.⁴ The incubation periods are 2 to 21 days for Ebola and 3 to 10 days for Marburg. Because of the possibly prolonged asymptomatic incubation period, the danger of delayed recognition and possible continued dissemination of disease exists. Initial clinical symptoms may include myalgia and arthralgia, fever, nausea and vomiting, abdominal pain, and a rash (petechiae, purpura, and ecchymosis) spreading from the trunk distally. As the hemorrhagic fever progresses, oliguria, hematemesis, melena, pericarditis, encephalitis, acute renal failure, and shock may occur. In severe cases the victim succumbs to disseminated intravascular coagulation.^{3,4,7} The classic dermatologic manifestations are quite common since patients generally exhibit a maculopapular rash within 5 days of illness. Although petechiae may be initially apparent, larger patchy lesions generally form and progress to confluent regions. Desquamation may occur

and may be the first skin lesion noted in non-Caucasian individuals. Victims may also complain of burning and paresthesias over areas of their skin. The other classic manifestation of viral hemorrhagic fever is bleeding. More than 70% of infected, symptomatic patients suffer from bleeding diatheses. Bleeding may be pronounced and present as melena, epistaxis, hematemesis, hemoptysis, bleeding gums, or puncture sites. The rate of bleeding complication does not appear to differ between survivors and nonsurvivors.⁴ Individuals who survive acute viral hemorrhagic fever may be left with long-term sequelae, including arthralgia, uveitis, orchitis, and hearing loss. The virus has been isolated from the urine and seminal fluid of patients who were recovering from the disease up to 3 months after the onset of acute disease.⁸

Specific polymerase chain reaction (PCR) or antibody studies are required to identify infection. These tests are generally only available at specialized laboratories. Reverse transcription-PCR (RT-PCR) has been demonstrated to be effective in the rapid diagnosis of the Ebola virus. Studies have also shown a correlation between disease severity and higher RNA copy levels.⁹ The PCR technique has also been used with success in field settings using TaqMan-RT-PCR on a portable SmartCycler during African Ebola outbreaks.¹⁰ The techniques of viral growth in tissue culture followed by electron microscopy and enzyme-linked immunosorbent assay (ELISA) testing have also been used to identify filovirus infection.¹¹ Immunohistochemical staining of skin biopsies may also prove to be an effective method for identifying infection.¹²

PREINCIDENT ACTIONS

As with any disaster or possible bioterrorism attack, hospitals and emergency departments should have preexisting disaster plans in place that are rehearsed before an event. In suspected cases of filovirus infection/terrorist attack, coordination of local, state, and federal agencies would be required to diagnose and manage the incident. Notably, state departments of public health, the CDC, and the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID) would need to be involved early in the process of identification and treatment. As always, universal precautions must be practiced. A high level of vigilance must be maintained by healthcare workers when patients present in clusters with febrile illnesses. This vigilance must be even greater if the patient reports recent travel to an area endemic with viral hemorrhagic fever or if there is a report of a recent outbreak. In the event of suspected cases of filovirus infection, facilities must be prepared for proper isolation of the patient, bodily fluids, and specimens. Protective gowns, gloves, high efficiency particulate air (HEPA) face masks, and eye protection should be used by clinical and laboratory personnel because of the theoretical risk of aerosol transmission.

POSTINCIDENT ACTIONS

Level of suspicion for filovirus infection should be high when patients present with the aforementioned signs and

symptoms, particularly once there are reports of recent cases or a terrorist attack with viral agents. When there is a high level of suspicion of a filovirus terrorist attack, as previously mentioned, state and federal authorities must be rapidly notified. If there are a limited number of patients, consideration should be given to transferring patients to dedicated Biosafety Level 4 facilities, namely the CDC in Atlanta or the USAMRIID in Fort Detrick, Md. In cases of suspected Ebola or Marburg infection, blood and bodily fluid samples must be handled with extreme caution. No material should be forwarded to the CDC or USAMRIID without prior consultation and arrangement. If a filovirus aerosol attack occurred, victims would begin presenting with illness about 1 week later; at this point, virtually no infectious virus should remain viable in the environment. Patients or staff contaminated with liquids or materials possibly containing a filovirus should be decontaminated via a vigorous hot shower with soap and water. Surfaces or items that may be contaminated should be sterilized with a dilute bleach solution or standard hospital quaternary ammonium or phenol disinfectants. Steam serialization, where applicable, is the most effective method for inactivating filoviruses.¹¹

MEDICAL TREATMENT OF CASUALTIES

Unfortunately, treatment for victims of filovirus hemorrhagic fever is largely supportive. As victims progress to disseminated intravascular coagulation and septic shock, usual treatment with blood, clotting products, and vasopressor medications should be instituted. Conventional antiviral agents such as ribavirin have not been shown to have any significant clinical benefit in either in vitro or in vivo studies. Interferon-alpha (INF-a) has shown some success in suppressing filovirus replication in cell culture and some promise in protecting Ebola-infected mice from the illness.¹¹ Attempts have been made to treat patients by passive immunization through the use of the convalescent blood and serum from recovered filovirus patients. After the transfer of IgG Ebola antibodies to infected patients, a lower mortality rate was observed. However, there were a small number of patients in these studies and questions have arisen about other confounders in their care.¹³ Purified IgG from horses hyperimmunized with Ebola-Zaire was shown to protect baboons and guinea pigs from disease when given to them shortly after virus challenge.¹⁴

A concerted effort to develop an Ebola vaccine is under way. Ebola-related deoxyribonucleic acid, liposome-encapsulated irradiated Ebola virus, and Ebola protein segments are all being studied for possible use as vaccines. Ebola virus-like particles, when injected into mice, allowed the animals to develop Ebola-specific antibodies and conferred protection from the lethal virus.¹⁵

UNIQUE CONSIDERATIONS

The filoviruses have the potential to be used as devastating biologic weapons. Their high level of virulence and

equally impressive mortality rate make them a tempting target for any terrorist organization wishing to obtain a weapon of mass destruction. Initial identification of a viral hemorrhagic fever attack will be difficult given the week-long incubation period and nonspecific signs and symptoms in the initial phase of disease. The high risk of transmission to healthcare providers is another factor that makes this threat even more ominous.

PITFALLS

- Failure of healthcare personnel to recognize the non-specific signs and symptoms of viral hemorrhagic fever and delayed institution of containment procedures
- Delayed reporting of possible cases of viral hemorrhagic fever to state and federal officials, leading to delay in appropriate diagnostic procedures and isolation of materials and patients
- Failure to practice simple universal precautions, leading to uncontrolled spread of the viral agent
- General public fear and reaction over release of information regarding possible cases of viral hemorrhagic fever

CASE PRESENTATION

A 25-year-old man presents to a suburban emergency department because he “does not look well.” He is febrile, tachycardic, hypotensive, and minimally responsive. Small amounts of blood are noted in his nares and on his gums, and he is still bleeding from several venipuncture sites. His fiancée states that he has been generally unwell for the past few days with low-grade fevers, body aches, and diarrhea. On further questioning, she reports that he returned from a trip to Europe 10 days ago. Given the patient’s history, examination findings, and symptoms, the health department is contacted because of the concern for viral hemorrhagic fever. You learn from the health officials that several similar cases have also just been reported in the region.

Viral Hemorrhagic Fever Attack—Flaviviruses

John D. Cahill and James McKinnell

DESCRIPTION OF EVENT

Flaviviruses belong to the family of arboviruses. More than 60 of these viruses are known to exist throughout the world. These viruses share some common features. Most are 40 to 50 nm in diameter and are enveloped, positive-sense, single-stranded ribonucleic acid (RNA) viruses that are transmitted from arthropods, particularly mosquitoes and ticks.¹ Clinically these viruses can cause hemorrhagic fevers and encephalitis. This chapter focuses on those causing hemorrhagic fever: yellow fever, Kyasanur Forest disease, Omsk hemorrhagic fever, and dengue fever. There is at least the potential for these viruses to be manufactured into biologic weapons.

It should be appreciated that in the natural setting, these infections have a wide spectrum of presentation: from mild to severe. From a clinical standpoint, these viruses can present in a similar fashion with findings that may include fever, often biphasic; relative bradycardia; hypotension; bleeding diathesis; petechiae; epistaxis; hemoptysis; hematemesis; melena; hematochezia; and hematuria. Laboratory findings may include leukopenia, thrombocytopenia, hemoconcentration, elevated liver function tests, and prolonged bleeding or prothrombin or activated partial thromboplastin times. Death in infected patients is often secondary to bleeding, shock, and organ failure. The differential diagnosis of these infections is broad and includes influenza, viral hepatitis, gram-negative sepsis, meningococemia, toxic shock syndrome, rickettsial infections, leptospirosis, typhoid fever, Q fever, malaria, other viral hemorrhagic fevers, collagen vascular diseases, acute leukemia, and platelet disorders.

Yellow fever, Omsk hemorrhagic fever, and Kyasanur Forest disease have been considered by the Working Group on Civilian Biodefense as having some key features that characterize biologic agents that pose particularly serious risks if used as biologic weapons against civilian populations: (1) high morbidity and mortality; (2) potential for person-to-person transmission; (3) low infective dose and highly infectious by aerosol dissemination, with a commensurate ability to cause large outbreaks; (4) effective vaccine unavailable or available only in limited supply; (5) potential to cause panic in the

affected population; (6) availability of pathogen or toxin; (7) feasibility of large-scale production; (8) environmental stability; and (9) prior research and development as a biologic weapon.² Dengue fever is not considered in this group since initial infection rarely causes hemorrhagic fever and it is not transmissible by small-particle aerosol.³ Yellow fever was weaponized by the United States offensive biologic weapons program until its cessation in 1969, but it may have been weaponized by North Korea.³

The incubation period of *yellow fever* is usually 3 to 6 days, then symptoms of fever, malaise, headache, photophobia, nausea, vomiting, and irritability may occur. Physical examination at symptom onset reveals a patient who is febrile; toxic in appearance; and who has hyperemic skin, injected conjunctiva, coated tongue, and epigastric or hepatic tenderness. Faget's sign, a relative bradycardia with a fever, may be present. After 3 to 5 days, either the patient recovers or enters the next stage of fulminate disease, in which there is extensive hepatic injury with jaundice (hence the name "yellow fever"). Renal failure is not uncommon. A hemorrhagic diathesis may occur, causing epistaxis, oozing at the gums, petechiae, ecchymosis, hematemesis often described as "black vomit," melena, hematuria, thrombocytopenia, and disseminated intravascular coagulation. Myocarditis, encephalopathy, and shock may also ensue. The case fatality rate is 20% to 50%. If one survives, a full recovery can be expected.

The diagnosis of yellow fever may be very difficult in isolated cases; when epidemics occur, physicians are vigilant and the diagnosis is more obvious. In the tropics, the diagnosis is often clinical. A liver biopsy may be performed in an effort to identify the characteristic pathologic changes, such as Councilman bodies and midzonal necrosis. However, the biopsy findings are not absolute and do not exclude the possible diagnosis. Moreover, liver biopsies in yellow fever can be associated with massive hemorrhage. Developed nations have specialized laboratories that can assist in the diagnosis. In such facilities the diagnosis can be made by viral cultures, polymerase chain reaction (PCR), or preferably from enzyme-linked immunosorbent assay (ELISA) tests looking for the IgM rise during acute infection, or IgG later on.⁴

In patients with *Kyasanur Forest disease*, after an incubation period of 3 to 12 days, a severe febrile illness may ensue that may be biphasic in nature. The patient may complain of the acute onset of headache, photophobia, myalgia, upper respiratory symptoms, vomiting, and diarrhea. Physical examination may reveal a febrile patient with a relative bradycardia; hypotension; facial erythema; conjunctivitis; palatal vesicles; lymphadenopathy; hepatosplenomegaly; and manifestations of a bleeding diathesis, including petechiae, epistaxis, hematemesis, hemoptysis, melena, and hematochezia. Patients may develop hemorrhagic pulmonary edema, which is the most common cause of death. The mortality rate may approach 8%.⁵ Renal or hepatic organ failure may occur. Between 20% and 50% of individuals will progress to the second stage of the illness after several days of apparent improvement. During this stage, symptoms of encephalitis may appear.⁶

The complete blood count may show leukopenia, hemoconcentration, and thrombocytopenia. Elevation of liver and renal function tests may also be seen. The virus can be directly isolated from blood during the first 12 days of illness. Appropriate laboratory precautions should be taken when handling these samples. Serologic studies are available for IgM and IgG.

In the natural setting, *Omsk hemorrhagic fever* is, fortunately, a self-limited acute infection with only a small minority of patients developing hemorrhagic complications. The mortality rate is 0.5% to 3%. Clinically there is an incubation period of 3 to 7 days and the patient has a presentation similar to that seen in patients with *Kyasanur Forest disease*; however, there is generally no central nervous system involvement. Diagnosis is made by detecting viral RNA by PCR or by serodiagnosis using ELISA IgM and IgG.

Dengue fever has a global distribution throughout the tropics. The frequency of dengue viral infections has been on the rise since the mid-1950s. Historically, dengue viruses caused sporadic and infrequent epidemics. However, during the last half century, dengue infections have grown to pandemic proportions and patients appear to be presenting with more severe clinical disease. By 1998, 1.5 million cases of dengue fever and dengue hemorrhagic fever from 56 countries marked the first worldwide pandemic. The pandemic in 1998 was followed 3 years later by another worldwide outbreak in 2001. During a span of 50 years, the incidence of dengue viral infection increased approximately 30-fold, affecting approximately 51 million people worldwide per year. In Puerto Rico alone more than \$250 million has been spent during the last 10 years in an attempt to deal with the consequences of this disease.⁷ The dramatic change in disease epidemiology has been attributed to the population shift from rural to urban centers and the rise in international travel and commerce that characterized the 20th century.

There are four serotypes of dengue virus: DEN-1, DEN-2, DEN-3, and DEN-4. All cause clinical dengue fever. Dengue can be separated from other tropical infectious diseases in that the immunologic response to viral infection is relatively unique. Resolution of the primary infection is thought to produce lifelong immunity to the infecting serotype but only brief protection from the

other serotypes. After the transient period of relative immunity, exposed patients become susceptible to secondary infections with other DEN serotypes. It is principally secondary infections, particularly with DEN-2, that are more likely to result in severe disease and dengue hemorrhagic fever.⁸ It has been convincingly argued that an antibody-dependent enhancement of secondary infections is responsible for increased viremia and the development of dengue hemorrhagic fever.

Patients with initial infections often present with dengue fever symptoms, whereas those with secondary infections with a different serotype may present with dengue hemorrhagic fever. The incubation period of dengue fever is 2 to 15 days. The classic presentation of dengue fever, or “break bone fever,” is a syndrome associated with fever, frontal headache, retro-orbital pain, severe myalgia, and severe arthralgia. Conjunctival injection, pharyngeal irritation, nausea, vomiting, and a fine maculopapular rash that spreads centrifugally may accompany the syndrome. Initially, the fever rises rapidly for 2 to 7 days and may then drop, only to reoccur 24 hours later (hence the name “saddleback fever”). Hepatic transaminase level elevations have been reported in more than 80% of cases, with some reports of fulminant hepatic failure. Thrombocytopenia can be seen 4 to 5 days into infection, although this is not a universal finding. Although dengue fever is usually a self-limited infection, it can be accompanied by bleeding complications. Severe bleeding, particularly gastrointestinal losses, can be a fatal complication of dengue fever.⁹⁻¹¹

Dengue hemorrhagic fever is differentiated from dengue fever on the basis of increased capillary leakage of plasma with associated hemoconcentration (hematocrit increase greater than 20%) and thrombocytopenia. Pleural effusions and ascites are possible complications of the microvascular leakage. Sudden extravasation of plasma, typically concomitant with defervescence, is responsible for the circulatory compromise associated with the dengue shock syndrome. The exact pathologic cascade behind microvascular leakage in dengue hemorrhagic fever is unclear but appears to be related to high viral titers causing complement activation and cytokine release, which in turn cause endothelial dysfunction and resulting plasma leakage.¹² Mortality rates may be as high as 50%. Diagnosis is made serologically. The tourniquet test can be used, but it is not disease specific.

PREINCIDENT ACTIONS

Healthcare providers must maintain a high index of suspicion for these diseases since they are sometimes difficult to diagnosis and since some of these agents may be used as biologic weapons. A clinician's level of suspicion should be increased particularly if a large number of individuals present with a “viral syndrome” or coagulation and bleeding problems. Providers should be familiar with the clinical presentation of these illnesses and the resources available to diagnose and manage infected patients. It should be anticipated that blood products will be in great demand if a large number of patients become infected with these viruses and present for care.

From a public health standpoint, rapid diagnosis would be of utmost importance, since an outbreak of Ebola would be handled very differently from a yellow fever outbreak. Institutions and public health officials should also be prepared to handle mass panic and a large number of psychologic casualties that overwhelm the health-care system. The availability of yellow fever vaccine and a plan for mass vaccination should be anticipated.

POSTINCIDENT ACTIONS

Since there is no publicly known experience of these viruses being used as biologic weapons, it is not completely clear how infected individuals would present. Standard isolation precautions should be taken by health-care personnel. Potentially exposed contacts should be placed under medical surveillance for several weeks, looking for evidence of fever and signs of viral hemorrhagic fever. Fortunately, in the natural setting, human-to-human transmission has not been reported. If the virus identified is vaccine-preventable, mass vaccination should begin as soon as possible. If viral hemorrhagic fever is suspected, local health officials must be notified to facilitate identification of the agent as well as access to vaccines, in coordination with state and federal health officials.

MEDICAL TREATMENT OF CASUALTIES

Treatment of all viral hemorrhagic fevers due to flavivirus infection is largely supportive and may include intravenous fluids, vasopressor support, blood products, vitamin K, avoiding nonsteroidal antiinflammatory medications and anticoagulants, and correcting electrolyte imbalances. Although the data are limited, ribavirin has not been shown to be effective in the treatment of flavivirus infection.

Beyond the provision of supportive care to infected patients, management of a yellow fever epidemic involves the institution of preventive measures, including vector control, surveillance, and immunization. A yellow fever vaccination is available. It is a live, attenuated vaccine and has several contraindications, including children younger than 9 months old, pregnancy, and immunosuppression. The vaccine can only be administered at a designated yellow fever center. The vaccination dose is 0.5 mL given subcutaneously in the upper arm. Immunity appears to last at least 10 years after a single dose.

Treatment for Kyasanur Forest disease and Omsk hemorrhagic fever is supportive. In endemic areas, patients should avoid ticks. A formalin inactivated vaccine is available in endemic regions for Kyasanur Forest disease.¹³ No vaccine is available for Omsk hemorrhagic fever; however, the tick-borne encephalitis vaccine may offer some cross-protection.¹⁴

Treatment of dengue hemorrhagic fever is also supportive. Preventive measures include eradication of mosquito breeding sites and personal protective measures. No vaccine is available; however, several vaccine trials are currently under way.

UNIQUE CONSIDERATIONS

To date, there is no specific treatment for flaviviral hemorrhagic fevers. Treatment is supportive, although with development of antiviral medications, there may be a role for their use in the future. Several of these diseases are vaccine-preventable, and vaccine trials are under way for dengue fever. Fortunately, unlike some of the other hemorrhagic fevers, the flaviviruses are not known to spread person to person.

PITFALLS

- Failure to obtain a detailed clinical history, which could result in these illnesses being mistaken for a “flu” or simple viral syndrome
- Failure to obtain careful travel history, including geographic locations, length of trip, activities undertaken, and exposure to mosquitoes or ticks
- Failure to determine the time of onset of symptoms and time of return from travel, since many of these illnesses have a specific incubation period
- Failure to obtain a past medical history that includes previous vaccines
- Failure to maintain clinical suspicion for these viruses when multiple individuals present with similar symptoms outlined in this chapter
- Failure to report suspected hemorrhagic fever cases to the public health officer or department of health

CASE PRESENTATION

The staff physicians at an urban hospital have been overwhelmed by an unusually early onset of the flu this season. The strain seems especially virulent, since several patients have died and the census in the emergency department has increased by 25%. As the week progresses, many of the patients admitted with the “flu” develop gastrointestinal bleeding, necessitating blood transfusions and intensive care unit support. Presenting symptoms of one such 30-year-old male patient include a fever to 101 °F, a heart rate of 80, and a blood pressure of 90/50 mm Hg. He has petechiae, is complaining of intermittent epistaxis, and has bloody stools. Laboratory findings include low white blood cell and platelet counts, an elevated hematocrit level, and elevated liver function tests. His bleeding time is prolonged as well.

Chikungunya Virus Attack

Heather Long

DESCRIPTION OF EVENT

The chikungunya virus (CHIK) is an alphavirus borne by *Aedes* mosquitoes. The virus is endemic to many tropical and subtropical regions throughout the world, including sub-Saharan Africa, southeast Asia, India, and the western Pacific. The CHIK virus was first isolated from human serum and *Aedes aegypti* mosquitoes in 1953 after an epidemic in Tanzania.¹

Even though the most common route of transmission is human-mosquito-human, the CHIK virus may also be aerosolized.² It is highly infectious, and many laboratory workers have been infected while working with the virus.³⁻⁵ As an agent of biologic terrorism, it would most likely be dispersed as an aerosol or by release of infected mosquitoes.⁶ No person-to-person transmission has been documented. To date, there have been no confirmed reports of terrorist acquisition or planned use of this agent. In the event of a CHIK virus attack, a large percentage of the exposed population would be expected to become ill after an incubation period of 2 to 10 days.² Illness associated with the CHIK virus is generally self-limited and short-lived; however, it may be temporarily debilitating, and a large number of affected patients would be expected to seek care for fever and severe joint pain. Hospitals with few isolation areas appropriate for screening patients with these presenting complaints may be overwhelmed.

Infection with the CHIK virus is characterized by the triad of fever, maculopapular rash, and arthralgia.⁷ Nausea, headache, vomiting, and myalgia are also common. Sudden onset of fever is characteristically the first symptom to appear after an incubation period of 2 to 10 days.² Arthralgia is the most prominent symptom, and the word *chikungunya*, translated from Swahili as “that which bends up,” refers to this joint pain.⁸ Severity ranges from mild weakness and stiffness to excruciating pain. The pain is typically symmetric and involves multiple joints. Previously injured joints and the fingers, wrists, elbows, toes, ankles, and knees are most commonly affected.⁶ Joints appear swollen and are tender to palpation. Frequency and severity of symptoms are generally less in children. Complete resolution of all symptoms occurs in most patients after 2 to 5 days; however, about 12% of patients will have a persistent arthropathy

that may last months to years.⁵ Persistent arthropathy is associated with high titers of CHIK virus antibodies.⁵

Although not classified as a hemorrhagic virus, hemorrhagic forms of the disease that mimic dengue fever and yellow fever have been reported.^{9,10} In some outbreaks of CHIK virus infection, up to 10% of patients were noted to have mild hemorrhage, including petechia, epistaxis, and bleeding gums. Cases of myocarditis and cardiomyopathy after CHIK virus infection have been reported.^{11,12} Rare deaths among the elderly and children have been associated with CHIK outbreaks, and the CHIK virus was isolated from one Sri Lankan child who died.^{13,14}

Diagnosis of CHIK virus infection in a patient without history of either travel to an endemic area or laboratory exposure to the virus would require a high degree of clinical suspicion. Results from routine laboratory tests are nonspecific. Laboratory confirmation via polymerase chain reaction (PCR) or enzyme-linked immunoabsorbent assay (ELISA) requires submission of serum to either the Centers for Disease Control and Prevention (CDC) or the U.S. Army Medical Research Institute of Infectious Disease (USAMRIID), and results take 2 to 5 days.⁶

PREINCIDENT ACTIONS

Prehospital services, hospitals, and local and state health departments should have implemented preparedness programs for bioterrorism and mass casualty events. Recognition of a CHIK virus event would require familiarity with the agent as well as a high degree of clinical suspicion. Maintaining a high level of alertness to abnormal patterns is critical to the recognition of any covert bioterrorist attack.

POSTINCIDENT ACTIONS

All suspected cases of CHIK virus infection should be reported to local and state health departments, who would then notify the CDC. Infection control professionals and laboratory personnel should be notified immediately. Biosafety Level 3 practices should be maintained in handling specimens. If CHIK virus infection is

suspected, 10 to 12 mL of serum from the affected patient(s) should be shipped cold or on dry ice in a plastic tube. Public health authorities, in conjunction with the CDC, should aid clinicians in preparing specimens for transport to a reference laboratory. (See "Packaging Protocols for Biological Agents/Diseases" at <http://www.bt.cdc.gov/Agent/VHF/VHE.asp>.) Laboratory personnel must be alerted to the possibility of small-particle aerosol generation to minimize their risk of infection. With prior notice, the CDC can offer a preliminary laboratory diagnosis after approximately 1 working day.¹⁵

In its natural state, the CHIK virus is not environmentally stable for long periods. Environmental Protection Agency-registered hospital disinfectants, moist heat, and drying all kill the virus. However, decisions regarding the need for decontamination after an attack should be made after expert analysis of the contaminated environment, the agent used, and the means of distribution. Similarly, contact and respiratory isolation of exposed and infected patients is not believed to be necessary, but specific recommendations should be made after expert analysis. Given that laboratory confirmation may take several days, stricter infection control practices may be warranted until an agent with person-to-person transmission is ruled out. Universal precautions should be taken with all patients.

MEDICAL TREATMENT OF CASUALTIES

The mainstay of treatment of CHIK virus infection is supportive care. Fluid and electrolyte balance should be closely monitored. Nonsteroidal antiinflammatory agents are the first-line therapy for fever and pain. Antiemetics may be required in cases of persistent nausea and vomiting. Antiviral agents, including ribavirin, 6-azauridine, interferon-alpha2b, and glycyrrhizin, alone and in combination, have demonstrated in vitro anti-CHIK activity.¹⁶ Whether any of these agents would be effective in postexposure prophylaxis or treatment remains unstudied. There is currently no U.S. Food and Drug Administration indication for the use of ribavirin after CHIK virus infection. Given the low morbidity and exceedingly rare mortality associated with CHIK virus infection in its natural state, ribavirin should be administered only after expert analysis under an investigational new drug application.¹⁵ There is presently no vaccine for the CHIK virus, but development is on-going; results of a phase II safety and immunogenicity study of a live CHIK virus vaccine were published in 2000.¹⁷

UNIQUE CONSIDERATIONS

The CHIK virus is highly infectious; a large percentage of people exposed to the agent would be expected to become ill. Illness with the CHIK virus is short-lived but temporarily debilitating and not considered lethal. Because there is no animal reservoir for the virus in Western countries and no person-to-person transmission, it is seen as a "clean" biologic weapon that may be a desirable agent for use against a civilian site.⁶

PITFALLS

- Failure to consider a CHIK virus infection or attack in patients presenting with the nonspecific symptoms of fever, rash, and arthralgia
- Failure to alert laboratory personnel to the possibility of small-particle aerosolization in suspected cases
- Failure to notify local and/or state health departments of suspected cases

CASE PRESENTATION

A 22-year-old woman with no significant past medical history complains of severe bilateral wrist, elbow, and knee pain since waking this morning. The patient had been in her usual state of health until 1 day before presentation when she had a sudden onset of fever and shaking chills while at work. The patient has no rhinorrhea, cough, or sore throat; she complains of headache and nausea but no vomiting or diarrhea. She has no chest or abdominal pain. She denies any sick contacts, trauma or falls, or recent travel. The only medication she takes is oral contraceptives.

Vital signs are as follows: temperature is 39.5°C, heart rate is 120, blood pressure is 118/74 mm Hg, and respiratory rate is 16. The patient appears flushed and in obvious physical discomfort but in no respiratory distress. Her physical examination is remarkable for slight swelling of the knees bilaterally; pain is elicited with active and passive range of motion of the knees, wrists, and elbows bilaterally. There is no warmth or erythema of the joints. Routine laboratory results including white cell count with differential are normal. The erythrocyte sedimentation rate is 40. Aspiration of the left knee joint reveals clear fluid negative for crystals with a white cell count of 200 cells/high-powered field.

Variola Major Virus (Smallpox) Attack

Robert G. Darling

DESCRIPTION OF EVENT

Smallpox may be responsible for more human deaths throughout history than any other known disease, with estimates that it has killed more than 100 million people since the beginning of recorded history.¹ Smallpox was declared eradicated in 1980 by the World Health Organization, and there have been no cases of smallpox anywhere in the world since 1978. By treaty there are only two official repositories of smallpox in the world today: one repository is at the Russian State Research Center of Virology and Biotechnology in Novosibirsk, Russia, and the other is at the Centers for Disease Control and Prevention (CDC) in Atlanta, Ga. A single case of smallpox should be presumed to be intentional unless it can be shown to be the result of a laboratory accident.

Terrorist use of variola as a biologic weapon could occur under one of several different scenarios. The simplest method might involve obtaining an illicit sample of the virus from a clandestine stock and then exposing a number of unsuspecting victims. These unfortunate individuals would then go about their daily business and serve as vectors for further spread of the disease once they become contagious. This might not be the most efficient manner to spread the infection since most victims become quite ill as symptoms develop and are unlikely to remain ambulatory. The most efficient manner to infect a large number of people would involve the deliberate spread of a weaponized aerosol of the virus.

The incubation period of smallpox averages 12 days, with a range of 7 to 17 days after exposure. Clinical manifestations begin acutely with malaise, fever, rigors, vomiting, headache, and backache; 15% of patients develop delirium. Approximately 10% of light-skinned patients exhibit an erythematous rash during this phase. Two to three days later, an enanthem appears concomitantly with a discrete rash about the face, hands, and forearms.

After eruptions on the lower extremities, the rash spreads centrally to the trunk over the next week. Lesions quickly progress from macules to papules and eventually to pustular vesicles. Lesions are more abundant on the extremities and face, and this centrifugal distribution is an important diagnostic feature. In distinct contrast to varicella, lesions on various segments of the body remain generally synchronous in their stages of development. From 8 to 14 days after onset,

the pustules form scabs that leave depressed depigmented scars upon healing. Although variola concentrations in the throat, conjunctiva, and urine diminish with time, the virus can be readily recovered from scabs throughout convalescence. Therefore, patients should be isolated and considered infectious until all scabs separate.

For the past century, two distinct types of smallpox were recognized. *Variola minor* was distinguished by milder systemic toxicity and more diminutive pox lesions; it caused 1% mortality in unvaccinated victims. However, the prototypical disease, *variola major*, caused mortality of 3% and 30% in the vaccinated and unvaccinated, respectively.²

Smallpox must be distinguished from other vesicular exanthems, such as chickenpox, erythema multiforme with bullae, or allergic contact dermatitis. Particularly problematic to infection control measures would be the failure to recognize relatively mild cases of smallpox in persons with partial immunity. An additional threat to effective quarantine is the fact that exposed persons may shed virus from the oropharynx without ever manifesting disease. Therefore, quarantine and initiation of medical countermeasures should be promptly followed by an accurate diagnosis to avert panic.

The usual method of diagnosis is demonstration of characteristic virions on electron microscopy of vesicular scrapings. Under light microscopy, aggregations of variola virus particles, called *Guarnieri bodies*, are found. Another rapid but relatively insensitive test for Guarnieri bodies in vesicular scrapings is Gispén's modified silver stain, in which cytoplasmic inclusions appear black.

None of the aforementioned laboratory tests is capable of discriminating variola from vaccinia, Monkeypox, or cowpox. This differentiation has classically required isolation of the virus and characterization of its growth on chorioallantoic membrane. The development of polymerase chain reaction diagnostic techniques promises a more accurate and less cumbersome method of discriminating between variola and other orthopoxviruses.³

PREINCIDENT ACTIONS

Pre-event preparations should focus on first responder, medical, and public health personnel education. This is

particularly important for healthcare providers since an astute clinician will be far more likely to diagnose a first case of smallpox before any surveillance system would lead public health authorities to suspect there is an epidemic in the community. Rapid identification and vaccination of contacts will be the keys to controlling an outbreak of smallpox.

Ideally, all first responders and medical and public health personnel will be vaccinated against smallpox before an outbreak and will have extensively drilled their local smallpox response plans. However, efforts by the CDC in 2003 to vaccinate up to 500,000 volunteers were unsuccessful, largely due to concerns about side effects of the vaccine and a general belief among the public that the threat of terrorist use of smallpox was low. To date the U.S. military has vaccinated more than 600,000 of its personnel with a relatively low rate of complications.⁴

A well-developed, integrated “all-hazards” hospital disaster response plan should be in place and tested regularly. It should include provisions to care for a rapid influx of large numbers of contagious patients. The local plan should be linked to other regional, state, and federal disaster plans.

POSTINCIDENT ACTIONS

A single case of smallpox should be treated as an international public health emergency. Hospital infection control and laboratory personnel; law enforcement authorities, including the Federal Bureau of Investigation; and local, state, and federal public health authorities, including the CDC, must be notified immediately. An epidemiologic investigation to identify all of those potentially exposed must be initiated so that a postexposure vaccination effort can commence. With a mortality rate of 30% and high morbidity, the vaccination risk-benefit ratio shifts markedly in favor of vaccination, even for patients with contraindications to receiving the vaccine. Patients who have been exposed to a smallpox patient should be vaccinated as soon as possible, even up to 5 to 7 days after exposure since the disease may either be prevented or ameliorated.⁵

The smallpox vaccine, using vaccinia virus, is most often administered by intradermal inoculation with a bifurcated needle. The current smallpox vaccine is the Wyeth DryVax, which is a licensed product derived from calf lymph. Future smallpox vaccines will be grown on human cell cultures.⁶ Primary vaccinees receive three punctures with the needle; repeat vaccinees receive 15. A vesicle typically appears at the vaccination site 5 to 7 days after inoculation, with associated erythema and induration. The lesion forms a scab and gradually heals over the next 1 to 2 weeks; the evolution of the lesion may be more rapid, with less severe symptoms in those with previous immunity.

Side effects include a low-grade fever and axillary lymphadenopathy. The attendant erythema and induration of the vaccination vesicle is commonly misdiagnosed as bacterial superinfection. More severe vaccine reactions include inadvertent inoculation of the face, eyelid, or other parts of the body; generalized vaccinia; and transient, acute

myopericarditis. Rare, but often fatal, adverse reactions include eczema vaccinatum (generalized cutaneous spread of vaccinia in patients with eczema), progressive vaccinia (systemic spread of vaccinia in immunocompromised individuals), and postvaccinia encephalitis.⁷

Vaccination is contraindicated in the following conditions: immunosuppression; HIV infection; history or evidence of eczema; other active severe skin disorders; during pregnancy; or current household, sexual, or other close physical contact with individuals possessing one of these conditions. In addition, vaccination should not be performed in breast-feeding mothers, in individuals with serious cardiovascular disease or with three risk factors for cardiovascular disease, or individuals who are using topical steroid eye medications or who have had recent eye surgery. Despite these caveats, most authorities state that, with the exception of significant impairment of systemic immunity, there are no absolute contraindications to postexposure vaccination of a person with a confirmed exposure to variola. However, concomitant vaccine immune globulin (VIG) administration is recommended for pregnant and eczematous persons in such circumstances.⁸

VIG is indicated for treating some complications of the smallpox vaccine, including generalized vaccinia with systemic illness, ocular vaccinia without keratitis, eczema vaccinatum, and progressive vaccinia, and should be available when administering vaccine. The dose for prophylaxis or treatment is 100 mg/kg for the intravenous formulation (first line), or 0.6 mL/kg for the intramuscular preparation (second line). Due to the large volume of the intramuscular formulation (42 mL in a 70-kg person), the dose would be given in multiple sites over 24 to 36 hours.

If VIG is not available, cidofovir may be of use for treating vaccinia adverse events. Limited data suggest that VIG may also be of value in postexposure prophylaxis of smallpox when given within the first week after exposure, and concurrently with vaccination. Vaccination alone is recommended for those without contraindications to the vaccine. If more than 1 week has elapsed after exposure, administration of both products, if available, is reasonable.⁹

In the event of a large-scale smallpox outbreak, the controversial issue of quarantine must be considered. Historically, imposition of quarantine was a key element in the eventual control of a smallpox outbreak, but it has been more than 50 years since any such measure has been taken in the United States.

MEDICAL TREATMENT OF CASUALTIES

People who have been exposed to known cases of smallpox should be monitored for a minimum of 17 days from exposure, regardless of their vaccination status; such individuals should be immediately isolated using droplet and airborne precautions at the onset of fever. Strict quarantine of asymptomatic contacts may prove to be impractical and impossible to enforce. A reasonable alternative would be to require contacts to remain at home and to check their temperatures daily.¹⁰ Any fever

greater than 38°C (101°F) during the 17 days after exposure to a confirmed case would suggest the development of smallpox. The contact should then be isolated immediately, preferably at home, until smallpox is either confirmed or ruled out and remain in isolation until all scabs separate. Immediate vaccination or revaccination should also be undertaken for all personnel exposed to a clinical case of smallpox. Caregivers should be vaccinated and continue to wear appropriate personal protective equipment regardless of vaccination status. Vaccination with a verified clinical “take,” defined as vesicle with scar formation, within the past 3 years is considered to render a person immune to smallpox.

Antivirals for use against smallpox are under investigation. Cidofovir has had significant in vitro and in vivo activity in animal studies.¹¹ Whether it would offer benefit superior to immediate postexposure vaccination in humans has not been determined. Even though cidofovir is a licensed drug, its use for treating smallpox is “off-label,” and thus it should be administered as an investigational new drug. Topical antivirals such as trifluridine or idoxuridine may be useful for treating smallpox ocular disease.

Supportive care is imperative for successful management of smallpox victims; measures include maintenance of hydration and nutrition, pain control, and management of secondary infections.

UNIQUE CONSIDERATIONS

Smallpox (*variola major*) is categorized as a category A critical biologic agent by the CDC because of its transmissibility, high morbidity and mortality, ability to cause panic in afflicted populations, and the extraordinary public health measures that would be required to contain an epidemic.¹² Of particular concern with smallpox is evidence that it can be transmitted person-to-person via airborne droplet nuclei. This has been seen among some smallpox patients who have prominent respiratory symptoms.¹³

Significant progress has been made in acquiring enough licensed smallpox vaccine for every American, and work continues on the development of a safer smallpox vaccine with fewer side effects.⁶ Recently, Australian researchers have demonstrated an interleukin-2 modified poxvirus that was able to defeat the current smallpox vaccine in an animal model.¹⁴ Research likewise continues on antiviral drugs that could be used to treat smallpox patients, and the drug cidofovir offers some promise.

PITFALLS

- Failure to recognize a case of smallpox on clinical grounds
- Failure to immediately institute airborne and droplet precautions among patients and hospital staff
- Failure to notify hospital laboratory personnel that clinical specimens may be from a smallpox patient

- Failure to immediately notify law enforcement and public health authorities of a suspected case of smallpox

CASE PRESENTATION

An 18-year-old male presents with a fever of 104°F, severe cough, a sore throat, a severe backache, and an erythematous maculopapular rash. He has a pulse of 120 that is regular, a respiratory rate of 18, and a blood pressure of 126/88 mm Hg. He appears quite ill. The cutaneous lesions appear all over the patient's body but may be slightly more prominent on the face and arms than on the trunk or lower extremities. The lesions on the face consist mostly of red papules; on the arms they are mostly reddish macules. The lesions all appear about the same stage of development.

Influenza Virus Attack

Anna I. Cheh

DESCRIPTION OF EVENT

Influenza is an acute respiratory illness of viral etiology. The influenza virus is a member of the Orthomyxoviridae family. The genome of this enveloped virus contains eight segmented, single-stranded, negative sense RNA. There are three immunologic types: A, B, and C. Type A is the primary pathogen for human disease. Its two surface glycoproteins, hemagglutinin (H) and neuraminidase (N), determine host immunity and subtype designation. Unlike types B and C that reside only in humans, type A also infects birds, pigs, horses, and sea mammals. The gene's segmented nature facilitates genetic reassortment during infection within this broad reservoir. Such genetic shifts (major) or drifts (minor) lead to the genetic diversity of type A.¹ Major antigenic variations underlie the deadly worldwide pandemics, such as that of 1918 and 1957. New concerns regarding disease epidemiology surfaced in 1997 as direct disease transmission from animals to humans caused fatalities in Hong Kong.

Influenza is not classified as a bioterrorism agent by the Centers for Disease Control and Prevention.² Among immunocompetent individuals, influenza infection is largely self-limited with low mortality rates. However, several factors support the possible role of influenza in an urban attack. Influenza is highly contagious. Transmission can be via respiratory droplets or fomites.³ Aerosol transmission of influenza, the method likely used in an attack, takes 27,000 times fewer virion than that required in direct respiratory contact to induce equivalent disease.⁴ The incubation period is short, ranging from 18 to 72 hours. A person is contagious within a day after infection and can remain so for a week after becoming symptomatic. Also, the influenza virus is readily available, unlike many other agents that are more difficult to obtain. More worrisome are recent advances that allow infectious agents to be directly produced in the lab without a natural template.⁵

The classic presentation of influenza is the abrupt onset of fever, headache, myalgia, and extreme malaise. The virus targets and reproduces within the ciliated columnar epithelial cells of the respiratory tract.¹ Therefore, signs of both upper and lower respiratory involvement can also be present. Constitutional symptoms are more pronounced during the acute phase

encompassing the first 3 to 5 days. The subsequent convalescence phase can last for weeks with lingering respiratory symptoms and malaise, often termed *post-influenza asthenia*.⁶

Complicated influenza has a predilection for individuals with chronic underlying illnesses. High-risk groups include those with cardiovascular or pulmonary disease, diabetes mellitus, renal disease, or immunosuppression. Pneumonia is the complication most responsible for the excess fatalities associated with influenza outbreaks. Other less-common complications include myositis, myocarditis, rhabdomyolysis, and Reye's syndrome. Central nervous system involvement such as encephalitis and aseptic meningitis has also been documented, although a direct relationship has been never clearly established. Viremia is rare.

Diagnosis is often based on clinical presentation. This is especially appropriate within an epidemic. However, during a possible terrorist attack, distinguishing between different viral pathogens will be imperative. Tissue cultures can be obtained within 48 to 72 hours of inoculation.⁷ Increasingly, rapid viral diagnostic tests such as enzyme immunoassays (EIA) and PCR are also available for diagnosis. These newer methods, however, cannot be used to identify the responsible subtype strain.

Although common, influenza can still be a formidable foe. Attack rates are between 10% and 20% in the general population but can exceed 50% during pandemics. Institutionalized and close-quartered populations are especially at increased risk. During non-pandemic years, approximately 20,000 annual deaths are attributed to influenza in the United States.⁸

PRE-INCIDENT ACTIONS

Influenza is possibly the most tracked virus in the world. The CDC and the World Health Organization (WHO) Global Influenza Network has in place an extensive worldwide surveillance system (WHO Flunet) to monitor disease activity and identify viral isolates for the development of the annual vaccine. Influenza has the distinct advantage of having this developed immunization infrastructure. Two types of vaccine are currently approved for use in the United States. The trivalent inac-

tivated vaccine contains a killed virus and is safe to use during pregnancy and breastfeeding. The newer trivalent live-attenuated cold-adapted vaccine (LAIV) is administered intranasally.

Effective surveillance and early detection of outbreaks is pivotal for agents such as influenza for which effective prophylaxis and immunization exist.⁸ Establishing population immunity to influenza will also aid in distinguishing it from the more deadly biological agents that have a similar initial prodrome.⁹ Therefore, increasing immunization rates should be part of a broader strategy against bioterrorism.

POST-INCIDENT ACTIONS

Recognition of an emerging pandemic is aided by influenza's classic presentation and clustering epidemiology. Initiation of a coordinated effort to expedite vaccine development and dissemination will be pivotal. During the initial period following a bioterrorist attack, antiviral agents are another key mechanism of containing morbidity and protecting exposed individuals.¹⁰ Public awareness campaigns regarding measures to reduce transmission and seeking early medical intervention should be quickly instituted to blunt the mortality of an outbreak.^{8,11}

MEDICAL TREATMENT OF CASUALTIES

Treatment of influenza is largely supportive. Specific antiviral agents such as amantadine and rimantadine are approved for both the treatment and prophylaxis for influenza A. Newer agents such as oseltamivir and zanamivir are effective for both types A and B. Although not proven to be any more efficacious, these agents are associated with fewer central side effects. Optimal efficacy of all drugs depends on starting the regimen within 48 hours after symptom onset. During possible acute outbreaks, these agents can provide effective chemoprophylaxis until vaccine-induced immunity can be established in target populations.¹⁰ Constraints on existing medical systems could reach critical levels, pending the extent of the attack.

UNIQUE CONSIDERATIONS

The potential advantage of influenza as a bioterrorism agent is its genetic variation. A variant strain from which wide human immunity does not exist could hold devastating potency.¹² Some experts estimate that a virus of comparable virulence to the 1918 strain could result in 100 million deaths today.¹³ Although the self-limiting course of influenza would fail to produce the dramatic and immediate effects that are the aim of terrorist acts, the real impact of an influenza outbreak will be its indirect costs. Modern influenza pandemics have evolved into economic disasters even as medical advances help to avert direct fatalities.¹⁴ For example, 3 million chick-

ens were slaughtered to prevent further transmission of the Hong Kong avian influenza virus in 1997.

Influenza is a virus that impacts certain segments of the population disproportionately. As the population ages and a greater segment live with higher risk morbidities, the impact of a pandemic will also escalate.

PITFALLS

- Failure to consider terrorism during the early phase of a pandemic because of influenza's natural existence.
- Failure to diagnose accurately. The broad spectrum of influenza symptoms often overlaps with many other possible bioterrorism agents. Clinicians should be educated for greater utilization of confirmatory tests and reporting positive cases to a central tracking database.
- Failure to institute mechanisms to ensure adequate supply of antiviral medications, currently unlikely to be able to meet prolonged demand.
- Failure of existing vaccine infrastructure to respond quickly to a novel virulent strain. Currently, a vaccine is almost a year out of date by time of administration.
- Failure to update immunization strategy to better address the unique threats of terrorism.
- Failure to anticipate the social and economic impact of a pandemic outbreak.

CASE PRESENTATION

In a large metropolitan city, public health officials are baffled by a surge of influenza cases earlier in the winter season than expected. CDC and WHO work overtime to identify the responsible strain, ultimately found to be a novel subtype different than any previously recorded. Nursing homes are virtually emptying out as residents are admitted to hospitals for pneumonia. Even the local colleges are feeling the effects as the school clinics are inundated with students complaining of debilitating myalgia and malaise. Parents pull children from school to avoid exposure. Doctors are flooded by calls from patients frustrated with being unable to fill their amantadine prescription at their local pharmacies. Antiviral medications are being depleted as people wait for the new vaccine to arrive, which is announced to be available in 8 months.

Public health officials predict one of the worst influenza seasons ever in economic costs as more people are calling in sick, productivity is lost, tourism shuts down, and hospital resources are stretched to the breaking point.

Monkeypox Attack

John D. Malone

DESCRIPTION OF EVENT

Monkeypox is an orthopox virus, recognized in 1958 in laboratory monkeys. The natural host may be an African squirrel, but the virus can also infect rodents and rabbits. Monkeypox is in the same genus as smallpox (*Variola major and minor*), *Molluscum contagiosum*, cowpox, and the vaccinia virus. Other non-human associated animal orthopox infections include volepox, skunkpox, raccoonpox, camelpox, and buffalopox. Monkeypox has been endemic in Ghana and Zaire and is associated with the hunting and consumption of infected monkeys and rodents.¹

In April 2003, six infected African rodents, Gambian giant rats, were imported into the United States. They transferred the monkeypox virus to prairie dog rodents housed in adjacent cages. Within 2 months, human cases were reported in individuals who had been bitten or scratched by the infected prairie dogs.² In the outbreak, there were 71 suspected cases and 37 confirmed cases.³ There was no laboratory-confirmed human-to-human transmission.

The patients presented with fever greater than 38° C and skin lesions. Skin manifestations ranged from nodular swellings in the wound margins to satellite and disseminated lesions. Papules progressed to vesicles and pustules. Significant symptoms include severe chills and sore throat. Lymphadenopathy and tonsillar hypertrophy were present. Along with an intimate rodent animal exposure history, adenopathy is a helpful sign for emergency physicians to differentiate monkeypox from a “flu syndrome” in those with minimal or subtle skin lesions and similar headache, fever, sweats, chills, and cough. Four of the initial eleven cases were hospitalized. The clinical course was self-limited with some central scarring of larger lesions.

With close cooperation of the Centers for Disease Control and Prevention (CDC) and multiple Midwestern state health authorities, the outbreak was controlled through an emergency embargo and quarantine orders against the “importation, sale, distribution, or display of prairie dogs or any mammals that had been in contact with prairie dogs after April 1, 2003.”⁴ Appropriate and aggressive animal control measures prevented the establishment of monkeypox in the North American rodent population; a vast improvement compared with the his-

tory of the plague bacillus, *Yersinia pestis*, that entered the Southwestern U.S. desert rodent population after a 1900 epidemic in San Francisco.⁵

The skin lesions for monkeypox are identical to those for smallpox: morbilliform, hard and pea sized on an erythematous base, and classically described as dew drops on a rose petal. The rash begins as maculopapular lesions 2 to 5 mm in diameter, progressing through papular, vesicular, pustular, and crust phases over a 14-day period.⁶ The lesions are initially located on cooler body parts, particularly the extremities including the palms and soles, and the face. Over the initial days, the lesions spread to the trunk. The initial papules become umbilicated vesicles, with all of the lesions in the same stage at the same time. The skin vesicles are a product of bloodborne viral seeding of the terminal capillaries in the initial viremia. The initial viremia is manifested by the sudden onset of fever, malaise, headache, and severe back pain, and manifested less often with abdominal pain and vomiting.⁷

As for the differential diagnosis of monkeypox, herpes viruses are much more likely to be an etiology of similar skin lesions. The Varicella Zoster Virus (VZV) produces varicella “chickenpox” vesicles that begin centrally on the trunk. The multiple lesions exist in different stages of maturation. VZV may also cause disseminated herpes zoster in an immunocompromised host. A varicella virus direct fluorescent antibody (DFA) test should be available in major emergency departments and initially performed to diagnose this infection. Coxsackievirus commonly occurs in children under 10 years of age in the autumn season. Secondary syphilis (syphilis serology should be positive), erythema multiforme, and drug eruptions can produce less typical vesicular rashes on the palm and soles. Rocky Mountain Spotted Fever, a rickettsial illness, is associated with a spring/summer tick exposure in the Southeastern United States. Meningococcal infection is characterized by rapid progression to shock. Molluscum infection occurs in healthy children and HIV-infected adults; the painless lesions do not cause fever.

Definitive laboratory diagnosis of monkeypox infection is required to ensure that smallpox is not present and for an appropriate public health response. Electron microscopy of vesicular scrapings will identify orthopox viruses by the appearance of an exceedingly large box with rounded corners. Polymerase chain reactions definitively

identify the specific species. Tissue from lymph nodes and blood specimens can also be evaluated. Specimen collection instructions are detailed by the CDC.⁸

It is not known whether the monkeypox virus was ever weaponized. However, the process would probably be similar to the method used to weaponize the smallpox virus. Scientists from the former Soviet Union accomplished this. Like smallpox, monkeypox is contagious but less so. If a stable, infectious monkeypox biological aerosol was produced and delivered as a fine particle aerosol under ideal atmospheric conditions over a targeted population, one would expect to see large numbers of casualties presenting at about the same time to local hospitals and doctor's offices with signs and symptoms as described here. The ensuing epidemic and secondary cases would probably not be as severe as one would expect to see if a smallpox weapon was used, since the monkeypox virus is not nearly as contagious as the smallpox virus. Of course, with the genetic engineering techniques that are available today, novel characteristics could be created and infectivity of the virus could be enhanced. There is no evidence to date that this has been attempted.

PRE-INCIDENT ACTIONS

Emergency departments should have well-rehearsed standard operating procedures to evaluate potentially contagious infectious disease patients using airborne transmission precautions (protective gowns, gloves, HEPA face masks). A small cadre of smallpox-vaccinated healthcare workers should be available to initially evaluate and care for patients with suspected orthopox infection. Along with concerns for patient transmissible bioterrorism agents, such as smallpox, pneumonic plague, and viral hemorrhagic fevers, clinical suspicion is necessary for the more common agents of SARS and rubeola virus in our highly mobile global society.

POST-INCIDENT ACTIONS

When presented with an initial case of monkeypox, great concerns about the possibility of smallpox are appropriate in this age of ongoing terrorist threats. In contrast to smallpox, monkeypox would be a poor agent for bioterrorism because of a very low mortality rate and respiratory transmission by large droplets that requires direct and prolonged face-to-face contact. Monkeypox is highly unlikely to be able to sustain itself in human communities. However, if suspected, appropriate local and state health authorities must be notified early to assist with agent identification.

MEDICAL TREATMENT OF CASUALTIES

Supportive therapy with antipyretics and fluids are indicated. Monkeypox has a low lethality (1.5% in a 1996 Democratic Republic of the Congo outbreak) and requires close family contact for transmission. Accumulating expe-

rience in the United States suggests a relatively low risk of person-to-person transmission. According to the CDC, all healthcare settings such as hospitals, emergency departments, and physician offices should have the capacity to care for monkeypox-infected patients and protect health care workers and other patients from exposure.⁹ A combination of standard, contact, and droplet precautions, which include gowns, gloves, eye shields, and surgical masks, should be applied in all healthcare settings when concerns for monkeypox exist. Because of a theoretical risk of airborne infection, airborne precautions using N95-rated respirator masks are recommended when possible. A negative pressure room should be used if available. Viremic individuals spread the disease through large respiratory droplets, most likely with the symptoms of cough, pharyngitis, and fever.

Unique Considerations

Smallpox vaccination with the vaccinia virus (Dryvax) is protective against monkeypox infection. The vaccinia virus likely evolved through a reassortment of the cowpox virus and the smallpox virus. During the 2003 monkeypox outbreak, CDC guidelines for vaccination included public health and animal control investigators, healthcare workers caring for monkeypox patients or those who may be asked to care for infected patients, or family members with close contact with someone who was symptomatic with monkeypox. Also included were veterinarians and their technicians who had direct physical exposure to an infected animal. Vaccination up to 14 days after exposure will attenuate or prevent monkeypox illness.

Extensive data from the Department of Defense exist over the safety and efficacy of the "Dryvax" smallpox vaccination.¹⁰ As of July 2005, more than 830,000 individuals have been vaccinated. A causal relationship to one death from a lupus-like illness after both anthrax and smallpox vaccinations has resulted along with 99 cases of myopericarditis with documented complete recovery in 64 cases. Among 27,700 smallpox vaccinated healthcare workers, there were no cases of transmission of vaccinia to a patient. Other investigators have also shown the risk of inadvertent vaccinia transmission from vaccination sites covered by occlusive dressings to be quite low.¹¹

Fear and panic are major issues for monkeypox viral infection. Commonality in name with smallpox raises anxieties and misperceptions in the public, patients, and healthcare providers. Significant psychological and economic impacts result. Preliminary knowledge of monkeypox, personal protective equipment, and effective leadership of the healthcare team will ensure appropriate patient care and avoid crisis and closure of emergency departments.

PITFALLS

- The skin lesions of monkeypox and smallpox are identical.
- Lymphadenopathy, tonsillar hypertrophy, and intimate rodent exposure will assist in differentiating monkeypox from a "flu syndrome."

- Monkeypox has relatively low risk of person-to-person transmission; however, airborne precautions (N95 mask) are recommended.
- A high clinical suspicion and well-rehearsed standard operating procedures are needed to safely evaluate potentially contagious patients.
- Emergency departments should have a cadre of smallpox-vaccinated healthcare workers.

CASE PRESENTATION

The right index finger of a child has a lesion with a raised border and necrotic center 14 days after a prairie dog bite and 11 days after a febrile illness.¹² Secondary lesions also present on the dorsum of the left hand. The pustules are raised, firm, several millimeters in diameter, and with erythematous flares. One day previously, her mother developed fever, sweats, malaise, and sore throat. The mother has smaller disseminated umbilicated vesicles. The family has multiple animals, including cats, dogs, horses, goats, and donkeys.

Hantavirus Pulmonary Syndrome Attack

Bonnie H. Hartstein and Curtis J. Hunter

DESCRIPTION OF EVENT

Hantavirus pulmonary syndrome (HPS) is characterized by rapidly developing non-cardiogenic pulmonary edema, which develops after infection with rodent-borne *Hantavirus*. Early recognition of HPS is essential as the initial flu-like symptoms of malaise, fever, and muscle aches can progress to shock and complete respiratory failure within a few days.¹ Although hantavirus has not been weaponized or used for bioterrorism to date, it is recognized by the Centers for Disease Control and Prevention (CDC) as a category C agent, an emerging pathogen that could be engineered for mass exposure in the future because of its presumed ease of production and dissemination, and potential for high morbidity and mortality.² A genus of the family Bunyaviridae, *Hantavirus* was first isolated in Korea in 1978 as the culpable agent in the Old World disease known as hemorrhagic fever with renal syndrome (HFRS), an acute prostrating febrile illness with renal failure and shock.^{3,4} In 1993 a mysterious clinical entity causing fever, rapid respiratory failure, and cardiopulmonary dysfunction killed 29 people in the southwestern United States.⁵ Linked by genetic sequencing to a previously unknown *Hantavirus* species but lacking the renal and hemorrhagic manifestations, the disease was named hantavirus pulmonary syndrome and changed the recognized spectrum of hantavirus disease.

Over 20 different sero/genotypes of *Hantavirus* have been identified, each maintained in nature by a single unique rodent species. Human infection occurs through inhalation of aerosolized virus shed in rodent saliva, urine, and feces, or by direct inoculation via rodent bites.⁴ The primary causative agent of the largest outbreak in the United States, the Sin Nombre virus, is carried by the deer mouse, *Peromyscus maniculatus*. Other hantaviruses known to cause HPS in the United States include the New York, Black Canal, and Bayou viruses hosted by the white-footed mouse (*Peromyscus leucopus*), the cotton rat (*Sigmodon hipidus*), and the rice rat (*Oryzomys palustris*). The rodent reservoir of the Seoul virus, *Rattus norvegicus*, thought to have been brought by cargo ship to the Western Hemisphere from Europe, has caused the only cases of HFRS documented in the United States.⁶ Nearly all of the United States falls within

range of one or more hantavirus-carrying rodent species, all of which cause HPS.

The incubation period for human hantavirus infections is documented from 4 to 42 days, with an average range of 12 to 16 days.⁷ HPS progresses through four clinical phases: prodrome, pulmonary edema and shock, diuresis, and convalescence.⁸ The initial prodrome lasts for 3 to 6 days and is characterized by malaise, myalgia, fever, tachypnea, and gastrointestinal symptoms such as nausea, vomiting, diarrhea, or abdominal pain. In 10% of cases the abdominal pain is reported to be severe enough as to mimic appendicitis.¹ Presenting symptoms may overlap with more common viral infections, challenging early recognition by healthcare workers. One study attempting to quantify a clinically distinct constellation of symptoms suggests excluding patients with rapid Influenza A proven infection from consideration and that the presence of sore throat or nasal symptoms and the finding of an injected pharynx are less likely to be associated with HPS.⁹

The subsequent cardiopulmonary phase is heralded by the acute onset of non-cardiogenic pulmonary edema.¹⁰ Clinically, patients have progressive cough and shortness of breath. On the cellular level, significant capillary leak in pulmonary endothelial cells occurs.^{7,10} The time interval from the development of dyspnea to the need for ventilator support is reported to be within 1 to 6 hours, underscoring the extremely rapid progression of respiratory collapse.^{1,8} Other signs include hypoxia and copious amber-colored non-purulent secretions with secretion protein/serum protein ratio greater than 80%.^{5,11}

Specific laboratory and radiographic findings that are suggestive of HPS assist in diagnosis and should raise clinical suspicion. A peripheral blood smear triad of thrombocytopenia, leukocytosis with left shift, and circulating immunoblasts are unique to HPS in North America.¹¹ Elevated lactate levels, and hemoconcentration up to 77% that corrects to anemic levels after fluid resuscitation, are observed.¹² Radiographically HPS is distinguished by the central location of infiltrates rather than the peripheral pattern typically seen in ARDS and the lack of focal consolidation common in most pneumonias.⁹

The sepsis syndrome observed in HPS features a diminished cardiac index and normal or elevated systemic vascular resistance, which is the opposite of that

typically seen in sepsis.¹³ Hypotension, which may be seen initially, is a result of low cardiac stroke volume resulting from inadequate left ventricular preload exacerbated by myocardial depression and is usually marked by hemoconcentration.

Death rates range between 50% and 70% with cardiogenic shock and pulseless electrical activity as the proximate cause.⁵ Survivors of the cardiopulmonary phase recover quickly with a spontaneous diuresis occurring 2 to 5 days after the onset of pulmonary edema, usually facilitating extubation within 1 week of initiating ventilator support. Convalescence ensues with minor residual respiratory impairment.⁸

Identification of the virus is achieved through serologic testing in the acutely ill for IgG and IgM antibodies to viral nucleocapsid proteins.¹ ELISA assays are available at most state public health laboratories or by state health department referral at CDC.⁶ Because of the time delay before results are obtained, a recombinant immunoblot assay in the form of a test strip is being evaluated.¹

PRE-INCIDENT ACTIONS

Exposure of individuals or groups to hantavirus might occur naturally as a result of increased exposure caused by an environmental change such as increased rodent food production or decreased rodent predator population, or because of a planned bioterrorist attack. Similar to the epidemic that heralded the discovery of HPS in the southwestern United States in 1993, individuals or groups of people can be exposed through contact with contaminated material. Increased rodent population or high-risk activities such as cleaning enclosed rodent-infested areas can lead to infection.

Disaster scenarios, either naturally occurring or as a result of terrorism, that displace populations, disrupt the sanitation infrastructure, or create living conditions where people are forced to reside in makeshift structures or sleep on the ground significantly increase the risk of hantavirus exposure. Risk reduction suggestions published by the CDC serve as a useful guide to mitigate risks. Actions to reduce exposure to rodents involve securing food and trash in rodent-proof containers; keeping items that attract rodents such as garbage cans, woodpiles, and bird feeders far from human dwellings; and using raised cement foundations in new construction of outbuildings or shelters.¹⁴

Hantavirus is recognized as an emerging pathogen for bioterrorism because of its relative ease of transmission and high mortality. Dissemination would most likely occur via aerosolization of infectious particles released over populated areas. Bioterrorists might use low-flying aircraft, munitions, or indoor contamination through air ducts to initiate exposure.

POST-INCIDENT ACTIONS

Suspicious patterns of disease presentation would be the first clue that an HPS outbreak had occurred at the hands

of bioterrorists. An understanding of the demographic distribution of naturally occurring hantavirus infection allows the healthcare professional to recognize unusual variations and to suspect bioterrorist activity. Infection caused by hantavirus and rodent hosts not recognized in the United States, an infectious disease consistent with HFRS in the New World, and disease in nonendemic areas or in patients with no travel history should all raise suspicion of an unnatural or deliberate infection. Virus isolation, genotyping, and comparison to known national and world prevalence data could unveil irregular geographic incidence patterns.

Cases of natural hantavirus have generally occurred in young adults and previously healthy persons because exposure occurred during activities like farming, cleaning, or camping.⁵ An attack generated by terrorism with infectious particles in high concentration on the ground or in soil in densely populated areas might affect children, who are smaller and shorter, in greater proportion than observed naturally. Also, an increase in disease incidence without a rise in the endemic rodent population or in persons not exposed to rodents should raise suspicion.

Universal precautions and respiratory isolation of affected individuals is recommended. Although person-to-person transmission is generally not recognized, during one hantavirus outbreak in Argentina, five health care workers involved in treating HPS patients may have contracted disease without known exposure to rodents.³

MEDICAL TREATMENT OF CASUALTIES

Supportive care is the mainstay of treatment for HPS. Volume replacement must be cautious and conservative because of the potential for significant pulmonary capillary leak. Pulmonary artery occlusive pressures higher than 10-12 mmHg are associated with significant pulmonary edema. Classic to HPS is a shock state characterized by decreased cardiac output and increased systemic vascular resistance, although frank hypotension is also observed. Use of inotropic agents such as dobutamine should usually be accompanied by judicious volume resuscitation. Despite the presence of severe pulmonary edema, adequate oxygenation can usually be maintained with mechanical ventilation and high levels of positive end-expiratory pressure.¹

Further studies on the treatment of HPS are needed to assess the role of immunologic therapy and inflammatory mediators on vascular function, as well as the use of antiviral agents such as ribavirin, which has been shown to reduce mortality in HFRS.⁶ It is also conceivable that some added benefit could be achieved by applying the principles of early goal-directed therapy, which is showing some promise among patients with sepsis.

UNIQUE CONSIDERATIONS

The importance of rapid recognition of HPS and the need for widespread dissemination of information

between other health care institutions and health departments is the key to effective management. Since nearly all infected patients become ventilator dependent, the prospect of a mass casualty situation caused by HPS could prove catastrophic unless adequate intensive care unit capabilities were mobilized and appropriately staffed to augment local healthcare facilities.

PITFALLS

- Failure to rapidly recognize the symptoms of HPS and to disseminate information to other health care institutions and health departments

CASE PRESENTATION

A 24-year-old male presents to the emergency department of a small community hospital with a chief complaint of flu-like symptoms and cough. He states that 3 days ago he awoke with a headache, general malaise, vomiting, diarrhea, and crampy abdominal pain, which he initially attributed to a hangover and food poisoning. Over the following days the symptoms persisted and worsened. Most concerning to him is a dry cough with amber-colored sputum that started last night, kept him from sleep, and prevented him from his normal routine of running in the morning. He states he just returned from a trip to White Sands Proving Ground, Arizona where he participated in a commemorative marathon honoring military troops killed in combat. He states that two of his close friends who also participated in the event are developing the same symptoms. His vital signs are pulse 86, respiratory rate 22, blood pressure 112/78, temperature 101.4 °F and pulse oximetry 99% on room air. A chest radiograph reveals early interstitial edema with Kerley B lines and peribronchial cuffing. The patient begins to complain of dyspnea and the pulse oximetry continues to decline despite switching to a non-rebreather mask with high flow oxygen. A portable chest radiograph reveals significantly worsening pulmonary edema and the patient is electively sedated and intubated for respiratory failure.

- Failure to recognize respiratory failure and initiate appropriate ventilatory support
- Failure to prepare for significant numbers of patients requiring ventilator support
- Failure to judiciously manage fluid balance and cardiovascular status

Hendra and Nipah Virus Attack (Hendra Virus Disease and Nipah Virus Encephalitis)

Kelly J. Corrigan

DESCRIPTION OF EVENT

Both the Hendra virus and the Nipah virus belong to the same subfamily, *Paramyxoviridae*. They have both been identified in various zoonotic disease outbreaks in Southeast Asia and Australia within the past 10 years. Formerly known as the equine Morbillivirus, Hendra virus was the first to be identified and has been implicated in three separate disease outbreaks in Queensland, Australia between 1994 and 1999. It was first isolated in 1994 following an outbreak of severe respiratory disease in both horses and humans in Brisbane, Queensland, Australia.¹⁻³ Out of 21 horses infected in the first outbreak, 14 died. Three human infections resulting in two deaths have been reported as a result of the Hendra virus. These individuals reportedly had severe flu-like symptoms and others have presented with severe, often fatal, pneumonia. Encephalitis-like clinical signs have also been reported. The primary source of the Hendra virus appears to be the black fruit bat, with birds having been implicated as carriers of the deadly virus as well.^{4,5}

The Nipah virus is genotypically similar to the Hendra virus, and they both belong to a new genus within the family *Paramyxoviridae*.⁶ Nipah has been implicated in outbreaks of encephalitis in Malaysia in 1998 and 1999. Investigations of these outbreaks concluded that the pigs and humans were likely infected with Nipah via the respiratory route. In April 1999, 100 fatal encephalitis cases were reported in Malaysia.⁷ Nipah was identified as the cause, and pigs were the primary source. However, Nipah does not appear to be transmitted from person to person.

Nipah-infected patients present with fever, headache, dizziness, vomiting, and altered mental status.⁸ Autonomic instability is also a common sequelae of infection that suggests brain stem involvement. Some patients who have undergone magnetic resonance imaging demonstrate widespread microinfarctions of the CNS, which are presumably the result of small vessel disease.⁸ This is supported by direct evidence from human autopsies that have revealed systemic CNS thrombotic occlusions and microinfarctions in victims of Nipah virus infection.⁹ The Centers for Disease Control and Prevention (CDC) has conclusively identified both of these viruses and has

developed serologic tests to detect both IgG and IgM antibodies to Hendra and Nipah.⁶ Both IgG and IgM antibodies can be detected in blood and cerebrospinal fluids.¹⁰

PRE-INCIDENT ACTIONS

In preparation for potential chemical and biological terrorist attacks, the Committee on Research and Development to Improve Civilian Medical Response recommends that major hospitals conduct mass-casualty planning and training; designate isolation rooms available for infectious diseases, create decontamination capacity, and be fully supplied with drugs, ventilators, and personal protective equipment.¹¹ The committee also encourages the CDC to keep medical care providers up to date on current dangerous biologic materials and promotes advance notice from law enforcement agencies regarding potential terrorist incidents. The CDC must maintain a containment level 4 laboratory in order to run the appropriate tests that identify Nipah and Hendra, without risking further human infection.

POST-INCIDENT ACTIONS

Suspicion of an outbreak of Hendra or Nipah virus infection should be reported to the proper authorities (local public health and CDC) immediately so that appropriate diagnostic and response measures can be taken. Isolation of the viruses, as previously mentioned, should only be done in a biosafety level 4 containment laboratory located at either The United States Army Medical Research Institute for Infectious Diseases (USAMRIID) or the CDC.⁶ Human-to-human transmission is not known. Infected patients should be treated by following standard precautions.

Infected animals apparently excrete the Hendra virus through their urine, therefore, in order to prevent further transmission of Hendra virus, it is recommended that horse stables follow strict hygiene guidelines.⁴ Nipah outbreak control has been accomplished in Malaysia through the mass culling of hundreds of thousands of potentially infected pigs and by banning the importation

of pigs into the country. Other efforts include educational programs directed at farmers and a national surveillance program to monitor for outbreaks of disease.¹

MEDICAL TREATMENT OF CASUALTIES

Supportive therapy should be initiated as appropriate, including airway management and ventilatory support. Previous work has demonstrated the drug ribavirin to be effective against both Hendra and Nipah viruses *in vitro*.² A trial of ribavirin in 140 patients infected with Nipah virus, with 54 of these patients serving as the control, showed 32% mortality in the ribavirin group compared with 54% mortality in the control group.¹² Given the low side effect profile of ribavirin in the acute treatment setting, ribavirin should be seriously considered in Nipah virus victims as well as Hendra virus infections, since they are similar sub-types.

The dosing of ribavirin is 30 mg/kg IV once (maximum of 2 g) followed by 16 mg/kg IV (maximum 1 g/dose) every 6 hours for 4 days, then 8 mg/kg IV (maximum 500 mg/dose) every 8 hours for 6 days. In the event of mass casualties, oral ribavirin may be given at the dose of 2000 mg loading, followed by 600 mg twice a day if greater than 75 kg, and 400 mg in AM, 600 mg in PM if less than 75 kg for 10 days. Children follow the same dosing guidelines, with the exception that oral ribavirin is given at 30 mg/kg loading, followed by 15 mg/kg/day divided into twice-daily dosing for 10 days.⁶

Research continues on the development of vaccine against Nipah virus infection.³

UNIQUE CONSIDERATIONS

Since Hendra virus infection may resemble severe influenza and since Nipah-infected patients present with symptoms similar to meningitis and encephalitis, suspicion for infection with these organisms will largely be based on an appropriate history. Hendra virus has been diagnosed only in humans who were exposed to secretions and bodily fluids of infected horses. Human Nipah infections were identified mostly in humans exposed to infected pigs; however, the World Health Organization has received recent reports of infections among children in Bangladesh who had no known exposure to swine.⁵ The fruit bat is suspected as the primary source in these cases, but the specific mode of transmission remains to be identified. No human-to-human transmission has been reported. Both Hendra and Nipah virus have short incubation periods and high mortality.

PITFALLS

- Failure to suspect Hendra or Nipah when the history suggests these as a possible etiology.

- Failure to immediately report suspicious cases to the CDC for definitive diagnostic studies in a level 4 bio-containment laboratory.
- Failure to consider treatment with ribavirin in the acute setting.

CASE PRESENTATION

A 41-year-old male presents to the emergency department with a 5-day history of flu-like symptoms, fever, cough, and now shortness of breath. He denies headache, rash, nausea, vomiting, diarrhea, or abdominal pain. He has no known medical problems and no HIV risk factors. He cleans horse stables for a living and a new shipment of horses came in 2 weeks ago from Australia. A co-worker has been complaining of some of the same symptoms since yesterday. His vital signs are: temperature 102.1°F, heart rate 110, blood pressure 123/79, respiratory rate 24, and room air oxygen saturation of 93%. His chest radiograph shows a small right lower lobe infiltrate.

SARS-CoV Attack (Severe Acute Respiratory Syndrome)

Suzanne M. Shepherd, Stephen O. Cunnion,
and William H. Shoff

DESCRIPTION OF EVENT

The events unfolding between November 2002 and June 2003, which heralded the advent of severe acute respiratory syndrome (SARS), effectively demonstrated one significant downside of globalization and air travel: the ability to rapidly disseminate lethal respiratory infections worldwide. Although SARS was a natural biologic pandemic, it tested the global medical community's ability to recognize and rapidly respond to a potential covert biologic weapon attack. Dispersion of a previously unknown biologic agent produced illness after a relatively short incubation period, when victims had already dispersed to five continents. Effective medical response depended upon the ability of astute clinicians, not sophisticated electronic surveillance, to identify the case cluster announcing the presence of a new illness.

Although many details regarding SARS-CoV, its origin, spreading mechanisms, full extent of illness, and effective management remain to be elucidated, much has already been determined. SARS-CoV, a novel *Coronavirus* species, produces a rapidly progressive atypical pneumonia. Coronaviruses are a family of enveloped, single-stranded RNA viruses that produce disease in several animal species, including humans. Seroepidemiologic data suggest that SARS-CoV originated as an animal virus, with live game animal markets hypothesized to be the potential site of recent interspecies transmission.¹⁻³ Isolation of SARS-CoV from several species, including the palm civet (*Paguma larvata*), suggests a wide range of host hiding places for SARS between human epidemics. SARS-CoV is the cause of SARS, as it satisfied all four of Koch's postulates. Reverse transcriptase polymerase chain reaction (RT-PCR) and virus isolation demonstrated virus from lung biopsy specimens, feces, urine, and respiratory secretions in SARS patients, but not controls. Seroconversion to SARS-CoV was shown in ill patients. Experimental cynomolgus macaque infection with SARS-CoV produced pneumonia pathologically similar to SARS in humans.⁴⁻⁹ No vector has been identified.

Several SARS-CoV characteristics make it an interesting bioweapon candidate. Its unique RNA-dependent

RNA polymerase allows for ready mutation and potential adaptation. It shows moderate transmission, with two to four secondary cases, and *occasional "super-spreader" events, involving transmission to multiple individuals.* Within months, more than 8000 individuals were infected and 774 individuals died in 26 countries on five continents. SARS-CoV has an incubation period of 2 to 10 days (median 4-7 days; range 2-14 days). Although mild and asymptomatic cases have been documented, they are uncommon and do not appear to contribute to infection spread. SARS-CoV is stable, surviving for many days in feces and for 1 or more days on hard surfaces.

The primary mode of transmission is via direct or indirect mucous membrane contact with infectious respiratory droplets or fomites.¹⁰ Fecal-oral transmission may be an important secondary means, as virus is found in large quantities in stool and profuse, watery diarrhea is not uncommon.^{5,11,12} Transmission is not described before clinical illness onset, which corresponds with peak viral load at day 12 to 14 of symptoms. As such, early patient isolation may facilitate transmission prevention.¹¹ Transmission occurs with close patient contact, with passage to casual contacts being unusual. Transmission is facilitated by aerosol-generating procedures in medical settings. Seasonality is suspected but remains to be elucidated.

SARS affects individuals of all age groups and immune status, although children appeared less severely affected in the 2003 epidemic. Infected individuals initially experience fever, myalgias, and chills. Cough is common early, but tachypnea and shortness of breath are more prominent later in the illness. The elderly may not present with fever but may manifest decreased appetite and malaise.¹³ Upper respiratory symptoms are uncommon, perhaps serving as one clinical clue differentiating a cluster of epidemiologically linked SARS patients from those with other atypical pneumonias. Pulmonary findings, such as rales, occurred in less than one third of SARS cases, and often did not correlate clinically with chest radiography (CXR) findings.^{7,14} Twenty percent of patients had prominent gastrointestinal symptoms, including watery diarrhea. CXR findings appear to correlate with the rapidity at which patients require

hospitalization. The most common initial findings on CXR are ground-glass opacifications or focal consolidations of the peripheral, subpleural lower lung fields. In 67% of patients with an initially normal CXR, findings appear on subsequent high-resolution chest tomography (HRCT). Pleural effusions, mediastinal lymphadenopathy, and cavitation are rare.¹⁶ One third of SARs patients showed improvement, with defervescence and radiographic resolution over several weeks. In the remainder, fever persisted and progressive shortness of breath, hypoxia, tachypnea, increasing auscultative findings, and often diarrhea were noted. Serial radiography, or HDCT, revealed progression to multifocal unilateral or bilateral air-space consolidation, and often non-iatrogenic pneumomediastinum. Approximately 20% to 30% of patients require intensive care. Death is usually due to respiratory failure and/or multiple organ failure, sepsis, or accompanying cardiac decompensation. Later lung findings include diffuse alveolar damage, edema, hyaline membrane formation, pneumocyte desquamation, giant cells, a high viral load, and an inflammatory infiltrate.^{6,14,17} Mortality risk factors, determined by multivariate regression analysis, include advanced age, co-morbid cardiovascular disease and diabetes, and high neutrophil and lactate dehydrogenase levels on presentation.^{17,18} Between 6% and 20% of recovered patients have some residual respiratory impairment.³

Clinical manifestations are nonspecific. In one study, the WHO case definition was shown to be 96% specific but only 26% sensitive.³ Laboratory data are nondiagnostic; however, lymphocytopenia is common and thrombocytopenia may be noted. Alanine aminotransferase, lactate dehydrogenase, and creatine kinase levels may be elevated. Although RT-PCR has been shown to be diagnostic in respiratory and fecal specimens, and viral RNA is detectable in serum and urine, the CDC and WHO do not deem RT-PCR currently reliable to rule out SARS infection.¹⁹ Lower respiratory tract specimens are the most useful but place healthcare providers at the most risk of transmission via aerosol generation.²⁰ Seroprevalence 21 to 28 days after symptom onset (whole-virus immunoassay via IFA or ELISA) remains the gold standard to confirm SARS infection.²¹

PRE-INCIDENT ACTIONS

Pre-incident actions focus on preparedness, healthcare provider education, and surveillance. Active syndromic surveillance for fever and respiratory symptom clusters should occur. Research focuses on improving testing sensitivity earlier in illness and on finding effective antiviral and immunomodulating agents.²¹

Emergency department, hospital, and outpatient facilities should have disaster plans in place that address bioterrorist attack/major infectious disease outbreaks, and they should regularly conduct mock attacks. The importance of incorporating travel, immigration, and contacts into routine history-taking must be reinforced. Facilities should upgrade isolation and ventilation systems, using increased air flow in clustered negative pressure rooms. Strict staff universal precautions, frequent

and thorough hand-washing, and the use of properly fitting N95 respiratory masks must be stressed.²² Measures should be delineated for changing triage guidelines to accommodate rapid increases in patient census; isolating patients; and safely holding large numbers of ill and infectious patients in the likely advent of hospital overloading. These plans, developed in coordination with those of local, state, and federal EMS, public health and government agencies should specify leadership and decision-making roles.²³ Policies regarding restricted public gatherings, contact quarantine, and prepared quarantine facilities, if individuals will not maintain home quarantine, should be in place.^{24,25} The possibility of contracting SARS-CoV by particle inhalation from laboratory culture is significant, and negative pressure measures and BSL-3 procedures within laboratories should be used.²⁶

POST-INCIDENT ACTIONS

Healthcare providers entertaining a high level of suspicion for a possible SARS-CoV attack should notify hospital infection control, the administrator on duty, and the local public health officer. Appropriate local, state, and federal public health and law enforcement authorities should be involved. In the healthcare area, provision of adequate supplies and reinforcement of patient isolation, mask placement, and thorough hand-washing precautions should be enforced immediately and strictly. Healthcare provider use of N-95 mask, eye protection, gown, shoe covers, and gloves must be enforced; adequate equipment ensured; and clearly marked biohazardous waste receptacles placed to facilitate use and disposal. Rooms, materials, and surfaces possibly contaminated by SARS-CoV patients should be disinfected appropriately with hypochlorite solution. Aerosol-generating procedures, such as intubation and bronchoscopy, if necessary, should be performed by highly experienced staff under the most strict infection control precautions. Exclusion from duty should be considered for exposed unprotected healthcare workers, with temperature and symptom monitoring. Visitors should be excluded from contact with suspected SARS-CoV patients and their close contacts.²⁵

MEDICAL TREATMENT OF CASUALTIES

Treatment of SARS-CoV patients focuses on emergency management of life-threatening complications and ventilatory support. Interventions to manage profound hypoxemia should be instituted, including intubation, sedation, paralysis, lung recruitment maneuvers, and high-frequency, low-tidal volume and inflation pressure ventilator management.²⁸ To date, no efficacious antiviral or antiinflammatory drugs are identified.^{3,27} Current research focuses on candidate antiviral agents and vaccine development. If patients are not sick enough to warrant admission, they should be sent home, with strict guidelines regarding activity restriction and hospital return if symptoms worsen.^{12,25}

UNIQUE CONSIDERATIONS

SARS-CoV has several potential advantages over other respiratory biologic weapons because of its clinical similarity to other common atypical pneumonias, its relative stability, and its spread potential by large droplets, stool, and on fomites. Its unique RNA-dependent RNA polymerase allows for mutation and adaptation to adverse conditions. SARS-CoV release into a community could produce a large number of casualties in a relatively short period and allow widespread dispersion of infected individuals before symptoms manifest. Potential disadvantages of SARS-CoV use include the lack of transmission before clinical illness onset, suggesting that early patient isolation may facilitate transmission prevention and its apparent uncommon transmission to casual contacts. An aerosolized SARS-CoV attack would most likely occur in a large urban setting transportation hub, allowing significant spread over large population areas globally. Identification of SARS-CoV as the cause, without the obvious epidemiologic clue of an outbreak in another country, would be delayed because of its clinical similarity to other atypical pneumonias during respiratory virus season.

PITFALLS

- Failure to prepare, and frequently test, a system's ability to respond to potential terrorist attacks in advance
- Failure to notify appropriate public health agencies when an outbreak of atypical lower respiratory illness is suspected
- Failure to ask an appropriate travel, immigration, and exposure history
- Failure to adequately isolate patients suspected of having SARS
- Failure of medical staff to use appropriate respiratory and contact precautions

CASE PRESENTATION

A 25-year-old student presents with fever and malaise for 2 days and increasing cough today and has right-sided rales on pulmonary examination. The patient is requesting a chest radiograph and a prescription for azithromycin, which has "worked in the past." A travel history discovers that she just returned 8 days ago from visiting her cousin in Singapore. She states that her cousin is proud of his job, testing antiviral agents against SARS-CoV, and she toured the facility and was introduced to his co-workers.

Staphylococcal Enterotoxin B Attack

Robert G. Darling

DESCRIPTION OF EVENT

Staphylococcus aureus produces a number of exotoxins including staphylococcal enterotoxin B (SEB). Such toxins are referred to as *exotoxins* because they are excreted from the organism that synthesizes them. Because they normally exert their pathologic effects on the gastrointestinal tract, they are also called *enterotoxins*. SEB causes a markedly different clinical syndrome when inhaled than it characteristically produces when ingested. Significant morbidity is produced in persons who are exposed to this toxin by either portal of entry to the body.

SEB is one of the most common causes of food poisoning. It is a pyrogenic toxin that commonly causes food poisoning in humans when improperly handled foodstuffs are contaminated with *S. aureus*, which in turn produces and releases SEB into the food that is subsequently ingested, causing illness. Often these outbreaks occur in a setting such as a picnic or other community event due to common source exposure in which contaminated food is consumed. Although an aerosolized SEB toxin weapon would not likely produce significant mortality, it could render a significant percentage of an exposed population clinically ill for 1 to 2 weeks.¹ The demand on the medical and logistical systems could be overwhelming. For these reasons, SEB was one of several biologic agents stockpiled by the United States during its biologic weapons program, which was terminated in 1969.²

Staphylococcal enterotoxins are proteins produced by coagulase-positive staphylococci. Up to 50% of clinical isolates of *S. aureus* produce exotoxins. They are produced in culture media and also in foods when there is overgrowth of the organism. SEB is one of at least seven antigenically distinct, moderately stable enterotoxins that have been identified. SEB causes symptoms in humans when inhaled at doses at least 100 times less than the lethal dose that would be sufficient to incapacitate 50% of those exposed.¹ This toxin could also be used to sabotage food or small-volume water supplies.

Staphylococcal enterotoxins belong to a class of potent immune stimulants known as bacterial superantigens.³ Superantigens bind to monocytes at major histocompatibility complex type II receptors rather than the usual antigen-binding receptors. This leads to the direct stimulation of large populations of T-helper lymphocytes while bypass-

ing the usual antigen processing and presentation pathway. This induces a brisk cascade of proinflammatory cytokines (such as tumor necrosis factor, interferon, interleukin-1, and interleukin-2), with recruitment of other immune effector cells and relatively deficient activation of counter-regulatory immune inhibitory mechanisms. This results in an intense inflammatory response that injures host tissues. Released cytokines are thought to mediate many of the toxic effects of SEB.⁴

Symptoms of SEB intoxication begin after a latent period of 3 to 12 hours after inhalation, or 4 to 10 hours after ingestion. Symptoms include nonspecific flu-like symptoms (e.g., fever, chills, headache, myalgias) and specific clinical features dependent on the route of exposure. Oral exposure results in predominantly gastrointestinal symptoms: nausea, vomiting, and diarrhea. Inhalation exposures produce predominantly respiratory symptoms: nonproductive cough, retrosternal chest pain, and dyspnea. Gastrointestinal symptoms may accompany respiratory exposure due to inadvertent swallowing of the toxin after normal mucociliary clearance of toxin-containing secretions from the respiratory tract.

Respiratory pathology is due to the activation of proinflammatory cytokine cascades in the lungs, leading to pulmonary capillary leak and pulmonary edema. Severe cases may result in acute pulmonary edema and respiratory failure.⁵ Fever may last up to 5 days and range from 103° to 106° F, with variable degrees of chills and prostration. The cough may persist up to 4 weeks, and patients may not fully recover for 2 weeks.

Physical examination in patients with SEB intoxication is often unremarkable. Conjunctival injection may be present, and postural hypotension may develop due to fluid losses. Chest examination yields unremarkable results except in the unusual case in which pulmonary edema develops, when rales may be heard on auscultation. The chest x-ray also generally has normal results, but in severe cases increased interstitial markings, atelectasis, and possibly overt pulmonary edema or adult respiratory distress syndrome may occur.

PREINCIDENT ACTIONS

It is essential that hospitals have a well-developed emergency response plan that is regularly exercised by hospi-

tal staff and is well integrated into community, state, and federal emergency response plans. There should be robust plans in place to expand patient care facilities to accommodate large numbers of sick patients who self-refer or who arrive by ambulance. At the present time, there is no vaccine available for human use to protect against aerosol exposure to SEB; however, studies in animals are promising, and human trials may begin soon.⁶

POSTINCIDENT ACTIONS

Identifying aerosolized SEB as the cause of a mass-casualty event will be difficult unless the healthcare provider considers exposure to this toxin early in the course of the event. One must maintain a high index of suspicion. The differential diagnosis for patients presenting with a febrile respiratory illness is quite large and involves most respiratory pathogens including many bacteria and viruses. Diagnosis of SEB intoxication is based on clinical and epidemiologic features. The symptoms of SEB intoxication may be similar to several respiratory pathogens such as influenza, adenovirus, and mycoplasma. Persons experiencing any of these symptoms might present with fever, nonproductive cough, myalgias, and headache. The epidemiologic pattern of the illness outbreak is an important clue for determining the causative agent of, as well as the circumstances leading to, the epidemic (i.e., a naturally occurring or biologic attack). SEB attack would cause cases to present in large numbers over a very short period of time, probably within a single 24-hour period. Naturally occurring pneumonias or influenza would involve patients presenting over a more prolonged interval of time. Persons with naturally occurring staphylococcal food-poisoning would not exhibit pulmonary symptoms. Because it is not an infection, SEB intoxication tends to plateau rapidly to a fairly stable clinical state, whereas inhalational anthrax, tularemia pneumonia, or pneumonic plague would all continue to progress if left untreated. Tularemia and plague, as well as Q fever, would be associated with infiltrates on chest radiographs. Other diseases, including hantavirus pulmonary syndrome, *Chlamydia pneumoniae* infection, and chemical warfare agent inhalation (e.g., mustard and phosgene) should also be considered.

Laboratory confirmation of SEB intoxication includes antigen detection enzyme-linked immunosorbent assay) and electrochemiluminescence on environmental and clinical samples and gene amplification techniques (polymerase chain reaction to detect staphylococcal genes) on environmental samples.⁷ SEB may not be detectable in the serum by the time symptoms occur; regardless, a serum specimen should be drawn as early as possible after exposure. SEB accumulates in the urine and can be detected for several hours after exposure. Therefore, urine samples should also be obtained and tested for SEB. Respiratory secretions and nasal swabs may demonstrate the toxin early (within 24 hours of exposure). Because most patients will develop a significant antibody response to the toxin, acute and convales-

cent sera should be drawn for retrospective diagnosis. Nonspecific findings include a neutrophilic leukocytosis, an elevated erythrocyte sedimentation rate, and chest x-ray abnormalities consistent with pulmonary edema.

Once a mass-casualty situation is recognized as a possible bioterrorism event, the hospital's emergency plan should be activated. Simultaneously, public health and law enforcement officials should be notified. An epidemiologic investigation should begin immediately.

Standard precautions are sufficient because SEB intoxication is not contagious and secondary aerosol production is unlikely. Decontamination with soap and water is sufficient.

MEDICAL TREATMENT OF CASUALTIES

Supportive care is the current mainstay of treatment. Attention to oxygenation and hydration is essential. Most patients' conditions will quickly stabilize after the acute phase of the illness; rarely, some patients may develop acute pulmonary edema requiring intubation and mechanical ventilation.

CASE PRESENTATION

Thirteen patients suddenly present to your emergency department after attending a major football bowl game earlier in the day. There was national interest in the game, and the press covered the event heavily on both radio and television. The national terrorism threat level had not changed from "elevated" prior to the game, and there was no unusual terrorist "chatter" being reported by the Department of Homeland Security.

Most of the patients presenting for care are young college students. All attended the bowl game that afternoon. Several are in acute respiratory distress. All have fever and cough. You immediately suspect some sort of toxic exposure. As you begin administration of supplemental oxygen and monitoring of several of the sicker patients, you begin to consider the differential diagnosis. You attempt to gather additional history and learn that nothing out of the ordinary occurred during the game. One of the students tells you there was an "awesome" halftime show involving a flight demonstration by a number of small airplanes that flew over the stadium performing aerobatics. One plane appeared to be producing more smoke than the others, and for a moment some thought the plane might be experiencing an engine malfunction, but when it continued to fly normally, this idea was dismissed.

Suddenly the phone rings. You are told by your local emergency medical systems director that hundreds of patients are requesting ambulance transport to your facility.

UNIQUE CONSIDERATIONS

SEB toxin is one of the most ubiquitous toxins in nature and, in its natural state, is one of the most common

causes of food poisoning. However, respiratory disease caused by exposure to an SEB aerosol is never a natural event and will almost certainly be due to either a laboratory accident or bioterrorism.

The U.S. government weaponized SEB in the 1960s and investigated its use on the battlefield as an incapacitating agent.² The toxin was especially attractive because of the extremely small doses required to cause incapacitating illness in soldiers. The incapacitating dose, or effective dose to produce 50% casualties (ED₅₀), was found to be 0.0004 µg/kg; the lethal dose (LD₅₀) was estimated to be 0.02 µg/kg. Both measurements were taken in terms of the inhalational route.²

Ingestion of SEB toxin causes classic food poisoning: nausea, vomiting, and diarrhea without fever. Aerosol exposure produces a far different clinical picture consisting of fever, headache, severe respiratory distress, and sometimes nausea, vomiting, and diarrhea. The gastrointestinal symptoms seen after aerosol exposure are most likely due to the swallowing of toxin from respiratory tract secretions and are not likely to be as severe as those seen in primary gastrointestinal SEB exposure.

Prophylactic administration of an investigational vaccine protects laboratory animals against aerosol exposure and is nearing transition for study in humans.⁶ However, it is not currently available for clinical use.

PITFALLS

Several potential pitfalls in response to an SEB attack exist. These include the following:

- Failure to consider aerosolized SEB as the potential cause for large numbers of patients presenting with an acute febrile respiratory illness

- Failure to notify laboratory personnel of a suspected case of SEB intoxication and failure to collect appropriate clinical specimens to aid in the diagnosis, including nasal swabs and urine
- Failure to notify appropriate law enforcement and public health authorities in the event of a suspected biologic attack

Clostridium botulinum Toxin (Botulism) Attack

Gary M. Vilke

DESCRIPTION OF EVENT

Botulinum toxin has been used by terrorists as a bioweapon, although unsuccessfully, on several occasions. *Clostridium botulinum* was obtained from soil and cultivated, and the toxin was then collected. The attacks likely failed due to faulty microbiologic techniques, deficient aerosol-generating equipment, or internal sabotage.¹ As with many biologic agents, it is not likely that a terrorist attack using botulinum toxin will be reported or even noticed at the time it occurs.

There is a variable delay before the effects of botulinum toxin poisoning become clinically apparent, depending on the route of exposure, with as little as 2 hours before onset of symptoms and up to a week or more after ingestion. Patients will initially present with prominent bulbar palsies including blurred vision, mydriasis, diplopia, ptosis, and photophobia. Dysarthria, dysphonia, and dysphagia also tend to present early in the clinical course. Patients will be afebrile with a clear sensorium and, as symptoms progress, will develop progressive, symmetrical, descending skeletal muscle paralysis to the point of respiratory failure when muscles of respiration become involved.

PREINCIDENT ACTIONS

Background knowledge of *C. botulinum*, the bacterium that produces botulinum toxin, is critical if diagnosis and treatment are to be rendered in a timely manner to prevent significant casualties from an exposure, either accidental or intentional. Botulinum toxins compose a family of neurotoxic proteins produced and secreted by the anaerobic bacteria *C. botulinum*. There are seven serotypes, A through G, that are produced by different strains of the bacteria, all acting by similar mechanisms and with slight variations in their effects. Although technical factors would make such dissemination difficult, a single gram of crystalline toxin effectively weaponized and aerosolized would kill more than 1 million people.¹ These toxins are the most poisonous substances known

with an oral dose lethal to 50% of an exposed population (LD_{50}) estimated to be 1 ng/kg.² This lethality is consistent in laboratory animals whether the toxin is given by the subcutaneous, intravenous, or intraperitoneal route. The inhalational route appears to have less toxicity, with the human LD_{50} for inhalation estimated at 3 ng/kg.³

Botulinum toxin's site of action is within the presynaptic nerve terminal of the neuromuscular junction and cholinergic autonomic synapses. Botulinum toxin is a simple dichain polypeptide that consists of a 100-kd "heavy" chain joined by a single disulfide bond to a 50-kd "light" chain. The toxin's light chain is a Zn^{++} -containing endopeptidase that cleaves one or more fusion proteins, which blocks acetylcholine-containing vesicles from fusing with the terminal membrane of motor neurons, thereby preventing the presynaptic release of acetylcholine.⁴ This disrupts cholinergic neurotransmission, generating the clinical findings of bulbar palsies, skeletal muscle weakness, and paralysis. Inhibition of acetylcholine release also causes dry mucous membranes, as is seen in anticholinergic poisoning. Although nerve agent poisoning also causes muscular paralysis, the cholinergic finding of copious secretions typically differentiates it from botulism.

If an intentional exposure threat is identified by intelligence, botulinum toxin vaccines can be considered for use. The vaccine is developed by treating the toxin with formalin, destroying its toxicity, but maintaining its antigenic properties. The toxoid protects against serotypes A through E and is administered at 0, 2, and 12 weeks, followed by annual booster doses. Eighty percent of patients receiving the vaccine will develop protective titers at 14 weeks, but almost all will not have any measurable titer just before receiving the first booster dose.⁵ The 1-year booster dose will result in a robust response in almost all patients. Clinical experience with the vaccine in many persons, mostly military personnel, reflects that it is safe and effective. A recombinant vaccine is also in developmental stages.⁶

It is also important to identify the local source of any botulinum antitoxin that can be required so that it can be located quickly if it is needed.

POSTINCIDENT ACTIONS

Postincident actions include early diagnosis and initiation of treatment. With the presentation of a single patient, the diagnosis can be challenging. The classic presentation is an acute, symmetric, descending flaccid paralysis with bulbar musculature involvement in an afebrile patient. Multiple cranial nerve palsies are always associated with symptomatic botulism exposures. However, the clinical presentation is often confused early with other neuromuscular disorders, such as myasthenia gravis, Guillain-Barré syndrome, or tick paralysis.⁷ In the evaluation of such a patient, the edrophonium (Tensilon) test for myasthenia gravis may have transiently positive results for botulism. Electromyography testing characteristically shows normal nerve conduction velocity and sensory nerve function, small amplitude motor potentials, and an incremental response (facilitation) to repetitive stimulation. The cerebral spinal fluid analysis in patients with botulism is normal. Laboratory testing is of little utility in the clinical diagnosis of botulism.

Diagnosis is confirmed with a mouse bioassay neutralization test, which demonstrates botulinum toxin in bodily fluids or blood. This test is available at the Centers for Disease Control and Prevention (CDC) and a number of state and municipal public health laboratories. Samples used for this assay can include serum, stool, gastric aspirate, vomitus, and suspected contaminated foods. Serotyping of the botulinum toxin is by neutralization of the bioassay with the appropriate botulinum antisera (serotypes A through G). Because a terrorist attack is a criminal event, it is important to treat all laboratory samples collected as evidence, maintaining an appropriate chain of custody between collection and delivery to the testing agency. Serum samples must be obtained before therapy with antitoxin because it nullifies the diagnostic mouse bioassay. The mouse bioassay can detect as little as 0.03 ng of botulinum toxin and usually yields results in 1 to 2 days.⁸ Fecal and gastric specimens can also be anaerobically cultured, with results typically available in 7 to 10 days. Toxin production by culture isolates is then confirmed by the mouse bioassay.

If a respiratory route of exposure is suspected, then persons in the area where the patient was exposed should wear full-face respirators to protect themselves from residual aerosolized toxin. Environmental persistence of botulinum toxin is difficult to determine after an initial release. Conditions such as weaponization techniques, humidity, temperature, wind, and size of aerosol particles will determine the rate of atmospheric dissipation. The toxin does not penetrate intact skin, so special protective clothing is not necessary for caregivers. Botulism is not contagious and is not transmitted person to person.

Local and state health authorities must be notified quickly for several reasons. They assist in obtaining botulinum antitoxin to treat current patients and to arrange for assay tests to confirm the toxin. Additionally, health authorities assess the route of exposure and initiate tracking of other potential victims who may benefit from early intervention. If a terrorist attack is suspected, local, state, and federal law enforcement and emergency

management agencies must be notified as early as possible. This will facilitate criminal investigations and initiate activation of federal response assets, such as the Strategic National Stockpile, if needed.

The toxin is heat sensitive; therefore decontamination of equipment can be accomplished by heating to 85°C for 10 minutes or using a 0.1% hypochlorite bleach solution.

MEDICAL TREATMENT OF CASUALTIES

The two main treatment modalities available for managing botulism patients are supportive therapy and antitoxin treatments. Treatment of botulism is largely supportive, including ventilatory support if respiratory failure develops. Some patients may be mildly affected, whereas others may become completely paralyzed, appear comatose, and require months of ventilatory support. The rapidity of onset and the severity of paralysis depend on the amount of toxin absorbed into the circulation. Symptoms of foodborne botulism may begin as early as 2 hours or as long as 8 days after ingestion of toxin.⁸ The time to onset of inhalational botulism in humans was approximately 72 hours after exposure in the three known cases reported of inhalational botulism from small amounts of reaerosolized toxin.⁹

Supportive therapy involves mechanical ventilation when appropriate, and often long-term enteral feeding is necessary. In patients who do not require mechanical ventilation but have some degree of respiratory insufficiency, reverse Trendelenburg's position of 20 to 25 degrees with cervical stabilization on a rigid mattress is reported to potentially improve ventilation and respiratory excursion by reducing entry of oral secretions into the airway and by suspending more of the weight of the abdominal viscera from the diaphragm.¹ Up to 20% of patients involved in foodborne outbreaks require mechanical ventilation, and more than 60% of children suffering infant botulism require ventilation.^{10,11} Repeated bedside spirometry is used to assess diaphragmatic function. Indication for intubation is a vital capacity less than 12 to 15 mL/kg.

Antibiotics have no role in most cases of acute botulism; however, it is often recommended that patients suffering from wound botulism be treated with penicillin to eliminate the source of the toxin.¹² Patients with botulism are prone to secondary infections, particularly pneumonia. If antibiotics are required for secondary infections, aminoglycosides and clindamycin are contraindicated because they can exacerbate neuromuscular blockade.^{13,14} Activated charcoal has no reported effect in foodborne botulism.

Unlike nerve agent exposures that involve excess acetylcholine at the neuromuscular junction due to inhibition of acetylcholinesterase, botulism is caused by a lack of acetylcholine in the synapse. Therefore, pharmacologic treatments such as atropine are relatively contraindicated and could worsen the symptoms.

Beyond supportive therapy, the mainstay of treatment rests with the early use of botulinum antitoxin. Early administration of passive neutralizing antibody is critical,

so that the agent might bind with circulating toxin before it becomes tissue bound. Antitoxin will minimize subsequent nerve damage and severity of disease but will not reverse existent paralysis.¹⁵ Antitoxin should be administered to patients with neurologic signs of botulism as soon as possible and must not be delayed for laboratory confirmatory testing. In the United States, botulinum antitoxin is available from the CDC via state and local health departments. There are three forms of the vaccine available. The licensed trivalent equine antitoxin contains neutralizing antibodies against botulinum toxin types A, B, and E, which are the most common causes of naturally occurring human botulism. It is provided in a single 10-mL vial that provides 5500 to 8500 IU of each type of specific antitoxin, is diluted at a ratio of 1:10 in normal saline, and is given as a slow intravenous infusion. This product has all of the side effects of any equine serum product, including anaphylaxis and serum sickness. An investigational heptavalent (ABCDEFG) antitoxin held by the U.S. Army could be used to cover for additional serotypes.¹⁶ Although it is said to be despeciated by cleaving the Fc fragments from the horse immunoglobulin G molecules, approximately 4% of equine antigens still remain. A monovalent human type A antitoxin is available for infant botulism from the State of California Department of Health Services.

Use of the equine antitoxin requires skin testing for horse serum sensitivity prior to use. This is performed by injecting 0.1 mL of a 1:10 sterile dilution of antitoxin intradermally and observing for 20 minutes. The skin test result is considered positive if there is any of the following: fever or chills; hypotension with a drop of 20 mm Hg in the systolic and diastolic blood pressures; hyperemic skin induration > 0.5 cm; nausea and vomiting; shortness of breath or wheezing; or skin rash or generalized itching. If any of these reactions occur, desensitization should be performed and allergy specialist consultation is advised. Even if the skin test result is negative, anaphylaxis may still occur unpredictably. If no allergic reactions occur, then the dose of 10 mL of antitoxin is given as a single intravenous dose in saline over 20 to 30 minutes. Pretreatment with intravenous diphenhydramine 50 mg and possibly an H2 blocker is recommended as well as having epinephrine immediately available in case an anaphylactic reaction does occur.

Recovery results from new motor axon twigs that sprout to reinnervate paralyzed muscle fibers—a process that, in adults, may take weeks or months to complete.¹⁷

UNIQUE CONSIDERATIONS

Four routes of exposure to botulism exist. Intestinal and wound botulism result from the production of botulinum toxin in devitalized tissue in a wound or the intestine. Neither is usually considered to be from an act of bioterrorism. However, foodborne botulism can be either natural or intentional, and the aerosolized route is highly likely to be intentional. No cases of waterborne botulism have ever been reported.¹⁸

The rapidity with which patients present largely depends on the route of exposure and the dose absorbed. Symptoms may not appear for several days if the toxin is inhaled at lower concentrations, but they may appear earlier if inhaled at higher concentrations or if absorbed by ingestion. With ingestion, the course from onset of symptoms to respiratory failure has progressed in less than 24 hours.

There is no indication that treatment of children, pregnant women, and immunocompromised persons with botulism should differ from standard therapy.¹ Children and pregnant women have received equine antitoxin without apparent short-term adverse effects; however, the risks to fetuses of exposure to equine antitoxin are unknown.¹⁹⁻²² A human-derived neutralizing antibody, Botulism Immune Globulin, decreases the risk of allergic reactions that are associated with equine botulinum antitoxin, but use of this investigational product is limited to suspected cases of infant botulism.²³

PITFALLS

Several potential pitfalls in response to a botulism attack exist. These include the following:

- Failure to consider the diagnosis of botulism in a patient presenting with descending paralysis
- Failure to notify local and state health authorities as soon as possible to access botulism antitoxin in an expedited fashion
- Failure to make the clinical diagnosis of botulism if multiple patients present with bulbar and cranial nerve palsies and a descending paralysis
- Exacerbation and prolongation of neuromuscular blockade with use of aminoglycosides and clindamycin in patients with botulism

CASE PRESENTATION

A patient presents with progressive bilateral symmetric descending flaccid paralysis that was preceded by ptosis and disconjugate gaze. The patient is afebrile, with unremarkable vital signs and a normal sensorium. There was no noted inciting event. No previous medical or neurologic history is present. The evaluation reflects a normal laboratory evaluation, including normal cerebrospinal fluid study results from lumbar puncture.

Clostridium perfringens Toxin (Epsilon Toxin) Attack

Lynne Barkley Burnett

DESCRIPTION OF EVENT

Because of their relative ease of manufacture, capability to be deployed without a sophisticated delivery system, and capacity to kill or injure significant numbers of people, biologic weapons have been termed the “poor man’s nuclear bomb.”¹ As the former head of a secret bioweapons research program said, “A small container of pathogens could kill a million people. It’s hard enough to secure fissile materials, which are large and easy to detect. How do you begin to control a substance that looks like nothing more than sugar?”²

Bioterrorists may use microorganisms that produce one or more toxins, biologically active proteins that are antigenic but do not grow or reproduce. In the case of a toxin bioweapon, it is the poison produced, rather than the microorganism that produced it, that is weaponized and is harmful.³

Epsilon toxin is one of numerous toxins produced by bacteria of the genus *Clostridium* that cause pathologic medical conditions including botulism, tetanus,⁴ “gas gangrene,” and food poisoning.^{5,6} Clostridia are gram-positive, nonencapsulated, spore-forming, fermentative, catalase-negative bacilli.⁷ Of approximately 90 species, fewer than 20 are known to be associated with clinical illness in humans.⁶

Clostridium perfringens, which may well be the most common bacterial pathogen,⁶ has five strains designated types A through E,⁵ elaborating more than 20 toxins.⁸ In humans, type A is notorious for producing alpha-toxin and causing clostridial myositis and myonecrosis, also known as *gas gangrene*. During World War II, at the infamous Unit 731, the Japanese tested the intentional contamination of shrapnel or fléchettes with *C. perfringens* to increase the likelihood of wound infection⁹—something modern-day terrorists might find attractive if explosive devices were used.

Epsilon toxin, the most potent clostridial toxin after botulinum and tetanus neurotoxins,⁴ is a permease enzyme made by *C. perfringens* types B and D.⁵ These are commensal organisms whose primary host is sheep, although they are occasionally isolated from other herbi-

vores such as goats and cattle¹⁰ and, rarely, humans.¹¹ In a natural infection in herbivores, a large dose of epsilon toxin results in increased intestinal permeability, facilitating entry of *C. perfringens* from the gut into the blood with hematogenous spread to all organs.¹² As a biologic weapon, epsilon toxin could be manufactured via fermentation of *C. perfringens* or genetically combined with a producer microorganism that could express the cloned gene for the toxin.¹³⁻¹⁵ Indeed, the gene producing epsilon toxin has been cloned¹⁶ and genetically combined with *Escherichia coli*.² After freeze-drying, it was placed into a sealed glass cylinder, inserted into a toothpaste tube along with a few grams of cooling gel to ensure a stable temperature, and transported into the United States. This was done to provide proof to government officials of a top secret project carried out by South Africa to develop bioweapons, such as anthrax, plague, salmonella, botulinum, and epsilon toxin, that have been genetically altered to make them harder to detect and to treat.

The literature is bereft of reports of human illness caused by this toxin,¹⁰ but a brief examination of its natural history readily demonstrates why epsilon toxin is designated a category B biologic agent by the U.S. Centers for Disease Control and Prevention (CDC).¹⁷ Epsilon toxin is not taken up into cells and does not appear to have any intracellular activity.¹² Its putative mechanism of action is cell membrane pore formation, producing wide, nonselective diffusion channels permeable to hydrophilic solutes, including potassium, sodium, and other ions.^{10,12} This disrupts the vascular endothelium, causing widespread osmotic alterations with extravasation of serum proteins and red blood cells and massive edema¹⁸ involving the brain,¹⁹ kidneys, lungs,¹⁸ and liver.²⁰ Subserous and subendocardial hemorrhages are also often seen.²¹ At a cellular level, formation of membrane pore complexes²² causes ion loss from cells, with a rapid decrease in intracellular potassium, a rapid increase in intracellular chloride and sodium, and a slower increase in intracellular calcium.¹² The efflux of intracellular potassium causes plasma membrane blebbing, cell swelling, lysis,¹⁰ and cell death.¹²

In animal studies, epsilon toxin administered intravenously accumulates preferentially in the brain, where pathologic changes are characterized by focal-to-diffuse⁴ liquefactive necrosis and, secondary to damage of vascular endothelial intercellular junctions,⁷ perivascular proteinaceous edema in the internal capsule, thalamus, cerebellar white matter¹⁹ and meninges.⁷ It appears likely that, at high doses, the neurotoxicity of epsilon toxin is due to stimulation of neurotransmitter release from glutamatergic and dopaminergic neurons.⁴ It is thought that the toxin binds to presynaptic glutamatergic nerve fibers, inducing excessive release of glutamate, resulting in postsynaptic dendritic damage and pyramidal cell death. Epsilon toxin also accumulates in the kidney,¹⁸ where necrosis of the renal cortex (“pulpy kidney disease”) may occur.^{7,21}

These pathologic effects in animals manifest clinically as cerebral edema,¹⁹ pulmonary edema,⁵ pericardial fluid collections,¹⁰ and diarrhea, with severe abdominal cramping and abdominal distention.¹³ Onset of neurologic signs¹⁹—including ataxia, trembling,²⁰ nervousness, opisthotonos, seizures, agonal struggling,¹⁰ and hyperesthesia—may be observed within 2 to 60 minutes after intravenous injection in calves.¹⁹ Surviving animals can have residual neurologic deficits resulting from focal symmetric encephalomalacia.²⁰ Epsilon-toxin toxicity results in hyperglycemia and glycosuria²¹ due to altered hepatic metabolism of glycogen²⁰ and a stress response caused by cerebral edema that initiates catecholamine release and activation of adenylate cyclase.²¹

The anticipated primary routes for mass dissemination of epsilon toxin would be as an aerosol¹⁰ or in foodstuffs or water. Epsilon toxin is taken up from the gut in naturally occurring disease in animals; thus, food contamination might be the most natural avenue for a terrorist attempt to cause human disease. In an aerosol toxin attack, the presumption is that the agent cloud retains its harmful potential for 8 hours.³ To use epsilon toxin as an effective aerosolized biologic weapon, terrorists would need to manufacture a respirable aerosol of the purified toxin,²³ with particles ranging from 0.5 to 5 microns—the “ideal” droplet size for absorption into the circulatory system via the inhalational route. Particles within this size range remain airborne for a prolonged period of time and are optimal for being carried to the distal airways, where retention and absorption of a toxin biologic weapon is maximized. Similarly, aerosolized *infectious* biologic agents (e.g., anthrax spores) achieve their highest rates of infection in the distal airways.³ However, unlike the spores of *Bacillus anthracis*, there is no evidence that spores of clostridia can be aerosolized to produce disease. Studies in sheep, goats, and mice⁵ suggest the most likely effects on humans following inhalation could be damage to pulmonary vascular endothelial cells, resulting in high-permeability pulmonary edema, with hematogenous spread and damage to the kidneys, heart, and central nervous system.¹⁰ Although such spread results in pulmonary edema, renal failure, shock, and multisystem organ failure,⁵ the central nervous system is the primary target of epsilon toxin.⁴

Further speculation on the clinical presentation in humans might include central nervous system manifesta-

tions such as weakness, dizziness, ataxia, and neurologic dysfunction.²⁴ Pulmonary manifestations include respiratory irritation, cough, bronchospasm, dyspnea,¹⁹ adult respiratory distress syndrome, and respiratory failure.²⁴ Cardiovascular abnormalities include tachycardia, hypotension, or hypertension.¹¹ Gastrointestinal distress including nausea, vomiting, and diarrhea may also be seen.²⁴

Pancytopenia is a late complication resulting in bleeding, increased susceptibility to bruises, and immunosuppression. Initial laboratory studies might reveal anemia caused by intravascular hemolysis, thrombocytopenia, elevation of serum aminotransferase levels, and hypoxia.²⁵

The estimated lethal dose via inhalation is 1 µg/kg.¹⁰ Onset of illness is anticipated to be within 1 to 12 hours of exposure.^{13,24} Death can occur within 30 to 60 minutes of symptom onset in affected animals²⁰; thus, the abrupt onset of clinical illness could eventuate rapidly in death.¹⁰

Clinical acumen, tempered by an appreciation of the context of the presentation, facilitates appropriate reporting, definitive diagnosis, and response to a biologic weapon attack using epsilon toxin.²⁶ Diagnosis of an epsilon-toxin attack would have to be based on clinical and epidemiologic grounds, possible confirmation by growth of *C. perfringens* in culture (only true if the actual organism [*C. perfringens*] were used in the attack; if the attacker used epsilon toxin, there is nothing to culture because it is a poison, not a live infectious organism), or identification of toxin via polymerase chain reaction genotyping⁵ or immunoassay.²³ Swabs of the nasal mucosa,²³ acute serum, and possibly tissue samples should be collected as soon as possible²⁷ in cooperation with the local or state health department or the CDC and sent to an appropriate reference facility^{25,27} via the laboratory response network. They must be properly packaged to preserve their biologic structure and/or activity. Because these samples are also evidence of a crime, they must be transported in a manner that maintains an appropriate chain of custody.

PREINCIDENT ACTIONS

Terrorist attacks are unpredictable, may vary in size, occur in multiple sites simultaneously or be conducted sequentially, and will likely overtax resources at every level of response: local, state, and national.¹ Thus, while there are no preincident steps to be taken insofar as epsilon toxin is specifically concerned, it is essential that emergency medical response (EMS) agencies, hospitals, and healthcare professionals proactively plan, organize, train, and obtain the supplies necessary for responding to terrorist incidents involving biologic agents.

POSTINCIDENT ACTIONS

It may be unclear whether the initial cases of an infectious disease outbreak are the result of a natural occurrence or an act of hostility. Thus, all apparent infectious disease outbreaks should be approached as possible

bioterrorist attacks until proven otherwise. Implications of such a posture for clinical practitioners include the immediate reporting of suspicious or clustered syndromes to local, state, or federal public health officials for investigation; immediate implementation of respiratory protection and/or body fluid precautions for all responders; and recognition that biologic samples and other materials (e.g., clothing), as well as laboratory results, have potential forensic, as well as clinical, relevance. Therefore, appropriate steps must be taken to preserve their evidentiary value.²⁶

Toxins are easier to remove by decontamination than are live organisms.³ Use of soap and water is the recommended approach.^{13,23} There is no known *person-to-person* spread of epsilon toxin by air.⁵ Direct contamination of consumables, such as water, food,^{19,24} or medications,³ is a possible route of dissemination and would be difficult to detect prior to the onset of illness because it is unlikely that appearance, taste, or smell would be significantly affected. Epsilon toxin is dermonecrotic⁸ and can be transmitted via contaminated wound discharge²⁴; thus, body fluid precautions should be observed.

MEDICAL TREATMENT OF CASUALTIES

The biggest challenge faced by EMS, emergency department, and community medical practitioners after a terrorist attack may well be the psychological trauma that may affect most of the population.¹ Insofar as epsilon toxin is concerned, there are no vaccines, antitoxins,⁵ antidotes,²⁴ or specific treatment²⁵ for humans, although *C. perfringens* epsilon toxoid has been prepared for use in animals.^{28,29} Supportive medical care, including airway management²⁴ and fluid replacement, with particular attention paid to electrolyte status because of potassium loss, would be the mainstay of therapy.¹³ Critical care in an intensive care unit setting, including mechanical ventilation and vasopressors, may be needed for the treatment of multisystem organ failure and shock.⁵

If weaponized and aerosolized *C. perfringens* were the biologic agent disseminated (as opposed to weaponized purified epsilon toxin), high-dose penicillin might be indicated, although a primary role for antibiotic therapy has not been established.⁵ A study of guinea pigs with gas gangrene (caused by clostridial alpha toxin) showed that protein synthesis inhibitors were more effective inhibitors of cell wall-active toxins than were antimicrobial agents with a different mechanism of action,⁶ with penicillin plus clindamycin considerably more efficacious than penicillin alone. There are also reports that rifampin stopped the lethal intoxication of the toxin microcystin in animal models when administered within 15 to 30 minutes of exposure to the agent.¹⁴

Adjunctive hyperbaric oxygen therapy for gas gangrene is based on blocking production of alpha toxin at a partial pressure of oxygen level of more than 250 mm Hg.²⁹ However, use of hyperbaric oxygen and its effect on the production of epsilon toxin have not been reported.

UNIQUE CONSIDERATIONS

Children who have been infected with epsilon toxin are more likely to decompensate if not monitored carefully and treated appropriately and are at greater risk from many bioterrorism agents. For example, aerosolized agents create special risks for pediatric patients. Compared with adults, their larger minute ventilation volume may result in the inhalation of a larger relative dose of an aerosolized agent and a more rapid onset of illness. Furthermore, children may absorb more of a given substance before its clearance from the respiratory tract. In addition, the breathing zone of children is closer to the ground, where many heavier-than-air aerosols may settle. Children are also at greater risk from agents that cause vomiting and diarrhea because they dehydrate easily and possess less physiologic reserve than adults. Thus, agents that cause minor symptoms in adults may precipitate hypovolemic shock in an infant.¹

PITFALLS

Several potential pitfalls in response to an epsilon toxin attack exist. These include the following:

- Absence of familiarity with weapons of mass destruction on the part of medical personnel, public health officials, and disaster planners is a pitfall.¹ All health-care providers are essential to community preparedness for a terrorist incident.²⁶
- Failure to recognize a bioterror incident early in its presentation may compromise the removal or decontamination of the agent, the appropriate medical care of casualties, and the criminal investigation to apprehend those responsible.²⁶
- Failure to consider *C. perfringens* epsilon toxin in the differential diagnosis of an outbreak of a gastrointestinal or neurologic syndrome can also lead to a less-than-optimal response.

The speed of the patient's decompensation had impressed everyone. A 28-year-old man, whose personal papers identified him as a foreign national, had been found alone, having apparently collapsed on his kitchen floor. His landlady had called 9-1-1 when she heard a loud sound, as if something heavy hit the floor, and there was no answer to her ringing of his doorbell or her telephone calls.

Police arrived on the scene at approximately 7:31 AM. The landlady reported the patient and his roommate had been making noise all night, something unusual for them. Initially, she said, her impression was that they were "making something...or cleaning," given the repeated sounds of objects being moved, water running, etc. Then, as the sounds of movement subsided, she noticed a lot of coughing—she wasn't sure whether it was one or both of them—with the coughing increasing in frequency and intensity as daylight approached.

She further informed the police that the patient shares the apartment with a male roommate of approximately the same age. Both are from the same country, and both work at the convention center, a venue that will be packed with 50,000 people for tonight's collegiate basketball championship.

On entering the apartment the police officer found, in addition to the patient, several empty boxes and multiple plastic containers—some empty, some partially filled. The officer assessed the patient, found him to be alive, and summoned paramedics, who arrived at 7:38 AM. Because of fluid on the floor, possibly used in an attempt to clean up some kind of spill, emergency personnel had to be careful they didn't slip as they worked in the kitchen. A fan was blowing, and the mist created by the fan was making them wet. Although it was cool in the apartment, they opted to keep the fan on because it helped dissipate the odors of vomitus, urine, and feces emanating from the patient.

Examination revealed a male with snoring respirations, mild bilateral wheezing, and rales on auscultation of the lungs; sinus tachycardia at a rate of 126 per electrocardiogram; blood pressure 144/82; Glasgow Coma Scale score of 6 (E1V1M4); pupils that were equal and reactive bilaterally at 4 mm; and pale, cool, wet skin. Paramedics intubated

the patient, confirmed correct tube position, and ventilated him with 100% oxygen. They also inserted a large-bore intravenous tube and administered glucose and naloxone, without effect. His wet, soiled clothes were removed and he was covered with a blanket before being taken to the ambulance.

The patient arrived at the emergency department at 8:05 AM, his clinical condition having markedly deteriorated since first assessed by paramedics 27 minutes earlier. The patient was in clinically obvious pulmonary edema, and he was hypotensive with muffled heart sounds. The patient was placed on a ventilator and a second intravenous tube was inserted. A bedside ultrasound revealed pericardial fluid.

While preparations were being made to perform a pericardiocentesis, the patient's cardiac rhythm changed to pulseless electrical activity. Resuscitation efforts lasting approximately 30 minutes, including pericardial decompression, were unsuccessful and the patient died. Lines and tubes were left in situ, the patient's body was moved to a holding room, and a call was placed to the medical examiner's office. Because of the patient's atypical presentation and rapid death, you agreed with the emergency department nurse who suggested that local public health officials be notified as well.

The medicolegal death investigator is the first to respond 3 hours after the patient's death. He indicates that he needs to interview you and also asks that you have the paramedics and police return to the hospital, so that all the interviews can take place in one location. You respond that you will have a nurse call the paramedics' dispatch center, as well as the police. However, at that very moment, you happen to see both paramedics walking through the emergency department doors. The difference in their appearance from that observed earlier, when bringing the patient to the emergency department, is striking. Both paramedics appear ill, have obvious wet coughs, and one paramedic seems to have an unsteady gate you had not previously noticed. On seeing you, the other paramedic says, "Doc, something's got to be going on here!"

Marine Toxin Attack

Wende R. Reenstra

DESCRIPTION OF EVENT

Marine toxins are poisons of biologic origin that may be used as chemical weapons. These toxins are produced by a variety of organisms ranging from small microbes to fish and snails. These toxins are not infectious. Exposure to the toxins either by invenomation, ingestion, or inhalation may lead to a death through paralysis of cardiac or respiratory muscles.

Several marine toxins discussed here are further classified as neurotoxins. These toxins can interfere with the transmission of the nerve impulse by blocking specific ion channels. The neurotoxins vary in mechanism of action. The concentration of the exposure to the toxin is not indicative of its effects. Several toxins can cause seizures or paralysis in nanomolar concentrations, others may cause gastrointestinal upset or blindness in much larger concentrations.

Three of the marine toxins classified as neurotoxins are saxitoxin, conotoxin, and tetrodotoxin. The fourth toxin—palytoxin—exerts its effects on all cell membranes and is not classified as a neurotoxin.

PREINCIDENT ACTIONS

As in other toxin attacks a robust public healthcare system is of most benefit in the preincident phase. Hospitals should have disaster plans that would be adaptable to a toxin attack and the subsequent surge of patients demonstrating the characteristic symptoms of the marine toxins. Adequate resuscitation equipment, including mechanical ventilators, should be part of the preparation of such an attack.

POSTINCIDENT ACTIONS

Emergency medical providers should recognize a rise in the number of patients exhibiting the characteristic paresthesias and progressive paralysis seen in marine toxin exposure. Once a trend is recognized, notification should be made to local and regional public health departments and adequate supplies to handle large numbers of symptomatic patients should be gathered. Rising

numbers of symptomatic patients should be an indicator of a potential terrorist attack using a marine toxin agent, especially in areas where such toxins are not commonly seen (e.g., inland regions). Once an attack is suspected, notification of law enforcement on the local and federal level should follow.

MEDICAL TREATMENTS OF CASUALTIES

Saxitoxin

Saxitoxin is one of the family of neurotoxins that cause paralytic shell fish poisoning (PSP). This toxin is soluble in water and stable at high temperatures.¹ The toxin is made by small organisms called dinoflagellates, which contaminate shellfish (clams, scallops, oysters). The toxin is also produced by blue green algae. The algae may grow rapidly, producing blooms called “red tides.” Human ingestion of filter-feeding crabs and lobsters or shellfish results in an intoxication.¹⁻⁴

Saxitoxin binds to voltage-gated sodium channels on nerve fibers and muscle cells. The binding of the toxin blocks conduction of the nerve impulse. General symptoms of saxitoxin poisoning are neurologic and respiratory paralysis.¹⁻³

Clinical Features

General: There is an initial latent period varying from 30 minutes to several hours following ingestion, before the onset of neurological symptoms.

Cardiovascular: There are no specific cardiovascular effects although in laboratory animals, saxitoxin caused hypotension and conduction defects.

Respiratory: Respiratory distress from muscular paralysis may occur up to 12 hours after intoxication. The respiratory paralysis may lead to death.^{1,5}

Gastrointestinal: Gastrointestinal symptoms may appear hours to days after ingestion. These symptoms may include nausea, vomiting, abdominal pain, and diarrhea.^{1,5}

Other: A tingling and burning sensation, initially occurring around the mouth and lips, is usually the first symptom. The numbness may be on the hands and spread

over the chest and abdomen.^{1,5} These symptoms may progress, with difficulty walking and arm and leg weakness.^{1,5} Involuntary movements and tremors may occur.¹

There are no specific antidotes for saxitoxin poisoning.¹ Treatment is symptomatic. If oral ingestion is suspected, emptying the stomach via emetic or gastric lavage is recommended. Intubation and mechanical ventilation with monitoring to support respiration may be necessary.¹ Routine laboratory studies are not helpful. Diagnosis is confirmed by detection of the toxin in food, water, or environmental samples.^{5,6}

Saxitoxin is water soluble and therefore can be easily aerosolized. It is toxic by both inhalation and ingestion.¹

Conotoxin

The venom of the cone snail is composed of small substances termed conotoxins. There are more than 2000 peptides identified⁷ that lead to a complex set of symptoms. The toxins are heat stable but are inactivated by the disinfectants glutaraldehyde and formaldehyde.⁷

The conotoxins mechanism of action can be divided into pre- and post-synaptic pathways. The presynaptic conotoxin blocks the release of acetylcholine.^{5,8} The postsynaptic conotoxin inhibits sodium, potassium, and calcium channels and blocks muscular contraction.⁵ The toxicity of the venom is thought to result from the additive effects and not the concentration of the toxin.

Clinical Features

General: The onset of symptoms is almost immediate upon injection. Common symptoms include localized pain, swelling, numbness, and ischemia at the injection site.^{5,7} The numbness, swelling, and tingling may spread rapidly from the injection site to involve the entire body.^{5,7}

Cardiovascular: No specific cardiac effects are seen.

Respiratory: Progressive weakness, droopy eyelids, headache, abdominal pain, and difficulty breathing, may occur. Death results from respiratory paralysis.^{5,7}

Gastrointestinal: Stomach cramps and nausea are common effects.

Other: The clinical course is characterized by rapid onset and deterioration for the first 6 to 8 hours.⁷ This is followed by improvement, and complete recovery may take 4-6 weeks.^{5,7}

Diagnosis is by clinical signs and symptoms, and there are no laboratory tests available. Treatment is to immobilize the limb or site of envenomation. Pressure dressings should be applied and pain medication and tetanus prevention provided.⁷ Intubation and mechanical ventilation may be necessary to support breathing.^{5,7}

Conotoxins are very small, stable toxins that theoretically may be weaponized and disseminated as aerosols. A search of the open scientific literature regarding their inhalation toxicity found no publications.⁷ They are poisonous by injection.

Tetrodotoxin

Tetrodotoxin is one of the best characterized marine toxins because of its involvement in fatal food poisoning.

The toxin is named from the pufferfish family (Tetraodontidae), where it has been found to be concentrated in the liver and other organs.^{9,10} The toxin can also be found in the Blue Ringed Octopus, Parrot fish, crabs, newts, and algae.^{2,5,9-11}

The toxin is made by a bacterium that forms a symbiotic relationship with the animals.^{5,12} Tetrodotoxin is a neurotoxin that interferes with transmission of the nerve impulse at the nerve-muscle junction.^{5,12} The toxin is heat stable and can be solubilized in acetic solutions.^{5,12} This toxin specifically blocks sodium channels on the nerve cell and inhibits transmission of the impulse.^{2,5,12} The target molecular channels are thought to be very similar to saxitoxin.⁹

Clinical Features

General: The first symptom is increasing numbness and tingling in the face and around the mouth.¹² These may extend to the extremities or become generalized.^{5,12}

Cardiovascular: Hypotension and cardiac arrhythmias may occur.^{5,12}

Respiratory: There is increasing respiratory distress. The victim usually exhibits difficulty breathing and cyanosis. Paralysis increases and convulsions, mental impairment, and cardiac arrhythmia may occur.^{5,12}

Gastrointestinal: Autonomic effects such as headache, diaphoresis, and chest pain may occur and gastrointestinal symptoms such as nausea, diarrhea, and/or vomiting may develop.^{5,12}

Other: A coagulation disturbance, which is an occasional complication, may lead to bleeding into the skin and mucosa, formation of blood blisters, and peeling of the skin. The neurologic involvement may start as muscular twitching and proceed to complete skeletal muscle paralysis, interfering with speech and swallow.^{10,12} The pupils, after initially constricting, may become fixed and dilated.¹² The victim may be completely paralyzed but conscious. Untreated, the death rate is 50-60% in some studies.^{5,12} Death usually occurs within 4 to 6 hours, with a known range of about 20 minutes to 8 hours.^{10,12} Management is supportive and standard management of poison ingestion should be employed if intoxication is by the oral route. These include gastric lavage or emetics, particularly after control of the airway has been obtained. Intubation and mechanical ventilation may be required in severe intoxication.^{5,12}

After weakness has become apparent, the treatment is symptomatic (e.g., maintenance of respirations, monitoring of vital signs and electrolytes).^{5,10,12} Because of the likelihood of consciousness being maintained with complete paralysis, periodic administration of a tranquilizer is recommended along with continuous reassurance.^{10,12}

Relatively little is known about TTX as a possible toxin weapon. A company in Japan is known to produce the toxin.¹² It is not known to be made in large quantities that could be used in weapons, and little or nothing has been published about its inhalational toxicity.¹²

Palytoxin

Palytoxin is one of most potent marine toxins known. It was isolated first from corals located in the South

Pacific.^{13,14} Originally it was thought that the toxin was made by the corals; now, however, it is known that the toxin is made by a dinoflagellate (a small single-celled organism) and the corals concentrate the toxin.^{2,8,13} It is estimated that the lethal dose for a human is less than 5 µg.^{3,10,13,14} Palytoxins are stable in seawater and alcohols.

Extensive pharmacological research has determined that palytoxin is not a neurotoxin.^{13,15} It instead acts at the cellular membranes to make them porous to charged molecules such as sodium, potassium, and calcium.^{13,15} Without the gradients of these ions, the cells are unable to function or maintain the cell shape.^{14,15}

Clinical Features

General: Symptoms are rapid, with death occurring within minutes.¹³

Cardiovascular: Initial symptom may be chest pain from constriction of the cardiac blood vessels. This may lead to cardiac ischemia and death of cardiac tissue. This may be seen on the EKG as peaked T waves or ST segment elevation.¹³ The next symptom may be the loss of consciousness as unstable blood pressure, particularly episodes of low blood pressure, reduce blood flow to the brain.¹³

Respiratory: There may be difficulty breathing, with symptoms of wheezing. This again may be due in part to constriction of blood vessels in the lungs.

Gastrointestinal: There are no specific gastrointestinal effects.

Other: Hemolysis (breakdown of blood cells) may occur as the cell membranes become permeable to various ions, the red blood cells swell and the membranes rupture. This results in decreased oxygen carrying capacity. Death is thought to result from decreased oxygenation.¹³

There are no known therapeutics for Palytoxin poisoning. Relatively little is known about Palytoxin as a possible toxin weapon. It is not known to be made in large quantities that could be used in weapons and little or nothing has been published about its inhalational toxicity.¹³

In summary these toxins act on a variety of sites. Table 134-1 summarizes their specific effects.

TABLE 134-1 SPECIFIC EFFECTS OF MARINE TOXINS

TOXIN	ORIGIN	EFFECT
Conotoxin	Marine snail	Blocks voltage-sensitive calcium channels; blocks voltage-sensitive sodium channels; blocks ACh receptors
Palytoxin	Soft coral	Activates sodium channels, ATPase
Saxitoxin	Dinoflagellate	Blocks voltage-sensitive sodium channels
Tetrodotoxin	Puffer fish	Blocks sodium channels

ACh, acetylcholine; ATPase, adenosine triphosphatase.

UNIQUE CONSIDERATION

Marine toxins should be considered when a number of patients present with the characteristic parasthesias and paralysis. It is highly unusual to have large numbers of such patients, particularly in non-coastal regions, and therefore a terrorist attack should be suspected when this is seen. Early intervention with supportive care, including mechanical ventilation if needed, can be life-saving.

PITFALLS

Several potential pitfalls in response to a marine toxin attack exist. These include the following:

- Failure to prepare adequate systems to respond to possible terrorist attacks before an attack occurs
- Failure to consider marine toxins as the cause for paralysis in patients
- Failure to consider a marine toxin attack in the setting of a large number of otherwise healthy people presenting over several hours with acute paralysis
- Failure to rapidly support the respiratory system with urgent intubation and mechanical ventilation
- Failure to notify appropriate public health and law enforcement agencies when marine toxin exposure is suspected or confirmed among persons with no aquatic environment exposure or seafood ingestion

CASE PRESENTATION

As an emergency physician in a small hospital outside of Chicago, you begin to see several patients during the first hours of your shift complaining of numbness and tingling in their face and mouth. During the next 3 hours you have four more patients present with the same symptoms while your original patients begin showing signs of respiratory distress. After intubating the patients in respiratory distress, you begin to suspect there may be more than just a coincidence occurring. You pick up the phone to make a call to your local Department of Public Health, only to find out a hospital 20 miles away is also seeing a surge in patients with similar symptoms.

T-2 Toxin (Trichothecene Mycotoxins) Attack

Frederick Fung

DESCRIPTION OF EVENT

The 1972 Biological and Toxin Weapons Convention is a major international treaty to control biologic and chemical warfare that prohibits state parties from developing, producing, and testing biologic and toxic weapons.^{1,2} However, with the expansion of terrorism, the possibility of using mycotoxins as a chemical weapon exists. In reality, there are three likely attack scenarios using T-2 mycotoxin as an agent of terrorism:

1. Product tampering: substantial human and economic damages caused by product tampering, such as the cyanide contamination of Tylenol in 1984, could happen. Use of T-2 mycotoxin to contaminate premade consumer products may be the most plausible attack scenario.
2. A second scenario is the use of T-2 mycotoxin as part of state-sponsored bioterrorism against a discrete population, group, or region.
3. The third scenario is related to food industry contamination: food, especially in the dairy industry (e.g., milk transported by tanker truck) is vulnerable to biologic and chemical attack. An attack on the food industry could cause local outbreaks of disease within hours or days, as well as enormous economic damage.

Trichothecenes (Fig. 135-1) are a large group of sesquiterpenoid chemicals characterized by a tetracyclic 12,13-epoxy ring commonly known as the 12,13-epoxytrichothecene and are classified into four groups. Group A includes T-2 toxin and diacetoxyscirpenol. Group B includes 4-deoxynivalenol and nivalenol. Many *Fusarium* species produce group A and B trichothecenes. *Baccharis megapota mica* produces the group C trichothecene baccharin. Group D mycotoxins include roridins produced by *Myrothecium roridum*, verrucarins produced by *Myrothecium verrucaria*, and satratoxins produced by *Stachybotrys atra*.³

It is important to point out that the more common and potent trichothecenes are produced by *Fusarium* species. There are nearly 150 toxins produced by fusaria and related fungi. They infect wheat and other grains that are important as sources of human food.

They are highly resistant to heat. T-2 toxin has been the most extensively studied. All trichothecenes are mycotoxins, whereas some mycotoxins belong to other chemical groups and are not trichothecenes.

T-2 is rapidly absorbed from the gastrointestinal (GI) tract. Although there are no human data on absorption through inhalational or dermal exposure, in vitro and animal studies have shown that trichothecenes are poorly absorbed through intact skin.⁴ Trichothecenes undergo deepoxidation and glucuronidation, resulting in less toxic metabolites. The elimination half-life is estimated at 1.6 ± 0.5 hours after intravenous injection of the toxin in a canine model.⁵ Another model using swine and cattle showed a half-life of 13 and 17 minutes, respectively.⁶ T-2 does not require metabolic activation to exert its toxicity. The presence of the reactive electrophilic 12,13-epoxide moiety accounts for a rapid onset of its toxicity. The mechanism of toxicity involves inhibition of protein and DNA synthesis.⁷ They also produce general cytotoxicity by inhibiting the mitochondrial electron transport system.⁸ The 12,13-epoxide of the trichothecenes is essential for the toxicologic activity. The deepoxidation of T-2 in mammalian systems results in loss of toxicity.⁹

The dose of trichothecene needed to cause symptoms in humans is unknown. There is great variability in the toxicity of these compounds in animal studies. The dose of trichothecenes that will be fatal to 50% of an exposed population ranges from 0.5 to 300 mg/kg, depending on the route of administration and animal model used.¹⁰

T-2 is a potent blistering agent. Purified trichothecenes have been investigated because of their potential use in chemical warfare. T-2 toxin was implicated in the “yellow rain” attacks in Southeast Asia. However, further investigations have been inconclusive.¹¹

Acute pulmonary hemorrhage in infants was purportedly associated with residential exposure to *Stachybotrys chartarum* and other toxigenic fungi. A detailed analysis of this report was conducted by the Centers for Disease Control and Prevention, which found methodologic shortcomings and concluded that the association was not confirmed.¹²

FIGURE 135–1. Structure of T-2 and HT-2. Trichothecenes:T-2 (R1 = OAc) and its metabolite HT-2 (R1 = OH).

An early report indicates that direct contact with trichothecenes produced irritant contact dermatitis after skin exposure.¹³ Mild to moderate abdominal pain has been reported to develop within 15 minutes to 1 hour after ingestion of foods contaminated with significant levels of trichothecenes. Throat irritation and diarrhea have also been frequently described after ingestion. GI tract symptoms usually resolve within 12 hours.^{14,15}

After a presumed T-2 attack, four clinical stages have been suggested.¹⁶ The first stage includes irritation and inflammation of the GI mucosa, leading to abdominal pain, vomiting, and diarrhea, which may last 3 to 9 days. The second stage occurs on days 10 to 14 after exposure and is a latent period; symptoms are not prominent, but progressive anemia, thrombocytopenia, and leukopenia with relative lymphocytosis develop. The third stage occurs over the ensuing 3 to 4 weeks. Clinically, patients may show petechial hemorrhages on their skin and mucous membranes, and a hemorrhagic diathesis from mucous surfaces occurs. Varying degrees of necrotic lesions may develop in the GI tract or larynx, and generalized lymphadenopathy may appear. Blood abnormalities become more severe, and the erythrocyte sedimentation rate is elevated. Infections and sepsis during this stage are usually fatal. The fourth is the convalescence stage, when there is a rebound in the white blood count, the necrotic lesions of the mucous membranes resolve, and the patient recovers completely. The current weight of scientific evidence does not support a causal relationship between purported inhalation exposure to fungi capable of producing trichothecenes in the indoor environment and specific health effects.¹⁷

High-performance liquid chromatography, gas chromatography, and liquid chromatography mass spectrometry^{18,19} have been used for trichothecene analysis in human blood and urine. However, these methods have not been validated by or used in sound epidemiologic studies. Serologic testing for antibodies specific to toxigenic fungi does not provide accurate information on exposure to trichothecenes or mycotoxins because the immunoglobulin is directed toward fungal antigens, not mycotoxins. Concerns on cross-reactivity in laboratory assays exist between *S. chartarum* antigens and fungi that are commonly found in outdoor environments.²⁰ Abnormalities in lymphocyte subset analysis have been reported in some studies, but consistent and specific findings have not been identified. The most appropriate diagnostic test to evaluate hematologic and immune sta-

tus associated with trichothecene exposure is a complete blood count (CBC) with white blood cell differential.

PREINCIDENT ACTIONS

Hospital, emergency department, and ambulatory care facilities should have general disaster plans in place in the event of mycotoxin attack. The plan should be well thought out, should include an “all-hazards” approach, should be robust enough to respond to large numbers of victims, and should be tested by periodic and realistic exercises involving all essential personnel. The early detection of illness outbreaks requires surveillance systems that are capable of finding and validating the diagnosis and providing a means of communication between clinicians and health departments.²¹ This would require coordination of local, state, and federal public health and safety resources. In the event of a large number of patients seeking medical care in a short timeframe, emergency medical services, hospital, and ambulatory care facilities need to be mobilized in a coordinated and expeditious fashion. Isolation and decontamination procedures should be in place and triage and decontamination personnel trained well before an attack occurs. Since most physicians and healthcare providers, as well as first responders, may not be familiar with mycotoxin attack, close contact with local poison control center or local health department may be important to identify and treat the initial cases.

POSTINCIDENT ACTIONS

Medical providers should maintain a high level of suspicion for possible mycotoxin attack should there be a sudden increase in the number of patients with similar symptoms and histories. Appropriate local, state, and federal public health and law enforcement authorities will need to be notified. Materials (e.g., clothing), bodily fluids, and surfaces possibly contaminated by mycotoxins should be decontaminated with 10% bleach (sodium hypochlorite) solution. Proper environmental sampling may be necessary for mycotoxin identification and documentation. Further epidemiologic investigations in collaboration with state or local health authorities may be necessary. CBC and liver function tests are recommended. Analysis of blood or urine samples may provide information concerning the metabolites of the mycotoxin. All samples should be stored and shipped using strict chain of custody procedures to preserve their evidentiary value.

MEDICAL TREATMENT OF CASUALTIES

There are no specific antidotes for trichothecene or T-2 poisoning. Standard supportive care is indicated for symptomatic cases after removal from the exposure and decontamination. These measures should include management of the airways, breathing, and circulation.

Supplemental oxygen can be given, if indicated. Contaminated clothing should be removed before skin decontamination occurs. The skin can be effectively decontaminated within minutes after T-2 exposure through washing with an aqueous soap solution. Polyethylene glycol 300 (PEG 300) is also effective at removing large doses of T-2 toxin from the skin.²² An animal model has shown dexamethasone may improve survival after low- and high-dose exposure to T-2 toxin.²³ T-2 toxin is tightly adsorbed onto activated charcoal and has been associated with improved survival when administered with oral or parenteral doses of T-2 toxin in a mouse model.²⁴ These findings suggest that activated charcoal may decrease toxin absorption from the GI tract and may possibly enhance elimination of toxin via enterohepatic circulation. Although human data are lacking, a single dose of activated charcoal is probably warranted after acute trichothecene ingestion.

Laboratory testing should include serial CBC and differential evaluations for thrombocytopenia, anemia, and effects on the various white blood cell lines. The development of significant immune suppression, including pancytopenia, warrants neutropenic precautions and antibiotic coverage for fevers. After ingestion, careful examination of the oral mucous membranes and GI tract is warranted to evaluate for the presence of petechial, necrotic, or ulcerative lesions. In cases of airway compromise due to blistering effects of inhaled T-2 mycotoxin, patients should be monitored in a critical care setting with aggressive airway management readily available.

CASE PRESENTATION

A previously healthy man comes to the emergency department complaining of blisters on his hands and the exposed skin of his neck and face that began to appear after he went jogging through a park a day prior. He also complains of nausea, vomiting, diarrhea, and abdominal pain but denies fever or chills. He also reports weakness, severe dizziness, and shortness of breath. Blood tests reveal that his white blood cell count is normal, but his lymphocyte count appears to be on the low side. On examination, there is evidence of extreme redness to his eyes, nose, and throat. There are a few hemorrhagic petechia noted on his trunk, arms, face, and oral mucosa. A general blood chemistry panel shows normal liver and kidney function. Due to his severe vomiting and diarrhea, he is hospitalized and treated with intravenous fluids. The next day, the local news media reports that an additional 50 people had been hospitalized or treated in local emergency departments for similar symptoms.

UNIQUE CONSIDERATIONS

Although skin blistering may be produced by dermal exposure to T-2, T-2 is most toxic when ingested. An attack using an aerosolized T-2 weapon is unlikely to produce sufficient inhalational dosages to cause significant

morbidity or mortality.²⁵ The most probable sign that a T-2 toxin or related mycotoxins attack has occurred may be the presentation of a large number of previously healthy persons over a course of hours to days with non-specific and systemic symptoms.

PITFALLS

Several potential pitfalls in response to a mycotoxin attack exist. These include the following:

- Failure to prepare adequate plans, to perform realistic training exercises, and to develop emergency response systems to respond to a possible terrorist attack before the incident occurs
- Failure to consider mycotoxin as the cause for non-specific, as well as systemic, symptoms in previously healthy patients
- Failure to consider mycotoxin attack in the setting of a large number of otherwise healthy people presenting over hours to days with a similar range of general as well as specific complaints
- Failure to notify appropriate public health, safety, and law enforcement authorities when a possible biochemical agent attack is suspected, especially when animals are affected along with people
- Failure to provide basic supportive medical care when a patient is suspected to have undergone exposure to a biochemical warfare agent

Ricin Toxin from *Ricinus communis* (Castor Beans) Attack

Angela C. Anderson

DESCRIPTION OF EVENT

Ricin is a potent biologic toxin derived from the castor bean plant *Ricinus communis*. After pressing for castor bean oil, 1% to 5% of the bean's dry weight is comprised of ricin.^{1,2} It is three to five times more toxic than the nerve agent VX. Although ricin is thought to be 1000-fold less toxic than botulinum toxin, it remains an important consideration as a potential terrorist weapon because it is stable in ambient conditions, readily available, and easily produced in mass quantities.² Ricin is technically difficult to disseminate in concentrations high enough to be an effective weapon of mass destruction. However, its potential use in smaller-scale terrorist attacks cannot be ignored. Ricin is classified by the Centers for Disease Control and Prevention (CDC) as a category B agent (i.e., an agent that is moderately easy to disseminate and causes moderate morbidity and low mortality).

R. communis is indigenous to Africa but can be found worldwide and can be purchased via the Internet. It grows wild in the southwestern United States and other parts of the world. The plant is cultivated commercially for the production of castor oil, which is used as an industrial lubricant, as a medical purgative and laxative, and as an additive in paints, shampoos, and cosmetics. Major producers include India, China, and Brazil. Castor oil contains no ricin because of the extraction process.

Extraction of ricin toxin from the oil is a relatively simple procedure that involves using hexane or carbon tetrachloride and the process of chromatography. During the extraction, the ricin-rich *resin* portion of the plant is separated from the non-ricin-containing *oil* portion. Any ricin remaining in commercially produced oil is heat inactivated. The ricin-rich resin that remains is known as castor meal or "waste mash" and contains 5% to 10% (dry weight) ricin. The maximum amount of ricin that can be extracted from a single bean is approximately 10 mg.³ Active ricin toxin can be produced in the form of a liquid, a crystal, or a dry powder.

Ricin exerts its effects by inhibiting protein synthesis. It belongs to a group of poisons known as A-B toxins. These toxins have a moiety (the B chain) that binds to cell surfaces and another moiety (the A chain) that enters the cell

and promotes catalytic activities that result in cell death. Bacterial toxins in this group include Shiga's toxin, diphtheria toxin, pseudomonas exotoxin A, and cholera toxin. Similar plant toxins are abrin, modeccin, and viscumin (from mistletoe).^{4,5} The ricin B chain binds to cell-surface glycoproteins and glycolipids that have a terminal galactose residue.^{4,6} Reticuloendothelial cells are particularly susceptible because they bear surface receptors to which ricin can bind. Once bound, ricin uses the cell's intracellular transport pathways to travel to ribosomes in the cytosol.^{4,7} The ricin A chain then removes a specific adenine residue from ribosomal ribonucleic acid (rRNA): the 28s rRNA subunit.^{6,8} Inactivation of the 28s ribosomal subunit blocks protein synthesis, which leads to cell death. Damage to endothelial cells results in extravascular fluid and protein leakage and tissue edema, which is known as *vascular leak syndrome*.

Clinical ricin poisoning requires ingestion, inhalation, or injection of a sufficient amount of the toxin. A summary of human clinical presentations is listed in Table 136-1. Contamination of food or water supplies or commercial products would be likely methods by which *oral* ricin poisoning would occur. Ingestion is the least toxic route because gastrointestinal absorption of ricin is poor and it is partially deactivated by passage through the stomach. Ricin toxin is complexed within the matrix of the castor bean, and intact beans pass through the gastrointestinal tract with little or no toxic effect. To cause significant toxicity by the oral route, the beans must be chewed or crushed to facilitate ricin release.

Lethal oral doses vary greatly between animal species. The dose of ricin that will be fatal to 50% of an exposed population (LD₅₀) in laboratory mice is 20 mg/kg with a time to death of 85 hours after intragastric administration.² The National Institute for Occupational Safety and Health Registry of Toxic Effects of Chemical Substances lists 2 mg/kg as the lowest published oral lethal dose in humans.⁹

Symptoms of mild ricin poisoning by ingestion include nausea, vomiting, abdominal pain/cramping, and diarrhea (often bloody), typically within 10 hours of ingestion. Moderate to severe toxicity causes significant fluid loss due to vomiting, diarrhea, hemorrhage, and third spacing of fluids into the tissues of the gastrointestinal tract with

TABLE 136-1 SUMMARY OF HUMAN CLINICAL PRESENTATIONS

EXPOSURE ROUTE	SYMPTOMS
Mild ingestions	Nausea, vomiting, abdominal pain and cramping
Moderate to severe ingestions	Extravascular fluid extravasation with resultant tachycardia, hypotension and mental status change, renal and hepatic failure
Inhalational exposure	Allergic symptoms including conjunctival irritation, rhinitis and bronchospasm. Cough, dyspnea, chest tightness, and arthralgias
Intravenous exposure	Flu-like symptoms and extravascular fluid extravasation leading to pulmonary edema, hypotension, and renal insufficiency
Intramuscular/Subcutaneous injections	Local necrosis, weakness, myalgias, nausea, hepatorenal failure, cardiorespiratory failure

resultant tachycardia, hypotension, oliguria, and possibly mental status change. Renal failure and hepatic failure have also been reported.

Fatality rates from ricin ingestion are low, ranging from 2% to 6%. Ingestion of fatal doses of ricin results in rapid onset of symptoms (less than a few hours). In these cases, death usually occurs within 36 to 72 hours of exposure. Autopsy findings include multifocal mucosal ulcerations and hemorrhages of the stomach and small intestine, mesenteric lymph node necrosis, hepatic necrosis, splenic inflammation, and nephritis.¹⁰

The ability to deliver ricin via the *inhalational* route is limited by two variables: (1) the estimated amount of ricin required to kill 50% of the people in a 100 km² area is significant: 8 metric tons¹¹; and (2) to cause significant ricin inhalation, one must succeed at the technically difficult task of aerosolizing the toxin into particles less than 5 μm.¹⁰ With these facts in mind, the toxic dose of ricin by inhalation is significantly less than that required for ingestion: 3 mcg/kg (in mice).²

The only human data regarding ricin inhalation come from reports of workers occupationally exposed to castor bean *dust*, which can be a potent allergen. Susceptible patients present with conjunctival irritation, rhinitis, urticaria, and possible bronchospasm.³

Human studies regarding inhalation of *aerosolized* ricin are sparse. In the 1940s, unintentional sublethal exposures led to fever, chest tightness, cough, dyspnea, diaphoresis, and arthralgias.¹⁰ Symptoms appeared within 4 to 8 hours of exposure and did not progress to severe illness or death. Mice exposed to the aerosol LD₅₀ of ricin (14 mcg/kg) developed an alveolar influx of inflammatory cells (predominantly neutrophils), pulmonary edema, type 2 pneumocyte hyperplasia, and peribronchovascular fibroplasias.¹² Bronchoalveolar lavage (BAL) revealed pulmonary inflammation with an increase in BAL protein.¹² Rats exposed to lethal ricin concentrations developed necrotizing interstitial and alveolar inflammation and edema, as well as fibropurulent pneumonia.^{2,13} These changes were delayed 8 or

more hours after exposure.^{2,12} Immunohistochemical evaluation revealed that ricin binds to bronchiolar cilia, alveolar macrophages, and alveolar lining cells.^{2,12} Death occurred 36 to 48 hours after exposure. It is likely that dose, duration of exposure, and particle size will affect clinical presentation and symptom progression.

Much of the information regarding *intravenous* ricin exposures is derived from persons with cancer who are treated with ricin as a means of targeting and killing tumor cells. Research evaluating the use of ricin as a chemotherapeutic agent evolved from the concept of replacing the binding moiety of ricin (the B chain) with a moiety that could recognize and bind cancer cell surface proteins (such as an antibody directed against cancer antigens). Administration of intravenous ricin immunotoxin in cancer patients at low doses (18 to 20 mcg/kg) has caused a flu-like illness (i.e., nausea, vomiting, fatigue, and muscular pain).¹⁴ Intravenous ricin immunotoxin at a dose of 30 mg/kg/day for 7 days caused fatal vascular leak syndrome.^{14,15} In fact, the dose-limiting adverse effect in ricin antitumor immunotherapy appears to be the development of the vascular leak syndrome.^{16,17} This syndrome is characterized by hypoalbuminemia, pulmonary edema, renal insufficiency, cardiac failure, and hypotension.¹⁷

Intramuscular and *subcutaneous* injections of ricin can cause local necrosis, weakness, myalgias, nausea, dizziness, hepatorenal failure, cardiorespiratory failure, and death. The lowest published lethal dose from subcutaneous injection in a human is 43 mcg/kg.⁹

Dermal ricin exposures are unlikely to cause significant toxicity if the skin is intact. It is unknown whether the addition of a solvent will increase dermal absorption. *Ocular* exposure of ricin in rabbits has caused severe inflammation and pseudomembranous conjunctivitis.¹⁸

PREINCIDENT ACTIONS

Currently there is no approved immunization or prophylactic agent against ricin. Most studies involve mice exposed to aerosolized ricin after immunization by various routes. Poli and colleagues¹⁹ found that treating mice with *aerosolized* specific anti-ricin immunoglobulin (Ig) G 1 hour prior to aerosolized ricin exposure improved survival and greatly reduced the lung pathology. Yan and others²⁰ demonstrated that *intranasally* administered microsphere-encapsulated ricin toxoid protected mice against lethal doses of aerosolized ricin. *Oral* administration of microencapsulated ricin toxoid induced IgG and IgA antibodies within 7 weeks and provided complete protection against death from aerosolized ricin exposure.²¹ Smallshaw and colleagues²² experimented with a recombinant *intramuscular* vaccine; they induced a single mutation of the ricin A chain at the site thought to cause vascular leak syndrome. These vaccines protected mice against 10 times the LD₅₀ of ricin without the toxicity associated with the vascular leak syndrome. *Parenteral* administration of ricin toxoid improves survival but is only

partially protective against lung damage caused by aerosolized ricin.¹⁹

The U.S. Department of Defense has submitted an investigational new drug application to the Food and Drug Administration (FDA) for the purpose of conducting ricin vaccine trials in humans. The administration of vaccine may prove to be protective; however, with the exception of the aerosolized vaccine by Poli and colleagues,¹⁹ most animal studies thus far have found that vaccination must take place weeks before ricin exposure to be effective.

POSTINCIDENT ACTIONS

The regional poison control center (1-888-222-1222), local health and law enforcement agencies, and federal authorities should be notified if ricin use is suspected. Ambulances, environmental surfaces, and equipment should be cleaned with 0.1% sodium hypochlorite solution (i.e., household bleach) or soap and water. Contaminated articles should be disposed of in a sealed plastic bag placed inside another sealed plastic bag.

MEDICAL TREATMENT OF CASUALTIES

Currently, there is no antidote for ricin poisoning. Additionally, there are few evidence-based data to direct the management of ricin-exposed casualties. Mouse studies evaluating the use of a monoclonal antibody to neutralize ricin toxicity are promising but have yet to obtain FDA approval.²³ Consequently, management options must be extrapolated from animal studies and previous experience with similar toxins.

The course of medical management is partially determined by the route of ricin exposure. All healthcare providers, regardless of the exposure route encountered by the patient, should use standard universal precautions including a disposable gown, disposable nitrile gloves, and respiratory and eye protection.

Ricin Ingestion

Gastric decontamination will likely be unsuccessful and unnecessary if intact, unchewed beans have been ingested. A single dose (adults, 50 g; children, 1 g/kg) of activated charcoal should be administered if the airway is protected. Fluid losses and cardiovascular instability should be treated with fluid resuscitation and vasopressors. Electrolytes, liver and renal function, hematocrit count, and white blood cell count should be monitored. Gastrointestinal blood losses should be treated with follow-up stool guaiacs, hemoglobin and hematocrit measurements, and blood transfusions as necessary. Ricin is a large (66-kDa) globular protein that is not dialyzable, therefore there is no role for hemodialysis in ricin poisoning except in the setting of renal failure.

Exposure to Aerosolized Ricin

Contaminated clothing and jewelry should be removed; this can potentially reduce additional patient contamination by as much as 90%¹⁰ and may prevent contamination of the emergency department, its staff, and other patients. Pulmonary effects, such as airway edema and necrosis and noncardiogenic pulmonary edema, should be treated supportively and aggressively. Continuous positive airway pressure or endotracheal intubation and ventilation may be necessary to manage pulmonary edema. Fluid and electrolyte abnormalities should be treated with intravenous fluid resuscitation and repletion of electrolytes. Allergic reactions should be treated with beta-2 adrenergic agonists, steroids, and antihistamines.

Parenteral Exposure

Routine burn and wound care can be used to treat local necrosis. Analgesia should be provided as necessary, as should replacement of fluids and electrolytes. Healthcare providers should watch for signs of systemic toxicity such as hepatic and renal failure. Cardiopulmonary collapse can be treated with vasopressors and ventilatory support.

Dermal/Ocular Exposure

If ricin has been dispersed in a powder form, skin decontamination at the scene is preferable. Contaminated clothing and jewelry should be removed, and skin should be washed with soap and water. It is unlikely that ricin will be absorbed to any significant extent through *intact* skin; however, it is prudent to decontaminate patients to prevent secondary contamination of healthcare providers and equipment. The eyes of patients with ocular exposures should be irrigated with tepid water for at least 15 minutes.

CASE PRESENTATION

Over the course of a few days, 10 patients present to local emergency departments complaining of nausea, vomiting, and bloody diarrhea. Within hours of presentation, patients experience severe fluid losses with associated tachycardia and hypotension requiring significant fluid resuscitation. Two days after presentation, many patients develop evidence of hepatic and renal failure. Routine stool and blood cultures all have negative results. All but two patients recover completely with supportive therapy. Further investigation revealed that all 10 patients had been at a small company picnic where they had ingested the same beverage. The beverage was sent to a laboratory response network, which found evidence of the ricin by fluorescence immunoassay. The presence of ricin was confirmed by the CDC. The amount of ricin ingested by each person, based on personal accounts of the patients before death, was approximately 2 mg/kg or greater.

UNIQUE CONSIDERATIONS

Ricin is stable at ambient temperatures. It can be detoxified by exposing it to temperatures of 176°F (80°C) for 10 minutes or 122°F (50°C) for 1 hour.²⁴

In 1999, the CDC established the Laboratory Response Network (LRN) to test for substances that could potentially be used in a terrorist event. Each of the 50 states has a state department of health laboratory called the *public health laboratory*. There are also other national, military, hospital-based, and state-based laboratories within this network. Suspicious samples of potentially toxic agents should be sent to an LRN reference laboratory. These laboratories currently can test for ricin by either of two methods: (1) time-resolved fluorescence immunoassay in which antibodies that bind to ricin are used; and (2) polymerase chain reaction, which searches for DNA of the gene that produces ricin protein. If a sample is found to contain ricin by a LRN reference laboratory, the sample is then sent to the CDC for additional testing, archiving, or storage. (Information on shipping procedures can be found at <http://www.bt.cdc.gov/labissues/index.asp>.) At present, testing can only document or confirm exposure. Testing results are not immediately available; therefore, its use as a diagnostic tool to aid in clinical decision-making is limited.

Ricinine is an alkaloid derived from the leaves and seeds of the castor bean plant. Recently, Darby and colleagues²⁵ developed a method using matrix-assisted laser desorption/ionization time-of-flight mass spectrometry and electrospray liquid chromatography/mass spectrometry to screen for and identify ricinine in samples. Thus far, tests for ricinine are not available for clinical use.

Ricin is very immunogenic. Circulating antibodies develop 2 weeks after exposure. Therefore, patients surviving at least 2 weeks after exposure can be tested for a humoral immune response.

Further information can be obtained from the following sources: the CDC Public Response hotline (1-888-246-2675); and the CDC Emergency Preparedness and Response Web site (<http://www.bt.cdc.gov>); the Agency for Toxic Substances and Disease Registry (1-888-422-8738); and the CDC's "Chemical Agents: Facts About Personal Cleaning and Disposal of Contaminated Clothing" (<http://www.bt.cdc.gov/planning/personalcleaningfacts.asp>).

PITFALLS

Several potential pitfalls in response to a ricin attack exist. These include the following:

- Exposure may mimic gastroenteritis or the flu.
- Ingestion can cause symptoms easily confused with iron, arsenic, or colchicine poisoning.
- Clinical presentation can mimic ingestion of bacterial pathogens such as salmonella and shigella.

- Inhalational ricin exposure may mimic infectious agents including community-acquired pneumonia, influenza, anthrax, Q fever, and pneumonic plague.
- Ricin inhalation may mimic inhalation of other toxins such as products of combustion from burning Teflon and Kevlar, nitrogen oxides, and phosgene.
- Patients may be exposed to more than one toxin, making the constellation of clinical symptoms confusing.

Aflatoxin Attack (*Aspergillus* Species)

Frederick Fung

DESCRIPTION OF EVENT

Aflatoxins are metabolites produced by certain strains of the fungi *Aspergillus flavus* and *Aspergillus parasiticus*. They were discovered during a disease epidemic in Great Britain that wiped out more than 100,000 turkeys in 1960. The source of the illness was traced to aflatoxin-contaminated turkey feed made of moldy Brazilian peanuts. Eventually it was discovered that all crops and foodstuffs, including corn, rice, wheat, barley, and nuts, can contain naturally occurring mycotoxins.¹

There are several aflatoxins and their metabolites (such as AFB₁, AFG₁, AFM₁) that are capable of producing human disease.² Aflatoxins are named by their fluorescence under ultraviolet light as blue (AFB) or green (AFG) as well as other analytic characteristics. Aflatoxins M (AFM), where M denotes milk or mammalian metabolites, are secreted in the milk of animals exposed to aflatoxins. There are two broad categories of aflatoxins according to their structures: aflatoxins B₁ and M₁ are within the difurocoumarocyclopentenone series (Fig. 137-1), and aflatoxin G₁ is of the difurocoumarolactone series (Fig. 137-2).

Exposure to aflatoxins is typically via ingestion of contaminated foodstuff. Dermal exposure results in slow and insignificant absorption.³ Inhalational exposure in humans has not been studied. In vitro metabolism studies have shown the following metabolic reactions for AFB₁: reduction produces aflatoxicol (AFL); hydroxylation produces AFM₁; hydration produces AFB_{2a}; and epoxidation produces AFB₁-2,3-epoxide. The epoxide is the most reactive metabolite and is thought to be responsible for both the acute and chronic toxicity of AFB.⁴ In an Indian report, ingestion of an estimated 2 to 6 mg/kg/day of aflatoxin over 1 month produced hepatitis, with some fatalities.⁵ However, a suicide attempt by acute ingestion of 1.5 mg/kg of pure aflatoxin resulted only in nausea, headache, and rash.⁶

The liver is the primary target of toxicity and may lead to hepatic failure. Early symptoms of hepatic injury from acute poisoning include abdominal pain, anorexia, malaise, and low-grade fever.⁷ Icterus and jaundice develop within several days, followed by abdominal distention, vomiting, ascites, and edema.⁸ Mortality rates from acute aflatoxicosis range from 10% to 76%.⁷ The chronic effects of aflatoxins are primarily carcinogenesis resulting in hepatocellular carcinoma. Laboratory tests of liver

function confirm the extent of hepatic injury in acute aflatoxicosis. Elevated aspartate and alanine aminotransferase levels frequently exceed 5000 IU/liter. Bilirubin levels are also increased. Acute jaundice and death have been recently reported in an outbreak of aflatoxin poisoning in Kenya.⁹ In cases of liver failure, elevation of the prothrombin time, metabolic acidosis, and hypoglycemia are the characteristic signs.¹⁰ Pathologically, there is extensive centrilobular necrosis in the perivenular zone (zone 3) extending to periportal zones (zone 1) with giant cell infiltration and cholestasis.¹¹

The 1972 Biological and Toxin Weapons Convention is a major international treaty seeking to control biologic warfare. It prohibits state parties from developing, producing, stockpiling, and testing biologic and toxic weapons.^{12,13} However, with the expansion of terrorism, the use of mycotoxins as weapons is a real threat. Possible attack scenarios include the following:

1. Product tampering: Substantial human and economic damage could result from consumer product tampering such as the cyanide poisoning of Tylenol in 1984.¹³ Tampering by spiking premade consumer products with mycotoxins may be the most plausible attack scenario.
2. Chemical weaponry: A second scenario is large-scale terrorism using aflatoxins as chemical weapons against a population group or region, such as the Anfal Operations against the Kurds of Northern Iraq.
3. Food tampering: Another scenario is an attack on food industries. The dairy industry is especially vulnerable to biochemical agents, probably because of the nature of manufacturing process and the reliance of animal feeds that could be contaminated with biochemical (mycotoxins) agents.¹³ Such an attack would cause local outbreaks of disease within hours or days. In September 2004, the Hungarian government pulled paprika off the market due to excessive levels of aflatoxin detected in much of their product.¹⁴

PREINCIDENT ACTIONS

Hospitals, emergency departments, and ambulatory care facilities should have general disaster plans in place to

AF	R
AFB ₁	H
AFM ₁	OH

FIGURE 137-1. Structures of AFB₁ and AFM₁ (see text).

FIGURE 137-2. Structure of AFG₁.

respond to a biochemical (mycotoxin) attack. Early detection of a biologic or chemical weapon attack requires a surveillance system that is capable of finding and confirming the diagnosis and serving as a means of communicating this information between clinicians and health departments in a timely fashion.¹⁵ Current syndromic surveillance appears to be directed more toward respiratory and flu-like illness, although several monitor gastrointestinal illness.¹⁶ Efforts should be made to include hepatitis syndromes in such monitoring efforts. This would require coordination of local, state, and federal public health and safety resources. In the event of an attack, emergency medical services, hospitals, and ambulatory care facilities need to be mobilized to care for potentially large numbers of patients seeking medical care in a short timeframe. Decontamination and triage procedures should be in place, and personnel properly trained, before an attack occurs. Since most physicians, healthcare providers, and first responders are not likely to be familiar with the characteristics of an aflatoxin terrorist attack, close contact with the local poison control center or local health department may be important in identifying the initial cases.

POSTINCIDENT ACTIONS

Medical providers should include aflatoxin toxicity in the differential of acute hepatitis. Appropriate local, state, and federal public health agencies and law enforcement authorities need to be notified. Aflatoxin-contaminated materials, body fluids, and surfaces should be decontaminated with a 10% bleach (sodium hypochlorite) solution. Bleach should not be used to decontaminate patients. Proper sampling by a qualified industrial hygiene profes-

sional may be necessary for aflatoxin identification and evidence documentation. Further epidemiologic investigations in collaboration with state or local health services may be necessary. Complete blood count and liver function tests are recommended. Analysis of blood or urine samples may provide information concerning the metabolites of the mycotoxin.

MEDICAL TREATMENT OF CASUALTIES

Treatment of acute aflatoxin exposure requires identification of and removal from the source of exposure. Activated charcoal is recommended in cases of recent ingestion. Aggressive supportive management, especially for acute liver failure, is indicated in all suspected cases. Hemodialysis and hemoperfusion are not expected to enhance elimination. Although there is no known antidote, *N*-acetylcysteine (NAC) may have a protective effect against aflatoxin carcinogenesis by increasing intracellular glutathione levels.¹⁷ An animal model¹⁸ found reduced hepatic injury when NAC was coadministered with high daily doses of AFB₁; however, efficacy in humans has not been demonstrated.

CASE PRESENTATION

There are several reports from Asia and Africa that suggest acute poisonings secondary to aflatoxins resulting from ingestion of a large amount of toxin over a short period of time. A typical presentation is as follows:

Two young children are taken to the local hospital emergency department from the neighborhood village. Patient's family members inform the emergency department physician that they have all consumed corn from a local farmers market. Over the last 5 days, the children developed swelling of their lower extremities, abdominal pain, vomiting, and diarrhea, but no fever. Further history reveals that the adults experienced similar but milder symptoms. On examination, the patients are lethargic. Also present is slight jaundice with an enlarged liver that is tender to palpation. The next day, it is reported in the news media that an additional 30 children have been admitted to surrounding hospitals and more than 100 adults and children have been seen in local ambulatory care clinics for similar but milder symptoms. They all report eating corn and fruits purchased from a local farmers' market. Laboratory testing of the initial two young children reveals elevated liver aminotransferase levels, low blood glucose, and elevated blood ammonia levels. These two patients fully recover after 1 week of supportive care and intravenous fluids.

UNIQUE CONSIDERATIONS

Diseases caused by mycotoxins such as aflatoxins are most effective when they are ingested. Aflatoxin attack using an aerosolized mechanism is unlikely to produce sufficient levels to cause significant morbidity or mortality.¹⁹

Several potential pitfalls in response to an aflatoxin attack exist. These include the following:

- Failure to prepare adequate systems to respond to possible terrorist attacks before an incident occurs
- Failure to consider aflatoxin as the cause for nonspecific as well as systemic symptoms of acute hepatitis
- Failure to consider aflatoxin attack in the setting of a large number of otherwise healthy people presenting over hours and days with a wide range of general and specific complaints
- Failure to notify appropriate public health, safety, and law enforcement authorities when a biochemical agent attack is suspected, especially when animals fall sick along with people
- Failure to collect specimens for identification of aflatoxins
- Failure to provide basic supportive care when a patient is suspected to have been exposed to a biochemical warfare agent

chapter 138

Coccidioides immitis Attack (Coccidioidomycosis)

James F. Martin and Jill A. Grant

DESCRIPTION OF EVENT

Coccidioidomycosis is a specific disease, caused by the fungus *Coccidioides immitis*. It was first defined as a syndrome in 1892 and shown to be a fungal infection in 1900. This disease is known as San Joaquin Valley fever, or valley fever, due to its native location in the San Joaquin Valley of California, Arizona, New Mexico, Texas, and Utah, as well as in Mexico and portions of Central and South America. There are approximately 25,000 clinically significant cases defined per year in the United States, with 75 deaths per year attributed to the illness.^{1,3} In 2001, the Arizona Department of Health reported 43 cases per 100,000 population, representing an increase of 186% since 1995.³ Although there are endemic areas, with the majority of long-term residents demonstrating evidence of prior *C. immitis* infection, those areas often experience intermittent sharp seasonal increases in the number of cases, demonstrating the infectivity of the disease as well as its capability for mutation.

C. immitis exists as both a saprophyte and a parasite at different times during its life cycle. It is in the saprophytic stage in which it grows in soil as a mold with septate hyphae. It is initially spread by airborne spores, with epidemics often occurring after large-scale soil disturbances such as earthquakes, excavations, or storms. Once disturbed, these hyphae are broken off, forming arthroconidia, which in turn become airborne. The parasitic phase occurs if an animal or human inhales the arthroconidia, which become lodged in the pulmonary alveoli. It is here that they grow into multinucleate spherules, producing thousands of uninucleate endospores, each of which can give rise to a new spherule. The endospores have been shown to spread in a suitable host within the lung or through the bloodstream. Dissemination through the bloodstream has been shown to lead to deposition in perihilar, peritracheal, and cervical lymph nodes. Multisystem involvement can include skin and soft tissue infection, joint and bone infection, and meningitis.

The majority of symptoms are pulmonary. In the 40% of acutely exposed persons displaying symptoms, the most common are cough, shortness of breath, chest pain, and sputum production, along with systemic symptoms

of fever, sweating, anorexia, weakness, and arthralgias.¹ These symptoms may last for several weeks, with spontaneous resolution. The average otherwise healthy person infected with *C. immitis* misses an average of 1 month of school or work.¹ If the disease becomes disseminated, multiple sites can be affected.⁴ The most common extrapulmonary site is the skin, with superficial maculopapules, keratotic nodules, verrucous ulcers, and subcutaneous fluctuant abscesses being found.² The pus may be described as “gel-like.” These lesions have a predilection for the nasolabial fold. Erythema multiforme and erythema nodosum may occur, more commonly in female patients. Erythema nodosum may be the initial presentation and reflects a heightened immune response. These patients rarely go on to disseminate.² The triad of fever, erythema nodosum, and arthralgias is called *desert rheumatism*.² Bone and joint infections may occur, in the company of dramatic effusions and synovial involvement, with dissemination. Joint lesions are unifocal in 90% of cases. The knee is the most commonly affected joint, followed by the ankle.^{1,2} Coccidioidal meningitis is the most life-threatening of manifestations, with mortality approaching 90% at 12 months if untreated.^{1,2} Usually the basilar meninges are involved, and presenting symptoms include fever, headache, vomiting, and altered mental status. Complications include hydrocephalus, cerebral vasculitis, and focal intracerebral coccidioidal abscesses.² Neurosurgical consultation may be urgent, for shunting or incision and drainage.

Diagnosis of coccidioidomycosis may be difficult and challenging, primarily due to a failure to consider the disease outside its endemic areas.⁵ A specific travel history is usually necessary in nonendemic areas to prompt suspicion of the diagnosis.⁶ Skin testing results become positive after the initial onset of symptoms in most patients with primary infections; anergy, however, is common in progressive disease.¹ Routine laboratory tests are not specific, although the erythrocyte sedimentation rate is usually elevated and the eosinophil counts are often increased.⁷

Culture and serologic testing are the most commonly available tests, although direct microscopic examination of tissue samples is deemed safest. The mycelial form of

the fungus has minimal growth requirements, growing after 3 to 7 days on most mycologic or bacteriologic media under aerobic conditions and at most temperatures.^{1,2} Mature colonies can have a myriad of appearances and are very highly infectious to laboratory workers.¹ In histopathology specimens, a mature spherule with endospores is pathognomonic of infection and is easily recognizable on wet mounts using potassium hydroxide or Calcofluor white.⁸ Spherules also can be easily seen with multiple staining techniques,¹ particularly with periodic acid-Schiff. The organism can often be seen in, or grown from, pus, sputum, and body fluid aspirates.¹ Serologic testing is almost entirely based on immunoglobulin (Ig) M and IgG antibodies. False-positive test results are rare.¹ IgM is detected transiently in 75% of acutely infected persons 1 to 3 weeks after onset of symptoms due to primary infection and may last 3 to 4 months. Complement-fixing IgG appears later after the acute infection and disappears in 6 to 9 months if symptoms resolve.⁸ Persistently elevated IgG antibody is observed in disseminated disease.

In the case of *C. immitis* meningitis, cerebrospinal fluid (CSF) cultures are usually negative in 85% of early cases.¹ The CSF will show an elevated pressure, a marked mononuclear pleocytosis, low glucose level, and high protein level.¹ A positive result of an IgG test of the CSF confirms the diagnosis.² Imaging studies are nonspecific but can aid in the diagnosis. Chest radiology may delineate cavities and granulomas. Magnetic resonance imaging may be useful to examine the brain for signs of meningitis or abscesses.² Radionuclide bone scanning may delineate bone lesions.

Coccidioidomycosis would appear to make a poor biologic weapon. Most immunocompetent patients are asymptomatic, with only 40% of infected persons displaying any type of symptom. Among those who are symptomatic, the most common form is an upper or lower respiratory tract infection, which usually resolves without specific therapy and can last up to 3 or 4 weeks and still go undiagnosed. Extrapulmonary manifestations have much higher morbidity and mortality but occur in only 0.5% of cases, may take up to a year to develop, and occur in subpopulations of immunocompromised persons with defects in delayed hypersensitivity, pregnant women in their third trimester, infants, or patients of Filipino, African American, or Mexican descent who are genetically predisposed to disseminate the disease. The organism is almost entirely contained in the "Western Hemisphere," with an estimated majority of those Americans who are living in the endemic areas already showing signs of prior exposure or infection. Thus, if the fungus were used as a weapon of mass destruction, a minority of the population would be symptomatic, with most symptoms resolving in a few weeks. In those few persons who do have life-threatening infections, it will usually occur in minority populations and could take up to a year to develop.

There are, however, some facts that demonstrate the potential lethality of coccidioidomycosis if used as a biologic weapon. First, each year, 25,000 new cases are diagnosed, and 75 deaths occur annually. These deaths almost always occur in those persons suffering from disseminated disease. The most common dissemination is to the

skin, closely followed by the meninges. If meningitis occurs, the 12-month mortality is 90% if not treated. Even with appropriate treatment, mortality rates from fulminant infections remain high. It is estimated that, even with our most advanced treatment, neurologic involvement by coccidioidomycosis has a 70% to 80% death rate. Hence, there is a significant mortality of the disseminated disease.

Second, the fungus has a very high virulence, with only a single *C. immitis* arthroconidium required to produce pulmonary infection.² However, devastating outbreaks have been demonstrated when coccidioidomycosis has been specifically grown in the laboratory setting, such as in the case of hospital laboratory personnel attempting to diagnose a patient. This occurrence demonstrates the increased virulence of the spore form of the organism when being grown in the laboratory. Add to this fact the apparent capability to mutate, and a potentially devastating biologic weapon could be developed.

Third, healthcare workers may not initially recognize a coccidioidomycosis attack. With the majority of patients asymptomatic, and those who are symptomatic displaying a nonspecific upper respiratory infection, initial cases may be ignored or diagnosed with a self-limited viral disease. Three to 4 weeks is the incubation period for the pulmonary manifestations, so a delay from the initial exposure may be present. For the sickest patients, an even longer incubation period of up to 1 year may be evident, further complicating the diagnosis and increasing the morbidity in the specific population of infected persons with the highest mortality. Although there has been no documented incidence of person-to-person spread through air droplets, the infectivity of these long-incubation patients is unknown. Use of *C. immitis* as a weapon could therefore cause a subtle increase in the workload of the healthcare system over time.

The most likely scenario of a *C. immitis* attack would consist of a large urban population with a large number of persons presenting over a few weeks with a nonspecific upper respiratory infection. Minority populations; pregnant women; infants; and immunocompromised patients, such as those with HIV, those having received organ transplant; and patients taking steroids would be the worst affected. An effective attack would require a large target population localized in a specific area that could be inoculated with airborne particles. Although evidence of prior infection may already be present in much of the population, a dramatic increase in clinical cases should alert healthcare workers, and once positive diagnoses are made, a biologic attack should be considered. The population should be followed up for as long as 1 year after the incident for evidence of chronic severe infection; this requirement in itself will increase the load on the healthcare system and could increase public fear, as those exposed would constantly worry that they might develop delayed and serious illness.

PREINCIDENT ACTIONS

In endemic areas, coccidioidomycosis can only be prevented by occupationally preventing susceptible per-

sons from working in high-risk situations; therefore, in these specific areas, focused educational programs for construction and agricultural workers should be in place, as well as for students, military personnel, and healthcare workers. Documented cases of mass infection with *C. immitis* show occurrence in one of three ways: (1) recent visit to an endemic area; (2) reactivation of a prior infection; or (3) exposure to spores brought out of an endemic area.

Hospitals, emergency departments, and outpatient facilities should each have a disaster response plan in place. Coordination of local, state, and national public health and public safety resources are required in the event of a mass-casualty situation such as biologic warfare. Both emergency medical services and hospital triage systems may need to be altered to account for the influx of patients with specific treatment requirements—in this case, respiratory ailments. Universal precautions should be in place, even though person-to-person transmission of coccidioidomycosis has never been documented.⁹ Diagnosis of the index case may be difficult, again, mainly due to a lack of suspicion for the agent in nonendemic areas. Special and specific care needs to be taken with the culturing of *C. immitis*: namely, specialized training for laboratory technicians, universal precautions, Biosafety Level 3 procedures, and negative pressure rooms. Cultures should be planted on slants rather than on culture slides. Physicians should be trained to highlight their suspicions for coccidioidomycosis when submitting culture specimens from suspect patients.

A real coccidioidomycosis attack or a major natural outbreak is unlikely; however, healthcare providers need to be aware of the disease and keep it on the differential diagnosis list. The possibly long incubation period, nonspecific complaints, and multiple organ involvement may make initial diagnosis extremely difficult. Universal precautions need to be in place, as well as a surveillance system that can recognize a trend in patient syndromes. With documentation of trends over time, a specific index incident may be able to be identified.

POSTINCIDENT ACTIONS

Healthcare providers with suspicion of, or a clear demonstrated case of, coccidioidomycosis need to contact specific public health officials because coccidioidomycosis became a nationally reportable disease in 1995.³ Also, any medical providers or disaster response teams that may come into contact with an infected party or a putative exposure location should be notified and screened. Such responders may include any hospital or clinic worker or physician who treated patients from a specific location, as well as emergency medical services, police, or fire personnel; clean-up crews; those working for the Red Cross and other relief organizations; and the military.

Disinfection of surfaces possibly contaminated with arthroconidia should be carried out with standard disinfectants or antiseptic agents.

MEDICAL TREATMENT OF CASUALTIES

Of the endemic fungal infections, coccidioidomycosis is the most resistant to therapy.¹⁰ The treatment and care of the primary respiratory infection is controversial, primarily due to the lack of controlled clinical trials.^{1,2} For the majority of patients, care should include symptomatic treatment and careful reexamination to ensure the resolution of symptoms. Follow-up radiology to monitor the resolution of pulmonary findings is also recommended. The goal of this approach is to monitor resolution in the event of not using antifungal therapy. Historically, initial pulmonary manifestations have a 95% spontaneous resolution rate. However, some authorities propose rapid and high-dose antifungal medications at the time of diagnosis for unusually severe infections or with comorbid conditions such as organ transplantation, HIV infection, diabetes, or steroid use. The severity of the disease should be estimated, with the following characteristics kept in mind: symptoms that persist longer than 2 months; weight loss greater than 10%; greater than 3 weeks of night sweats; infiltrates involving greater than 1 lung; development of anergy to skin tests; prominent or persistent hilar adenopathy; Filipino, African American, or Mexican ethnic background; pregnant female patients in their third trimester; or an antibody test result demonstrating antibody to *C. immitis* in a titer greater than 1:16.²

For persons with severe infections, the two treatment options consist of surgical debridement or chemotherapy. Surgery should be determined on a case-by-case basis and is an option in the case of extensive bone or skin involvement. The theory behind the use of debridement is that the spherule wall (1) is a strong stimulus for inflammation, (2) cannot be degraded by the body, and (3) cannot be cleared by macrophages.² Thus, continued tissue damage can occur until the spherule is physically removed. Also, pulmonary cavities have been shown to react poorly to chemotherapy.^{1,2}

In cases of disseminated disease, chemotherapy should always be initiated.¹ Chemotherapy is achieved with either amphotericin B or antifungal azoles (ketoconazole, fluconazole, itraconazole).^{1,2,10,11} Although known for potent side effects, amphotericin B is preferred due to the more rapid onset when compared with the azoles. Also, whereas the azoles as a group are categorized as pregnancy class C, amphotericin B is a class B agent. Standard precautions and monitoring with the medications should be performed. Amphotericin B is administered for a total of 2 months, or until the disease becomes inactive. Although the azoles are taken orally, and thus better tolerated, they are currently not approved for this use by the U.S. Food and Drug Administration. Efficacy seems to be similar between the two classes of drugs, but frequent relapses have shown that therapy with the azoles needs to be continued for 6 months.^{1,2,10} Future treatment may involve novel azole agents (e.g., posaconazole, voriconazole), caspofungin (an echinocandin that inhibits glucan synthetase), or sordarin derivatives (drugs that specifically inhibit fungal protein synthesis).¹⁰

CASE PRESENTATION

You have a follow-up visit with a patient who was initially seen 1 week ago in the emergency department by one of your peers. He is an elderly diabetic man, and his initial complaints were fever, night sweats, and vague upper respiratory complaints of a productive cough, sputum production, and shortness of breath. He states he was in his usual state of health until this past week, with his only unusual activity being 4 weeks ago when he was a guest at an archaeological dig in New Mexico. When an initial workup yielded negative results, he was treated for a viral respiratory infection and discharged home.

The patient returns today with the continuation of his initial complaints, but now he complains of a rash over his entire body, pain and swelling in his right knee, difficulty concentrating, and a persistent irritating headache. While reviewing the charts of the emergency department, you notice that there have been at least 10 other patients with similar symptoms in the past week, with seemingly the worst affected being a pregnant woman and a renal transplant patient.

UNIQUE CONSIDERATIONS

Coccidioidomycosis is a fungal infection that usually causes self-limited upper respiratory or febrile illnesses, but which, when disseminated, can cause life-threatening extrapulmonary disease. Its manifestations are similar to many common nonspecific illnesses and thus may elude diagnosis when the diagnosis is not sought. Although it is considered a possible biologic weapon due to the high virulence of the arthroconidia and severe mortality of the disseminated disease, *C. immitis* would likely make a poor bioweapon due to the fact that it is not a virulent infection in normal hosts. Terrorists would need to either find a way to cause immune suppression in a normal population in advance of seeding the infection or target a compromised host population. More important are its very long incubation period, that 60% of infected persons are asymptomatic, and that the majority of patients spontaneously recover. The use of coccidioidomycosis as a biologic weapon would be ineffective, and the identification of infected persons would be extremely difficult; a natural outbreak is far more likely but poses similar diagnostic pitfalls. The main points to remember are to keep this organism in the differential diagnosis and remember that appropriate therapy requires a multidisciplinary approach, using symptomatic therapy, antifungal chemotherapy, and surgery to produce the best outcome.

PITFALLS

Several potential pitfalls in response to an attack exist. These include the following:

- Failure to have a disaster response plan
- Failure to consider coccidioidomycosis as a possible cause in patients with mild symptoms
- Failure to adequately diagnose persons suspected of having the disease process
- Failure to adequately treat patients with both surgical options as well as antifungal agents
- Failure to have adequately prepared and trained laboratory capabilities
- Failure to notify laboratory workers of a high suspicion for coccidioidomycosis in submitted specimens, so that they may take appropriate precautions to limit their own exposure
- Failure to notify and screen possibly infected persons who were involved with the index incident
- Failure to notify local, state, and federal agencies in the instance of a suspected case

Histoplasma capsulatum Attack (Histoplasmosis)

Carol L. Venable and Elizabeth L. Mitchell

DESCRIPTION OF EVENT

Histoplasma capsulatum, the organism responsible for histoplasmosis, is a dimorphic fungus that is endemic to many parts of the world, most notably the United States and Latin America. *H. capsulatum* spores are present in soil, especially soil that has been contaminated by bird or bat excrement.¹ In the Americas, histoplasmosis is found primarily in the regions of the Ohio, St. Lawrence, Mississippi, and Rio Grande river systems.² Humans come into contact with aerosolized spores of *H. capsulatum* when they engage in occupational or recreational activities in endemic areas. Construction or demolition work, bridge cleaning or repairs, farming, gardening, and exploring caves are all high-risk activities for infection.² In the endemic region, skin testing demonstrates that a majority of the population has had prior infection with *H. capsulatum*, and up to 25% of patients with acquired immunodeficiency syndrome (AIDS) in these areas will have active disease.³

Histoplasmosis has numerous clinical manifestations. The majority of infected persons are asymptomatic, which complicates the identification of outbreaks of this disease. When present, symptoms usually begin within 1 or 2 weeks of exposure.² The most common clinical form of disease from *H. capsulatum* is acute pulmonary histoplasmosis, which typically presents with fever, fatigue, dry cough, and headaches.¹ Acute pulmonary histoplasmosis tends to be self-limited and often resolves on its own over the course of 2 to 3 weeks.⁴ The disease may be so mild that affected patients may not seek medical attention. More severe or prolonged cases may prompt patients to visit clinics or emergency departments. Less commonly, patients will present with severe respiratory failure and, in these cases, acute pulmonary histoplasmosis can be fatal if not rapidly diagnosed and treated.⁵ Other, more chronic forms of histoplasmosis exist, such as chronic lung disease from *H. capsulatum* in patients with preexisting emphysema, but these disease manifestations do not have relevance to acute outbreaks or attacks.

In patients with AIDS, hematologic malignancies, transplants, or some other source of immunocompromise,

there is a much greater risk of developing disseminated histoplasmosis, the manifestation of *H. capsulatum* that affects almost every organ system and is also potentially fatal.⁵ Infants and elderly persons may manifest this form as well, even in the setting of an apparently healthy immune system.¹ Disseminated disease may progress rapidly and may present as dysfunction of the reticuloendothelial system, shock, and multiorgan system failure.⁵ In immunocompetent patients who are not at the extremes of age, disseminated histoplasmosis is less common and more indolent. It may present as a fever of unknown origin without many other associated symptoms.⁵

Despite having some virulent disease manifestations, there is no evidence that *H. capsulatum* has ever been weaponized. Although its spore form might lead one to believe that it could be easily manipulated, in fact, there are several features of the organism that make it difficult to use as an intentional biologic weapon. First, in areas where *H. capsulatum* is endemic, a significant percentage of the population has at least partial immunity to histoplasmosis, having been previously exposed at some level.² This lowers the likelihood that a biologic attack would cause widespread, severe disease in these areas. Second, the toxic exposure limits for *H. capsulatum* are not known, making it difficult for an aggressor to know what level of concentration to produce for use as a weapon.² Finally, histoplasmosis causes a broad spectrum of disease, the majority of which is nonfatal, self-limited, and treatable. Even in AIDS patients with disseminated disease, antifungal therapy has reduced the mortality to less than 25%.⁴

One can hypothesize, however, a variation on an intentional disaster scenario in which *H. capsulatum* would inadvertently become a biologic weapon. If an explosive device detonated in an area with soil containing *H. capsulatum*, there is a high likelihood that histoplasmosis could be a secondary cause of morbidity and mortality in victims or rescue workers who inhale the spores. Again, the prior consideration of partial immunity would hold for people living in the endemic area. However, if the soil contained a high enough spore concentration and was dispersed widely enough by the explosion, large numbers of people might still be at risk for significant infections.

A far more likely disaster scenario would be a completely unintentional exposure. In the past, unintentional exposures and the subsequent outbreaks they have caused have originated from a number of different sources. In Acapulco, Mexico, in the spring of 2001, the source of *H. capsulatum* that infected hundreds of American travelers is thought to have been the soil in the utility shaft adjacent to a central stairway in a major tourist hotel.⁶ In Nicaragua in October 2003, several tourists were infected during a visit to a bat-infested cave.⁷ Outbreaks have been reported in Tennessee, Kentucky, Indiana, Michigan, and several other states in which people cleaned, constructed, or demolished bridges or buildings that were surrounded with soil contaminated by bat or bird excrement.^{3,8-10} Many of these outbreaks theoretically could have been predicted, and prevented, if the workers or their employers had considered the risks of manipulating potentially contaminated soil and either decontaminated the area first or used protective gear.

Diagnosis of histoplasmosis requires having a high clinical suspicion and obtaining a thorough travel and occupational history. The differential diagnosis is extensive and includes atypical pneumonia, influenza, tuberculosis, sarcoidosis, and other fungal diseases. Physical examination may be unrevealing, although in disseminated disease, patients may have hepatosplenomegaly or lymphadenopathy. Routine laboratory test results are likely to be normal in cases of acute pulmonary histoplasmosis. Disseminated disease may be associated with pancytopenia, as well as elevated liver function test results. Chest radiographs in cases of acute pulmonary histoplasmosis may be normal or may show reticulonodular infiltrates, often with hilar or mediastinal lymphadenopathy. The majority of cases of disseminated disease yield abnormal chest radiographs, also with interstitial or reticulonodular infiltrates.⁵

Cultures, fungal stains, serologies, and antigen detection permit the laboratory diagnosis of *H. capsulatum*. Cultures can detect between 80% and 90% of cases of disseminated disease but have a much lower sensitivity for acute pulmonary histoplasmosis.¹¹ In addition, they may take several weeks of growth before they turn positive.⁵ This makes culture suboptimal in an outbreak setting. Serologic tests can be performed either by immunodiffusion or complement fixation technology, of which the complement fixation is the more sensitive although less specific test.² The serologic tests have a sensitivity of greater than 90% for acute pulmonary histoplasmosis, although their sensitivity for disseminated disease is lower.¹² The difficulty with these tests is that up to 6 weeks may be required before the serology yields positive results. In addition, positive serologic test results may be due to prior infections or infections caused by other fungi.⁵ Despite these limitations, complement fixation is a viable option for detecting acute pulmonary histoplasmosis in outbreaks, especially in patients with severe disease, because the test has a much better sensitivity in highly symptomatic patients.¹²

Urine antigen testing is the test of choice in the majority of patients during an outbreak. It has a turnaround time of 1 to 2 days and has a sensitivity of approximately 90% in patients with disseminated disease and approxi-

mately 75% in patients with acute pulmonary histoplasmosis.¹² Serum antigen testing can also be performed but is less sensitive than urine antigen testing. Like the serologic tests, antigen testing has the potential drawback of cross-reaction with other fungal agents.¹¹ The only other test as rapid as antigen testing is tissue fungal stain, which can be used if tissue is obtained from a patient—for example, from a transbronchial or bone marrow biopsy. The accuracy of fungal stain results is dependent, however, on a given laboratory's skills in distinguishing among different types of fungal organisms.⁵

PREINCIDENT ACTIONS

Histoplasmosis has a wide range of disease severity. Patients are likely to present to clinics, urgent care centers, and emergency departments with this disease. Rapid identification of an outbreak, therefore, requires a preexisting system of coordination among ambulatory care centers, emergency departments, and state or national public health authorities. Healthcare providers, especially those in endemic areas, need education about possible presentations of outbreaks and specific instructions as to the best way of reporting any suspected cases.

If there were any threat of an explosion of a building in an area endemic for histoplasmosis, steps could be taken to eradicate *H. capsulatum* as a secondary threat. For example, obvious targets such as skyscrapers, bridges, and major government buildings could have soil testing performed in the area surrounding them. Any soil with significant concentrations of *H. capsulatum* could then be treated with a 3% solution of formalin, which inactivates the spores.^{13,14} This would eliminate at least the threat of an inadvertent biologic disaster in the unfortunate case of an explosion. A similar approach is recommended, and has been used in the past, in the setting of building construction, demolition, and cleaning.²

POSTINCIDENT ACTIONS

Histoplasmosis is not transmitted from one human to another.² Therefore, isolation of potentially infected patients is not necessary. The two critical postincident actions that need to be taken are as follows: (1) rapid identification of *H. capsulatum* as the cause of the outbreak and (2) decontamination of any remaining *H. capsulatum* spores. Diagnosis can be performed by any of the methods listed above, but, in general, serologic and urine antigen testing will be the most useful modalities in an outbreak.

Soil testing around the presumed site of an outbreak, along with subsequent formaldehyde decontamination of any *H. capsulatum*-containing soil, is critical for preventing continued exposures and infections. Investigators involved in outbreaks need to wear appropriate protective gear when evaluating possible sites of exposure. In particular, powered, air-purifying respirators with full face piece are optimal. These should be used along with disposable clothes and shoe coverings.²

MEDICAL TREATMENT OF CASUALTIES

Not all cases of histoplasmosis require treatment, and in a disaster setting, antifungal agents must be restricted to those patients most in need. In the setting of acute pulmonary histoplasmosis without acute respiratory failure, treatment should only be given to patients who fail to improve after experiencing symptoms for 1 month. Oral itraconazole at a dosage of 200 mg daily for 6 to 12 weeks can be used in this group. For immunocompetent patients with severe manifestations of acute pulmonary histoplasmosis (e.g., requiring a ventilator), the treatment of choice becomes amphotericin B administered at a dosage of 0.7 mg/kg/day. Prednisone (60 mg) taken daily for 2 weeks may be used in conjunction with amphotericin B in immunocompetent patients, although the data studying this are limited. After discharge from the hospital, the patient's treatment can be maintained on itraconazole (200 mg) taken once or twice daily to complete a 12-week antifungal course.⁴

Patients with disseminated histoplasmosis are subdivided for treatment purposes into persons with AIDS and those without AIDS. Patients with AIDS undergo a total of 12 weeks of therapy with amphotericin B (0.7 mg/kg/day) followed by itraconazole (200 mg twice daily) on discharge home. Patients who never require hospitalization can be treated with itraconazole (200 mg) three times daily for 3 days followed by twice daily for a total of 12 weeks. After the initial 12 weeks, a life-

long maintenance regimen of itraconazole (200 mg) once or twice daily is recommended.⁴

Patients with disseminated histoplasmosis who do not have AIDS are treated with amphotericin B (0.7 to 1.0 mg/kg/day) if they require hospitalization. The amphotericin B can be switched to oral itraconazole once the patient defervesces. Itraconazole (200 mg) once or twice daily can be continued for 6 to 18 months for completion of therapy. Duration of treatment can be determined by serial measurement of *H. capsulatum* antigen concentrations.⁴

UNIQUE CONSIDERATIONS

Low mortality and a vast range of disease manifestations make outbreaks of *H. capsulatum* difficult to detect. In addition, histoplasmosis resembles many other pulmonary and infectious diseases. Patients may not be identified as part of an outbreak unless a careful occupational, recreational, and travel history is obtained. A history of close contacts, especially those who went on the same trip or participated in the same job, may also be extremely helpful in diagnosis.

PITFALLS

Several potential pitfalls in response to a histoplasmosis attack exist. These include the following:

- Failure to consider histoplasmosis as a possible cause of secondary morbidity and mortality in natural disasters or explosions in areas in which *H. capsulatum* is endemic
- Failure to obtain a complete occupational and travel history in patients presenting with nonspecific pulmonary complaints
- Failure to consider histoplasmosis as a possible diagnosis during influenza season or during known outbreaks of other pulmonary illnesses
- Failure to consider decontamination or protective gear for *H. capsulatum* as a protective option when attempting to evaluate the site of a possible outbreak
- Failure to consider in advance the importance of decontamination of soil containing *H. capsulatum* surrounding buildings, bridges, and other structures that could be threatened by explosions or that are scheduled for cleaning, construction, or demolition

CASE PRESENTATION

A 30-year-old male construction worker in Tennessee presents to his primary care physician (PCP) in December with the chief complaint of having had a dry cough for the past 2 weeks. He is an otherwise healthy man with no history of any lung disease. During a review of systems, he notes that he has had some headaches, mild fatigue, and low-grade, subjective fevers. He denies any exposure to tuberculosis or any risk factors for human immunodeficiency virus. He states that none of his family is sick but that several of his coworkers have had "the flu." He says that a couple of them are actually in the hospital, but he does not have any further details. The results of his lung examination are unremarkable, but because of the duration of the cough, the PCP obtains a chest radiograph, which is notable for diffuse reticulonodular infiltrates bilaterally.

On reinterviewing the patient and focusing on occupational history, the PCP learns that he and his coworkers have been tearing down an old building previously infested with bats. They started the demolition process about 3 or 4 weeks prior. There are approximately 100 workers at the site. The PCP then contacts the state health department with her concerns about a possible outbreak of histoplasmosis. The health department instructs her to obtain serologic and urine antigen testing for *H. capsulatum* at that visit. She instructs the patient to return for antifungal therapy if he has worsening symptoms at any point or still has his current symptoms in 2 more weeks.

Cryptosporidium parvum Attack (Cryptosporidiosis)

Miriam John and Carol Sulis

DESCRIPTION OF EVENT

Human cryptosporidiosis is a disease caused by the protozoan cryptosporidium, an obligate intracellular parasite. *Cryptosporidium parvum* is the most common species in humans, but other species have been identified in immunocompromised hosts. The human pathogen *C. parvum* (genotype 1) and the bovine pathogen *C. parvum* (genotype 2) are the most important agents in human disease.¹ Reservoirs for *C. parvum* include humans; domesticated animals such as cows, goats, and sheep; and wild animals, such as deer and elk. Tyzzer and Clarke discovered cryptosporidia in the stomach of a mouse in 1907. The first human case was reported in 1976 in a child with diarrhea. Since 1982, and the beginning of the AIDS epidemic, cryptosporidia have been increasingly recognized as a cause of diarrheal illness in both immunocompromised and immunocompetent human hosts. Cryptosporidiosis is the leading cause of diarrhea due to protozoal infections worldwide.²

C. parvum is classified by the Centers for Disease Control and Prevention (CDC) as a category B bioterrorism threat agent and, more specifically, as a water safety threat. Cryptosporidia are highly infectious enteric pathogens that are resistant to chlorine, are small and difficult to filter, and are ubiquitous in many animals, making them a persistent threat to the U.S. water supply.³ *C. parvum* is also a hardy organism that can survive for 18 months at 4°C in surface water and for 2 to 6 months in groundwater.⁴ Oocysts have been found in 87% of untreated water samples tested in the United States and Canada.⁵ Cryptosporidia are resistant to common water disinfection techniques such as chlorination, treatment with sodium hypochlorite, and filtration (if the filter pore size is greater than 1 micron).¹ A recent study of 66 water treatment plants in 14 states and one Canadian province showed that 27% of filtered water samples contained *Cryptosporidium* oocysts.⁴

Cryptosporidium infection occurs after ingestion of fecally contaminated food or water. Transmission can also occur directly from animal to person or person to person. The infectious form of *C. parvum* is the thick-walled 4- to 6-micron oocyst.¹ The dose at which 50% of those

exposed become infected ranges from 10 to 300 oocysts.⁵ Ingested oocysts undergo excystation in the upper small intestine after being exposed to reducing conditions, proteolytic enzymes, and bile salts. Sporozoites invade the intestinal brush border epithelial cells and mature into merozoites, leading to inflammation, villous blunting, malabsorption, and diarrhea. Merozoites undergo sexual reproduction to produce thin-walled oocysts, which continue autoinfection in the host, or thick-walled oocysts, which are excreted and can then infect other hosts.^{3,5} *Cryptosporidium* infection can be found at rates of 2.2% to 6.1% in immunocompetent persons with diarrhea in industrialized and developing countries, respectively. HIV-positive persons with diarrhea showed *Cryptosporidium* infection in 14% to 24% of cases in industrialized and developing areas, respectively.^{3,6}

There have been numerous well-documented outbreaks of cryptosporidiosis in the United States. Most are waterborne outbreaks due to contamination of drinking water or recreational water, such as swimming pools or wading pools. There were approximately one dozen documented outbreaks of cryptosporidiosis in the United States between 1993 and 1998. The largest waterborne outbreak in U.S. history occurred in March and April 1993 in Milwaukee, Wisc., and affected an estimated 403,000 persons. This constituted a 52% cryptosporidiosis attack rate among those served by the South Milwaukee water works plant. Person-to-person spread has also been documented in institutions such as daycare centers and hospitals and may be especially difficult to control because infectious oocysts may be excreted for up to 5 weeks after diarrheal illness ends.^{3,6}

The clinical manifestations of *C. parvum* infection are largely host dependent. In an immunocompetent host, cryptosporidiosis is primarily an intestinal disorder with a 1- to 2-week incubation period followed by symptoms of watery diarrhea, abdominal cramps, anorexia, nausea, vomiting, and possibly a low-grade fever. The disease is self-limited, with an average duration of 9 to 12 days. The main risk is dehydration. In the immunocompromised host, cryptosporidiosis can be an acute dehydrating diarrheal syndrome or a chronic diarrheal and wasting

syndrome. Patients with CD4 counts greater than 180 cells/mm³ tend to have the self-limited syndrome. *Cryptosporidium* infection of biliary and pancreatic ducts leading to cholangitis or acalculous cholecystitis has been documented in patients with CD4 counts less than 50 cells/mm³.^{1,5} There are also infrequent reports of pulmonary and tracheal cryptosporidiosis in immunocompromised hosts, which manifests as cough with low-grade fever, usually accompanying severe intestinal illness.²

Diagnosis of *C. parvum* is made using modified acid-fast staining on unconcentrated fecal smears. However, cryptosporidiosis is likely underdiagnosed in industrialized countries because relatively few laboratories routinely process stool ova and parasite specimens for cryptosporidium or other acid-fast enteric pathogens. Direct fluorescence antibody (DFA), enzyme-linked immunosorbent assay, and polymerase chain reaction testing are more sensitive and less user dependent than routine acid-fast testing, but these are newer and less commonly available.^{1,5}

PREINCIDENT ACTIONS

Since cryptosporidia are ubiquitous and persistent in the environment and highly transmissible, these organisms are well suited to be used in a covert biologic attack. Mortality in a bioattack would be low, except among immunocompromised patients, but morbidity could be extremely high, especially since there can be person-to-person transmission of cryptosporidiosis. Physicians, particularly those working in emergency departments, must remain vigilant to distinguish cryptosporidiosis from routine viral gastroenteritis. Large numbers of persons can be affected in an outbreak and may seek medical attention because of the frequency of stools (average of 12 to 15 per day), prolonged course of diarrheal illness (average of 9 to 12 days), or severity of illness if the person is immunocompromised.⁵ Patients with suspected cryptosporidiosis should undergo laboratory analysis of stool samples including modified acid-fast staining or DFA to confirm the diagnosis. Examples of pre-event public health surveillance might include monitoring the volume of antidiarrheal medication sold, monitoring HMO and hospital logs of patient chief complaints, or monitoring the incidence of diarrhea in nursing homes or daycare centers.⁷

To protect against widespread outbreaks, the public water supply should be monitored closely. Water filtration and flocculation techniques that can eradicate oocysts are not routinely performed at many plants. Waterborne outbreaks have occurred even when the water supply met required turbidity levels. Methods such as reverse osmosis, membrane filtration, ozone treatment, or irradiation can eradicate infectious oocysts from the water supply but are not cost-effective. Ozone treatment is likely the most effective chemical means of inactivating *Cryptosporidium* oocysts.³

POSTINCIDENT ACTIONS

Public health authorities should be notified when cryptosporidia are confirmed by laboratory analysis of a stool

sample. If an outbreak is suspected, an epidemiologic investigation involving appropriate public health authorities should be initiated promptly to identify the source of the outbreak and to rapidly institute corrective measures. In addition to standard precautions in hospitals, contact precautions should be instituted for diapered children and incontinent adults. Rigorous handwashing by hospital staff is necessary to prevent nosocomial spread. Public health authorities would likely issue a boil-water advisory if the public water supply were contaminated. Information and education about *Cryptosporidium* species should be provided to the general public and should include instructions specific to immunocompromised groups. Boiling water is the most certain method of eradicating *Cryptosporidium* oocysts. Use of microstraining water filters capable of removing particles less than or equal to 1 micron, or using sterile water, can also reduce the risk of cryptosporidiosis.⁷⁻⁹

MEDICAL TREATMENT OF CASUALTIES

There is no definitive therapeutic agent that eradicates cryptosporidiosis. The disease is self-limited in immunocompetent hosts requiring only supportive care and monitoring hydration and volume status. The disease is often sufficiently severe in immunocompromised hosts to warrant specific therapy, even though currently available therapeutic options have limited efficacy. The most commonly used medications are paromomycin and azithromycin. Paromomycin, a poorly absorbed aminogly-

CASE PRESENTATION

In late July, an urban emergency department in a major metropolitan city begins to see a large number of otherwise healthy small children with prolonged courses of diarrhea, abdominal cramps, and vomiting. An astute physician notes that all the children she has treated belong to the same daycare center. She notifies local public health authorities about these cases. Their investigation yields similar findings in numerous emergency departments in the city. The investigation also shows that numerous immunocompetent and immunocompromised adults are also experiencing this illness. Public health authorities request that stool samples be analyzed for cryptosporidia, in addition to routine ova and parasites. This testing yields many stool samples with a positive modified acid-fast stain for cryptosporidia.

The CDC and Environmental Protection Agency also become involved in the epidemiologic investigation. Water sample analysis from water treatment plants yields a heavy *Cryptosporidium* oocyst concentration at a municipal water plant that serves the daycare center and many other regions of the city. As control measures to quell the cryptosporidiosis outbreak, public health authorities change residents in the affected area to an alternative water supply, issue a boil-water advisory, and continue water sample analysis. The hunt for the source of the water contamination continues.

coside, has been shown to decrease stool frequency and oocyst excretion at doses of 2 g/day. It is approved in liquid formulation for pediatric use. Nitazoxanide, a nitrothiazole benzamide compound, has been shown to reduce both diarrhea and oocyst shedding in controlled trials conducted in Mexico; however, it is not currently approved by the Food and Drug Administration for use in the United States. Immune reconstitution in HIV disease, using highly active antiretroviral therapy (HAART), results in decreased stool frequency, weight gain, and fecal oocyst clearance. However, there is rapid relapse after discontinuation of HAART, suggesting that cryptosporidial infection had been suppressed rather than cured.¹

UNIQUE CONSIDERATIONS

C. parvum is a small, highly infectious and transmissible protozoan. These features make it a possible bioweapon and water safety threat. Although there is low mortality, there is substantial morbidity associated with cryptosporidiosis. A *Cryptosporidium* attack will be extremely difficult to identify and distinguish from routine viral gastroenteritis due to the similarity of illness presentation and lack of routine laboratory stool testing for *C. parvum*. Therefore, healthcare providers must be vigilant while treating diarrheal illness, especially in immunocompromised patients. Without appropriate supportive care and institution of paromomycin treatment, cryptosporidiosis can lead to high mortality levels in immunocompromised populations.

PITFALLS

Several potential pitfalls in response to a cryptosporidiosis attack exist. These include the following:

- Failure to consider cryptosporidiosis as the cause of diarrheal illness

- Failure to request specific laboratory analysis of stool samples for *C. parvum*
- Failure to aggressively treat immunocompromised patients with diarrheal illness
- Failure to notify public health authorities about suspected or confirmed cases of cryptosporidiosis
- Failure to notify public health authorities about a suspected or confirmed cluster of patients with diarrheal illness

Introduction of Explosions and Blasts

Michael I. Greenberg and Dziwe W. Ntaba

DESCRIPTION OF EVENT

Physics of Blast Injury

Although the exact physical parameters of bomb explosions are typically not known at the time of a given event, a basic understanding of the effects of blast wave physics can allow an estimation of the respective spectrum of blasts.¹

An explosive blast is essentially an intense exothermic reaction generated by triggering a rapid chemical conversion of a solid or a liquid into a gas.¹⁻³ The resulting compressed energy release leads to detonation and a massive increase in local pressure.⁴ Conventional explosive devices are typically categorized into two broad categories: “ordinary explosives” and “high explosives.” *Ordinary explosives* include materials such as propellants (e.g., gunpowder) and are designed to release energy relatively slowly.² *High explosives* (e.g., trinitrotoluene [TNT]) are designed to detonate very rapidly, typically within only a few microseconds.⁵

As a consequence of the phase transformation mentioned above, a “pressure pulse” rapidly expands into the surrounding medium at speeds exceeding the speed of sound.⁶ This expanding pressure pulse moves, as a blast wave, in all directions. The leading edge of this blast wave is known as the “blast front.”^{1,5} As the blast front spreads, it slows down and loses strength.⁷

The potential for a given explosive to cause injury is related to the concept of *overpressure*. Blast overpressure represents the increased pressure, in excess of atmospheric pressure, associated with a blast. It is a dynamic phenomenon wherein a highly pressurized cascade superheats air molecules with which it interacts, propelling the blast wave at supersonic speeds.⁶ When the blast front encounters an object, it causes a virtually instantaneous rise in the atmospheric pressure from an ambient static pressure to a peak overpressure.^{1,4,7} The duration of overpressure is typically less than 100 milliseconds (ms) for conventional explosive devices, but may exceed 100 ms for other events such as nuclear detonations.¹ With continued expansion of gases from their point of origin, the ambient pressure at a fixed point subsequently and exponentially drops below predetonation levels, temporarily creating a relative vacuum known as

underpressure. Eventually, the blast wave deteriorates and forms acoustic waves.⁶

Substantial overpressure may impart a force of impact known as a “shock wave,” which possesses a characteristic termed *brisance*, or shattering effect.^{1,5} The magnitude of the shock wave at the blast front, known as *positive phase impulse*, is an important factor determining the severity of blast-related injury.^{5,7} Other factors include the duration of overpressure and the medium in which it is propagated.¹ Underpressure associated with a particular explosion generates a “blast wind,” which may attain speeds in excess of 800 miles/hour.^{4,5} Whereas overpressure is the major force generating primary blast injury (PBI), underpressure forces are the principle mechanisms involved in producing secondary and tertiary blast injury.

Specific characteristics of the environment in which an explosion occurs are important modulators of blast effect.^{1,6} Explosions occurring in an open space are associated with peak pressures and overpressure durations related to both the size and nature of the explosive charge, as well as to the distance from detonation.^{1,7} Explosions in confined spaces involve reflecting surfaces that cause an extended duration of overpressure and lead to very complex wave patterns.¹ If a pressure wave is reflected from a solid object, the pressures generated from the reflecting surfaces may be more than 20 times that of the incident wave.^{5,7} Consequently, a blast wave capable of causing only minor blast injury in an open space may be lethal for victims in closed spaces.^{1,7} This explains the popularity of the terrorist use of explosive devices inside confined spaces such as buses. Water, due to its incompressible properties, generates a greater speed of wave propagation, and the incident wave in underwater explosions conserves energy over distance and time. The lethal radius around an explosion in water is approximately three times what it would be in air.^{5,7}

Physiology of Blast Injury

The clinical spectrum of blast injury is usually described as involving primary, secondary, tertiary, and quaternary or miscellaneous blast injury. Combinations of these may also occur.

PBI is a direct result of blast overpressure forces.^{1,5,6,8} Overpressure forces tend to damage air-containing

organs or those made up of tissues with internal varying densities such as the ear, lungs, intestine, and brain.⁶ Experimental studies conducted in the early 1940s showed that PBI of internal organs involves direct conduction of forces derived from a blast wave coming in contact with external bodily surfaces.⁵

The mechanism of blast injury, or *blast load*, can be further subdivided to include concepts of irreversible work, inertial effects, spalling, and implosion.^{2,4,5} *Irreversible work* results when blast loading results in extreme pressure differentials. The resultant external force creates two forms of stress on the body known as a *stress wave* and a *shear wave*, both of which are propagated into underlying tissues.^{3-6,9} The potential for injury induced by the stress wave is directly related to the peak amplitude. Damage caused by the shear wave is related to velocity.¹⁰ *Inertial effects* may occur when two adjacent objects of different densities are acted on by the same force.⁷ The lighter object accelerates faster than the denser object, creating a shearing stress at the boundary between the two.^{4,5,11}

Spalling is the tendency of a boundary between two media of different densities to disrupt when a compression wave in the denser medium is reflected at the interface.^{7,11} When the components of a blast wave interact with a fluid-filled organ, the velocity and potential for injury are intensified.^{4,5} *Implosion* is defined as the forceful compression of a gas bubble by a shock wave in a liquid medium resulting in the pressure within the bubble rising higher than the initial compressive pressure.⁷ This leads to a disruptive reexpansion of tissue.^{4,5,11}

The cumulative damage of blast overpressure forces can be illustrated by examining pulmonary PBI. Blast waves tend to strike the torso in a manner similar to any form of blunt trauma.¹ Inward displacement of the chest wall causes compression of air within the lung parenchyma at a rate that is slower than the compression of the hollow respiratory tracts (inertial effects).^{3,4} This leads to a contained system within the air sacs that can generate internal pressures that match or exceed the initial blast overpressures.⁵ Compression and reexpansion (implosion) of the alveoli causes a form of lung injury similar to adult respiratory distress syndrome (ARDS), which is then complicated by disruption of the alveolar-capillary membrane (spalling) and potential introduction of air emboli into the vascular space.^{3,4,12}

Secondary blast injury results from so-called missile effects generated by an explosion and has the broadest potential range of injury with regard to distance from the detonation site. Objects accelerated by the energy of an explosion may cause blunt and/or penetrating injuries.⁵ Blast-related debris may include fragments originating from the casing of the charge (shrapnel) or secondary fragments such as pieces of glass, wood, stones, and other materials.¹ Skin and clothing may offer protection from debris at long ranges. Tiny particles of dust may be embedded in the skin, producing a discoloration known as "dust-tattooing."¹

Tertiary blast injury results from deceleration forces after a victim's body has been set in motion by the pressure and high winds of an explosion.¹ Once a victim's body is in motion, it is at risk of injuries sustained from

striking and/or being impaled with stationary objects.⁵ The following survivor's recollection of an explosion in Northern Ireland presents a sobering account of body displacement:

"... as I started to pull the door open, there was a terrific noise. It was a tremendous whoosh. It was a similar noise made by a pool of petrol being ignited, only much magnified. Accompanied by this, I was aware of a great deal of debris and glass flying about. I was thrown up sideways towards the southern wall of the bar. This was as if by a terrific amount of pressure, not unlike the forces rendered by a very large sea wave. I was thrown sideways for a distance of about 6 feet..."¹

Quaternary, or miscellaneous, blast injury is a broad category of injury including thermal and chemical burns, inhalational exposure, and crush-related trauma. Flash burns may result from heat generated by the initial explosion.⁴ Conventional thermal burn injury may result from the release of hot gases, secondary fires in the surrounding environment, and contact with hot dust-laden air.¹ Chemical exposures result from the release of chemicals in the surrounding environment along with the inhalation of dust, chemically complex smokes, and carbon monoxide.^{1,13} Crush injury may result in the event of structural collapse of a building after an explosion.

HISTORICAL CONTEXT

Increasing Prevalence and Lethality of Explosive Devices

An accident in the early twentieth century demonstrated to the world the potential for death and destruction from an explosive blast. In 1917 two ships, the *Imo* and the *Mont Blanc*, collided in Halifax Harbor, Nova Scotia. Their cumulative cargoes included 35 tons of benzene, 2300 tons of picric acid, 10 tons of gun cotton, 200 tons of TNT, and 300 rounds of ammunition.¹⁴ The collision resulted in the largest manmade, non-nuclear explosion in history. Casualties reportedly included over 2000 deaths and 9000 injuries. One of the ships was reportedly blown a mile into the air. Approximately 2.5 km of the city was leveled, and the blast shattered windows 100 km away.¹⁴

Current events suggest that we are in the midst of a growing epidemic of terrorist bombings worldwide. The first documented terrorist bombing was probably in 1587, in Antwerp, Belgium, where 7 tons of gunpowder was used to destroy a bridge on the River Schelt.¹⁴ There was a 10-fold increase in terrorist bombings around the world between 1968 and 1980, with 5075 events documented between 1973 and 1983.¹⁴ From 1980 to 1990, 12,216 bombings and suspicious explosions occurred in the United States alone.¹⁴

Prognostic Factors and Critical Mortality Rates

An instructive terrorist explosive attack occurred in 1983 in Beirut, Lebanon, where the U.S. Marine Corps barracks was bombed using an ammonium nitrate-based explosive device with an equivalent of roughly 6 tons of

TNT. The blast resulted in the near complete collapse of a four-story building with 234 immediate deaths (68% of all victims).¹⁴ Several first responders were killed by sniper fire from waiting terrorists carrying out a “second hit” tactic. Most of the survivors had noncritical injuries; however, 19 survivors (17%) did suffer critical injuries, and seven of these initial survivors ultimately died. Six of the seven late deaths were among victims who were rescued and treated more than 6 hours after the blast.¹⁴ Conversely, among all initial survivors rescued within 4 hours (n = 65), only one died. The reported causes of mortality in this event included the following: (1) head trauma as the cause of immediate death (71%) and late death (57%); (2) chest trauma as the cause of overall death (29%) (rare among survivors); and (3) burns as the cause of overall death (29%).¹⁴

Analysis of this event provides important lessons regarding the medical response to explosive device detonation. Most striking is the effect of early and aggressive resuscitation as a key prognostic factor for long-term survival. However, expeditious evacuation and treatment must be balanced with the danger to personnel when terrorists make use of secondary devices meant to kill responder personnel.¹⁴ Other lessons include the clear impact of both explosive magnitude and building collapse on survival and the importance of anatomic site and nature of injury as prognostic factors. In an excellent review discussing the medical response to terrorist bombings, Frykberg¹⁴ proposed the use of a “critical mortality rate” (the death rate only among those critically injured) as an appropriate measure when calculating vital statistics for a terrorist event. Since overall mortality rates may be falsely diluted by the number of noncritical survivors, the critical mortality rate more accurately describes those victims actually at risk for death.

Triage Efficacy

A major terrorist event in Buenos Aires, Argentina, occurred when the Argentine Israeli Mutual Association (AMIA) was bombed in 1994. This explosion involved the detonation of ammonium-nitrate material (430 lb TNT-equivalent), leading to the complete collapse of a seven-story building. There were 286 casualties reported, with 82 (29%) immediate deaths.^{14,15} In the immediate aftermath of the explosion, the closest hospital emergency department (ED) faced rapid overcrowding by ambulatory survivors and medical personnel offering to help. Of the 204 survivors, 40 were eventually hospitalized, 7% (n = 14) in critical condition, among whom 4 later died. These figures represent a 3.4% overall mortality rate and a 29% critical mortality rate.¹⁵

Among survivors, 58% (n = 50) of those who visited the ED suffered minor injuries, 12 of whom were admitted. Moderate injuries were reported among 19% (n = 16) of survivors presenting to the ED, with 13 ultimately admitted. Major injuries were reported among 21% (n = 18) of presenting patients, 12 of whom were sent directly to the operating room or intensive care unit; seven later died.¹⁵ A total of five survivors were extricated from rubble, two of whom later died. Only five patients underwent laparotomy, and hepatic lacerations

were found in two of these. Three patients were found to have pneumothorax, and two others showed bilateral infiltrates consistent with PBI of lung.¹⁵

The AMIA bombing demonstrated that hospitals in close proximity to a major explosion suffer rapid and early overcrowding of their EDs with patients who have sustained minor and moderate injuries. This illustrates the need for disaster management plans that emphasize appropriate and effective triage to be carried out both in the field and at the ED entrance.

A retrospective analysis of triage efficiency in the AMIA bombing showed only one case of “under-triage” and four cases of “over-triage.”¹⁵ Frykberg¹⁴ has demonstrated a linear correlation between critical mortality and the rate of over-triage in a series of terrorist bombings. He concluded, “[I]n mass casualty settings, over-triage can be as deadly as under-triage.” Kluger¹⁰ has suggested that a designated triage physician “guide medical teams as to the appropriate evaluation algorithms, considering the type of explosion (closed space vs. open space), explosive, and [presence of] metal projectiles... [and] on the proper use of auxiliary diagnostic modalities and the proper sequence of transferring patients to the operating rooms.”

Building Collapse

Another example of a terrorist explosion resulting in a building collapse was the bombing of the Alfred P. Murrah Federal Building in Oklahoma City, Oklahoma, in 1995. In this incident, an ammonium nitrate-based bomb exploded with the equivalent of two tons of TNT, causing 759 total casualties with a 21% immediate mortality rate (n = 162).¹⁶ Fourteen percent of survivors (n = 83) were hospitalized, of which 52 were critically injured. Five of these later died (representing a 9.6% critical mortality rate).¹⁶ As with the AMIA bombing, the highest mortality and most severe morbidity in Oklahoma City occurred among victims who were located in collapsed portions of buildings at the time of blast.¹⁶

There were 506 survivors of the Oklahoma City bombing. The injury pattern among survivors included 85% who suffered soft tissue injuries, including lacerations, abrasions, contusions, and puncture wounds.¹⁶ Among survivors, 210 (35%) were reported to have musculoskeletal injury, with 60 patients suffering from fractures and/or dislocations and the remainder suffering from various sprains and/or strains. Smaller numbers of patients had severe soft tissue or musculoskeletal injuries.¹⁶

Head injuries were reported in 80 survivors, with 44% of these hospitalized (n = 35).¹⁶ Severe head injury was reported in eight patients, with four open skull fractures, two subdural hemorrhages, and two depressed skull fractures. Of 59 reported ocular injuries, there were nine ruptured globes, four of which were accompanied by detached retina.¹⁶ Internal organ injuries included four patients with intra-abdominal injury (lacerated spleen, kidney, liver, and partial bowel transection), four patients with ARDS, six patients with pneumothorax (four closed, one open, one hemopneumothorax), and three patients with pulmonary contusions.¹⁶

Severe burns (up to 70% body surface area) were reported in nine survivors, seven of whom were hospitalized. Four of these patients were near the point of detonation at the time of the blast.¹⁶ Auditory damage was found in 35% of survivors by self-report (n = 210), but only 78 of these patients had a documented medical diagnosis of auditory damage. Tympanic membrane perforation (unilateral or bilateral) was reported in 22 patients. Tinnitus, vestibular injury, or otalgia was reported in 12 patients.¹⁶

The majority of survivors of the Oklahoma City bombing incurred injuries caused by flying glass, other debris, and collapsed ceilings. A review of this event by Mallonee and colleagues¹⁶ suggests that the role of building collapse and flying glass should be a consideration in future building designs and in retrofitting of existing buildings. In addition, the National Research Council has published recent recommendations on blast hardening technologies.¹⁷

Open Air versus Confined Space

Another important variable affecting the pattern of injury involves the occurrence of blast within a confined space. Leibovici and colleagues¹⁸ compared open air (OA) versus confined space (CS) terrorist bombings in Israel. This was a review of 297 victims from four separate events—two OA bombings and two bus bombings. The explosive devices used and victim density in proximity to each bomb were similar in all four incidents. The authors compared PBI, significant penetrating trauma, and injury severity score between the OA group and the CS group. A higher incidence of mortality and a greater severity of morbidity was reported from CS explosions, compared with a higher total volume of injuries in the OA settings.¹⁸ In addition, a higher incidence of PBI was seen in the CS group. These findings may be due to unique blast wave behavior within the relatively small confined spaces of buses.¹⁸

The two OA explosions in this review occurred at a bus station and a marketplace. Of the 15 fatalities in the OA group, only one died after admission to hospital. The two CS explosions reviewed both happened on buses, and there were fewer total casualties but a significantly higher mortality rate (Table 141-1). Of the 46 fatalities in the CS group, five died after admission to the hospital, all from injuries that were secondary to pulmonary PBI.¹⁸

There was a similar incidence of mild injury in both the OA and CS groups, with an injury pattern that included psychological stress, auditory damage with intact tympanic membrane (TM), and minor penetrating/musculoskeletal trauma. However, among the

severely injured patients in both groups, the OA population had a lower overall injury severity and more favorable initial clinical presentation than those in the CS comparison group.¹⁸

Published reports of predominantly outdoor bombings tend to show consistent patterns of mostly noncritical injuries with relatively low immediate and late death rates. A review by Adler and others² discussed terrorist bombings occurring between 1975 and 1979, in Jerusalem, Israel. Various locales included 19 OA (e.g., seashore, street, marketplace) and five CS settings (bus, other public transport). Of the total 511 casualties, 340 were evacuated to an ED with 272 hospital admissions, three of which later died of their injuries. Injury severity was recorded using an Abbreviated Injury Scale (AIS), with results showing 87% “light,” 3% “medium,” and 10% “severe” injuries at presentation in the ED.²

These reviews clearly describe an increased mortality for victims of CS bombings. Survivors of CS bombings suffer from more severe injuries, as well as burns with a larger surface area compared with survivors from OA bombings. CS victims have a higher incidence of PBI than OA victims, particularly pulmonary PBI. Leibovici and colleagues¹⁸ postulated that the mechanism of increased mortality and severity of injury among CS explosions was linked due to the relatively sustained and markedly increased amplitude of overpressure (generated by comparatively similar explosive charges) as a result of reflective phenomenon within the confined spaces. The more extensive and severe burns in the CS group were thought to be due to containment of an initial fireball generated on detonation within the closed space. Conversely, the OA group showed a larger number of total casualties because these explosions were not contained within a closed space, therefore bomb fragments and other shrapnel were ejected to a considerable distance, with a capacity to injure more people.¹⁸ Other important lessons included the observation that the AIS score established in the ED was a valid prognostic factor when used to triage patients. Specifically, ED use of AIS scores correlated very well with subsequent and more detailed injury severity score on follow-up.²

MEDICAL TREATMENT OF CASUALTIES

The most common injury patterns seen among explosion survivors are due to secondary and tertiary blast injury.¹⁹ The incidence of PBI varies according to explosive charge, proximity of the victim to the blast, and the

TABLE 141-1 CHARACTERISTICS OF OPEN AIR (OA) VERSUS CONFINED SPACE (CS) BOMBINGS

SETTING	MORTALITY RATE	PULMONARY PBI	AUDITORY PBI	GI PBI	VICTIMS ADMITTED TO HOSPITAL	BURNS: BSA AFFECTED
OA (n = 209)	7.8%	6.8%	12.1%	0%	13.1%	18.3%
CS (n = 93)	49.5%	57.6%	40.4%	3.8%	59.6%	31.4%

PBI, primary blast injury; GI, gastrointestinal; BSA, body surface area.

environment in which it occurs.^{3,13} However, given the general lack of familiarity with the assessment and management of PBI among U.S. civilian medical personnel, the following discussion will emphasize PBI at the expense of the more commonly encountered mixture of secondary and tertiary blast injury.

Anatomically, the structures at greatest risk for PBI are the auditory system, thorax, and abdomen.^{11,13,19,20} The greatest potential for avoiding preventable deaths due to PBI lies in the appropriate treatment of thoracic PBI. Although injuries to the central nervous system (CNS) and extremities may involve some contribution from PBI, most of the injury burden to these areas results from the secondary and tertiary forms of blast injury. Survivors of explosions that occur in confined spaces or underwater may manifest a higher incidence of PBI.^{3,18} Most severely injured survivors of blasts have multiple injuries.¹⁰

Primary Stabilization

As with any trauma patient, initial management begins with conventional priorities outlined in the advanced trauma life support protocols, which have been well described elsewhere. There are, however, several important caveats unique to the stabilization of a patient with suspected PBI. These include the potentially harmful consequences of prehospital intubation and the need for cautious fluid resuscitation. The potential for prehospital pain relief to mask latent abdominal PBI may be a valid concern.²¹ Wherever possible, blast victims should be kept at rest because some reports describe an increase in mortality in victims undergoing strenuous activity after an explosion.^{7,13}

Auditory Injury

The ear is the organ most frequently injured by an explosion.⁹ However, auditory PBI is frequently overlooked in the context of more serious co-existing injuries during mass-casualty scenarios.⁶ The auditory system is uniquely predisposed to PBI because the TM acts as an efficient means for transmitting pressure waves to the middle and inner ear.^{3,7} Auditory PBI rarely requires emergent intervention, and the important considerations involve recognition and appropriate referral to reduce long-term morbidity.⁹ All survivors of blast should have an otologic assessment and audiometry at some time in their after-care.^{3,6}

Symptoms of auditory PBI include tinnitus, otalgia, and a feeling of aural fullness.⁹ Perforation of the TM is a hallmark of auditory PBI and is typically seen as multiple “punched out” lesions or radial lacerations.⁶ The pars tensa is usually involved.^{3,5,7} Other signs include hearing loss, blood and/or debris in the ear canal, and disruption of the ossicles.¹³ The presence of tinnitus and hearing loss may be initially profound; however, these findings are usually self-limited and both improve quickly.³ Prolonged duration of these symptoms may be seen in survivors of blast occurring in confined spaces.⁹

Vertigo is uncommonly due to auditory PBI, and its presence should prompt evaluation for neurologic

injury.^{6,13} The complication of perilymph fistula should be considered in a patient with vertigo and sensorineural hearing loss, particularly if these findings are fluctuating. This is the only component of auditory PBI requiring prompt surgical treatment (i.e., emergent tympanotomy and fistula repair).³ Cholesteatoma may be a late complication (12 to 48 months) of TM perforation.^{3,6,22}

Eighty percent of TM perforations heal spontaneously, and nonoperative management is appropriate for most cases.^{3,6,9,13} Large perforations may warrant surgical repair, but elective tympanoplasty can safely be delayed for up to 12 months with good outcomes.³ Antibiotics are not indicated unless underlying infection is suspected.⁶

It is important to note that TM perforation correlates poorly with PBI involving other organ systems and should not be used as a marker of latent PBI elsewhere in the body.³ In a study of 647 survivors of explosion, 9.3% had blast lung in the absence of TM rupture.⁸ Furthermore, of those survivors with *isolated* TM rupture at initial presentation, none went on to develop PBI of the lungs or intestine.⁸ Current evidence suggests that patients presenting with TM perforations in the absence of clinical features of other blast injuries, and with a chest radiograph having a normal appearance, may be safely discharged after 6 hours of observation.⁸

Thoracic Injury

PBI has been shown to be a major cause of death in patients who survive initial resuscitation from blast injury.^{4,12} PBI involving the respiratory system can lead to a constellation of findings known as “blast lung.”^{1,7,13} Blast lung injury (BLI) involves pulmonary hemorrhage, edema, and associated disruption of alveolar architecture leading to air embolism.^{3,11,12} Gross lesions can range from scattered or multifocal petechiae to large confluent hemorrhages involving an entire lung.^{3,6} Certain regions of the lung tend to be more severely affected, including lung parenchyma proximal to the mediastinum and in the costophrenic angles.⁴ Bruising of the intercostal spaces has also been observed and paradoxically called *rib markings*.^{3,6} Pleural and subpleural hemorrhages tend to be bilateral but are usually more extensive on the side facing the source of blast.^{5,6} Recent studies show that the prognosis from BLI is significantly improved with aggressive treatment.^{12,23} Victims of explosions within confined spaces are at considerably greater risk of BLI.¹²

The etiology of BLI may be associated with disruption of alveolar membranes and interalveolar septa via implosion and spalling caused by the blast wave leading to shearing of the lung parenchyma from vascular structures with subsequent hemorrhage into the distal branches of the respiratory tree.^{1,3-6,12,13} These changes cause a ventilation-perfusion mismatch and reduced compliance resulting in hypoxia and increased work of breathing.^{3,5,13}

Traumatic alveolar-capillary fistulae may form, and air may be introduced into blood vessels leading to air embolism.^{3,12} Carotid artery doppler ultrasound studies have demonstrated showers of intravascular bubbles in

blast-injured animals for up to 30 minutes after exposure, suggesting that PBI can affect the CNS.^{7,20} Ultrastructural damage of type II epithelial cells may disrupt surfactant production and further exacerbate pulmonary injury.^{3,6}

Progressive pulmonary insufficiency has been described in many patients with BLI and is thought to be due to the cumulative effect of several mechanisms including blast effects, inhalation injury, hypovolemic shock, sepsis, aspiration and/or aggressive fluid resuscitation.⁶ Clinically, the pulmonary function of patients with BLI resembles pulmonary contusion and ARDS with symptoms including dyspnea, difficulty completing sentences in one breath, cough, hemoptysis, and chest pain.^{3,5,7} Clinical findings associated with BLI include tachypnea with rapid, shallow breathing; poor chest wall movement (due to decreased compliance); dullness to percussion; decreased air movement; hemopneumothorax; subcutaneous emphysema; and retinal artery emboli.^{3,5,6,11,24} The diagnosis is suspected on clinical grounds and is subsequently confirmed with radiographs. Signs and symptoms usually develop within hours after an explosion but may be delayed as long as 24 to 48 hours.^{3,12}

Chest radiography is required for all patients exposed to blast forces to gauge the initial severity of injury and to monitor progression. Diffuse pulmonary opacities may develop within a few hours and will become maximal within 24 to 48 hours. They typically occur in a “butterfly distribution” of bilateral patchy infiltrates.²⁵ Any changes that develop after 48 hours will most likely be due to complications such as ARDS or pneumonia.¹³ Other radiologic findings may include hemopneumothorax, pneumomediastinum, subdiaphragmatic free air, subcutaneous emphysema, and foreign body impaction.^{13,25} Computed tomography (CT) of the chest is not currently part of the routine evaluation, but some authors suggest a role for it in select patients because CT has shown a higher sensitivity than x-ray in the detection of early parenchymal lesions in patients with non-blast-related pulmonary contusion. CT may be useful in predicting which patients will require mechanical ventilation.³

Although the general management of BLI is similar to that of pulmonary contusion and ARDS, the relatively higher risk of significant barotrauma (i.e., alveolar rupture, systemic air emboli, and pneumothorax) in patients incurring BLI is a critically important feature.^{3,12,23} Persistent observations show that the use of positive pressure ventilation, especially high levels of positive end-expiratory pressure, increases the risk of and/or the exacerbation of pulmonary barotrauma and should therefore be avoided whenever possible.^{6,13,23,26} Furthermore, patients with BLI may be at increased risk of pulmonary complication related to overly aggressive fluid resuscitation.^{3,6,26}

Various strategies aimed at ameliorating these risks have shown some success, including (1) permissive hypercapnia with a reduction of tidal volume and peak inspiratory pressure, (2) use of intermittent mechanical ventilation and continuous positive airway pressure to facilitate reversion to spontaneous breathing as soon as possible, and (3) prophylactic insertion of chest tubes.^{3,6,12,13,18,23,26} Patients with unknown neurologic status pose a particular challenge for the use of permis-

sive hypercapnia because of concerns regarding increased intracranial pressure. Some authors recommend bilateral tube thoracostomy for pulmonary PBI patients requiring aeromedical evacuation.^{3,6} The use of dual-lumen endotracheal tubes (i.e., independent lung ventilation) or high-frequency jet ventilation is recommended for patients with bronchopleural fistulae.^{5,12}

Case reports have shown that high-frequency jet ventilation provides adequate oxygenation, whereas superimposed low-frequency positive pressure ventilation can improve ventilation with the lowest possible airway pressures.¹² Expedient use of hyperbaric oxygen therapy has been shown to reduce mortality in animal models and has been recommended in humans with BLI, although convincing evidence supporting this practice in humans is lacking.^{6,13,26} Extracorporeal membrane oxygenation has been used, but this modality is controversial.^{3,18,23,26}

A retrospective study of patients sustaining BLI from explosions on civilian buses in Israel established that the first 24 hours after injury constitute a critical period for effective management.¹² These authors proposed that a BLI severity score (BLISS) may be useful in the initial stabilization phase to direct treatment and predict outcome. The BLISS is derived from objective signs of hypoxemia, chest radiograph findings, and the presence of bronchopleural fistula.¹² Based on the initial BLISS, none of the patients in this study who were classified as mildly injured went on to develop any form of lung injury. Of those classified as moderately injured, 33% went on to develop ARDS. All those classified as severely injured either developed ARDS or later died.¹²

Most importantly, this study showed that aggressive and complex interventions, guided by stratification of BLI severity, can lead to dramatic improvements in outcome. A follow-up study showed that most patients who survive BLI will regain good lung function within 1 year, although most of the patients involved were relatively young and healthy.²⁷

Cardiovascular Injury

In addition to conventional causes of hemodynamic instability seen in trauma patients, there are special factors particular to the management of victims with suspected blast injury. Although there are numerous reports of changes in heart rate and blood pressure that are thought to be due to effects of PBI, much of what is known about the PBI of the cardiovascular system has been gleaned from experimental studies in animal models.⁵ Beginning in World War I, it was observed that “men subjected to the concussion of large shells often developed a condition of shock that was unrelated to obvious trauma since no external wounds were visible.”⁶

A World War II study of 200 casualties assessed *immediately* after blast exposure showed that more than 25% of them had heart rates of less than 60 bpm and that over 90% had heart rates of less than 80 bpm. This review also found that hypotension was nearly universal, with blood pressures of 80 to 90 mm Hg (systolic) and 40 to 50 mm Hg (diastolic) being common.²⁸ The bradycardia observed after blast exposure has been consistently

reproduced in animal studies and may be a vagal effect as experiments have shown the bradycardia can be prevented with bilateral vagotomy.^{28,29}

Irwin and colleagues²⁹ proposed that vagally mediated cardiovascular changes in humans are initiated by the so-called pulmonary defensive reflex. This reflex acts when acute pulmonary congestion and edema lead to fluid shifts in the lung, stimulating pulmonary C-fibers and triggering increased cholinergic activity with consequent systemic effects. This mechanism is supported by the clinical observation of brief periods of apnea after blast exposure, followed by rapid shallow respirations.^{3,24} This phenomenon has been observed in experimental blast injury models using artificial stimulation of pulmonary C-fibers.²⁹

The hypotension observed in the World War II study has also been reproduced in animal simulations. Several studies have reported a greater than 50% decrease in mean arterial pressure in animals immediately after blast exposure, with spontaneous resolution over time.^{6,11,30}

Clinically, the contribution of these various mechanisms for cardiovascular PBI may be complicated by co-existing factors such as hemorrhage. Given the importance of judicious fluid administration (including blood products) for appropriate cardiorespiratory resuscitation, in the context of potentially exacerbating soft tissue injury with suboptimal fluid resuscitation, invasive monitoring to guide therapy is often necessary.^{2,3,13,26} Colloid solutions are generally the resuscitation fluid of choice.

Various electrocardiographic changes have been observed immediately after blast and are also thought to be due to blunt thoracic trauma and/or coronary air emboli.^{6,29} These may include atrioventricular and bundle branch blocks, nonspecific ventricular ectopy, low-voltage QRS complexes, and T-wave and ST-segment abnormalities. Blast-induced electrocardiographic changes typically revert to normal sinus rhythm within a few minutes but may deteriorate into sustained dysrhythmias, including lethal ventricular arrhythmias. Ischemic changes may also occur due to complications of air emboli.^{6,29}

Abdominal Injury

Nonlethal abdominal PBI is almost exclusively found in gas-containing organs and is likely caused by forces including shearing, spalling, and implosion. Solid organ damage may present as subcapsular hematomas or lacerations of the liver, spleen, and kidney.^{3,6,7} These injuries are thought to be due to acceleration-deceleration caused by either the initial effects of the blast wave and/or from secondary and tertiary mechanisms of injury.^{5,13} The incidence of intestinal PBI may be higher in victims of underwater or CS explosions.

The classic lesions of intestinal PBI involve small, multifocal intramural hematomas. These are morphologically similar to those caused by blunt abdominal trauma.³¹ Initial bleeding in submucosal regions may range from scattered petechiae or large confluent hematomas.^{3,6} Partial- or full-thickness lacerations may occur and may lead to immediate or delayed perforation

of the bowel.⁵ Since the ileocecal region and colon are the most likely areas to contain gas, these areas are the most prone to perforation during blast exposure.^{2,6,7}

Since it is relatively uncommon, intestinal PBI presents a particular diagnostic challenge. Signs and symptoms of intestinal PBI include abdominal or testicular pain, nausea, vomiting, tenderness, absence of bowel sounds, and other peritoneal signs. Initial evaluation may be complicated by the overall acuity of a multiply injured patient or prior administration of pain-control medication.

Gastrointestinal injury may be delayed as long as 48 hours after initial blast exposure.⁶ However, this may be more often due to latent injury with delayed perforation as opposed to delayed diagnosis.²¹ No reliable clinical predictors exist to help clinicians determine which patients may progress to delayed perforation.⁶

Abdominal CT, ultrasound, and diagnostic peritoneal lavage have been shown to be useful modalities for the evaluation of intestinal PBI.^{5,12} Kluger¹⁰ reported that diagnostic peritoneal lavage is particularly useful when treating blast injuries involving abdominal wall penetration by multiple metal projectiles. Colonoscopy has been suggested for the surveillance of large bowel contusions. But given the potential for iatrogenic perforation, colonoscopy may be ill advised in the post-blast period.³ Indications for urgent laparotomy are similar to those established for blunt abdominal trauma.³

Musculoskeletal/Extremity Injury

Most blast injuries involving the musculoskeletal system are due to secondary and tertiary blast injury. There are numerous reports of traumatic amputation in blast victims that are thought to be due to PBI, but these injuries are rare among survivors.³ Blast-related amputations often traverse the proximal third of the tibia but rarely traverse joints such as the ankle and knee. This anatomic distribution may reflect an initial disruption of soft tissue and bone by the incident shock wave, followed by completion of the amputation by other components of overpressure forces.³²

In an extensive review, Covey³³ discussed important considerations in the physical examination of blast injuries of the musculoskeletal system. He highlighted the following: "(1) fragments do not always travel in straight lines, (2) small tissue wounds may be associated with extensive internal injury, (3) entry wounds in the buttocks, thighs, or peritoneum can be associated with intra-abdominal injury, (4) a high degree of suspicion for compartment syndrome should be maintained, and (5) an entry wound in the groin, or hematoma elsewhere may mean major vascular injury."

The conventional military approach to small fragment wounds has involved treating penetrating wounds in an aggressive fashion with early exploration, debridement, and delayed primary closure.^{33,34} However, recent evidence suggests that a more conservative approach may be appropriate provided that bacterial colonization is prevented with appropriate antibiotic coverage.³⁴ Bowyer³⁴ reported success with a conservative approach when the following criteria were met: (1) involvement of soft tissue only with no breach of pleura or peritoneum

and no major vascular involvement and (2) an entry or exit wound of less than 2 cm in maximum dimension that was (3) not frankly infected and (4) not caused by a mine blast.

Although successful in wartime, nonoperative treatment of fragment wounds remains controversial. Microbial threats to fragment wounds include *Clostridium* species and *Pseudomonas* species for severely contaminated and high-grade open fractures.³³ Appropriate antimicrobial coverage should be administered and tetanus immunization addressed. Primary closure of blast wounds greatly increases the risk of infection; therefore delayed primary closure is performed once the wound is clean and granulation tissue has appeared.³³

CNS Injury

CNS injury from explosions is an important entity because secondary and tertiary injuries to the head are common and are leading causes of immediate (71%) and delayed mortality (52%).^{3,14} Arterial air emboli may cause secondary damage to the CNS and are important causes of immediate death among blast victims.^{6,13} Although PBI of the CNS is poorly understood, there is increasing evidence that this mechanism may be a factor. Anxiety and adjustment reactions are nearly universal among survivors of explosions. Posttraumatic stress disorder (PTSD) is to be expected in victims and their families as well as in the responders and medical providers who care for them.

Signs and symptoms of CNS PBI include headache, vertigo, ataxia, seizures, altered mental status, retinal artery emboli, tongue blanching, and anterograde or retrograde amnesia.² If any of these findings are present, immediate administration of adequate oxygen therapy is appropriate. Expedient administration of hyperbaric oxygen may be helpful for suspected CNS PBI. Previous recommendations of placing the patient in Trendelenburg's position to avoid complications of arterial air emboli should be abandoned; the left lateral decubitus position with the head down is instead recommended.¹³ There have been several reports of transient motor paralysis with sensory preservation that may be due to blast effects on peripheral nerves.^{20,29}

PTSD may also have an organic basis linked to CNS PBI. Cernak and others³⁵ have speculated that behavioral alterations observed in the posttraumatic period, in the absence of structural changes, may be due to a variety of chemical alterations in the CNS after blast exposure. They report a substantially increased incidence of PTSD in patients after blast exposure. Mental health referral for blast victims is indicated for general counseling and surveillance of serious postincident morbidity. Critical incident stress debriefing sessions for providers are recommended.

PITFALLS

A variety of pitfalls may be encountered when evaluating and managing survivors of blast injury incidents.

Perhaps the most critical issue in mass-casualty scenarios involves meeting the requirement for precise and effective triage. Several scoring systems with proven effectiveness have been developed or adapted for use in evaluating blast injury patients (e.g., AIS and BLI scores).^{2,12}

Physicians and emergency medical systems that traditionally err on the side of over-triage in everyday operations must understand the direct relationship between over-triage and increased mortality observed in terrorist events.¹⁴ Understanding the epidemiology of past explosion scenarios will help providers allocate resources appropriately. For example, survivors of CS explosions will present with a much higher incidence of PBI than survivors of OA explosions, who tend to have predominantly fragmentation injuries.^{3,12}

Experience shows that auditory injuries are commonly underestimated or overlooked during initial evaluation. The possibility of missing latent gastrointestinal injuries with the potential for delayed perforation must be kept in mind. Patients who are exposed to a significant blast with subsequent depressed mental status or after taking narcotic analgesics are at increased risk of missed diagnoses. Some authors recommend that such patients be observed for at least 48 hours and undergo serial abdominal examinations.^{7,21}

Providers should anticipate a high incidence of psychological stress after an explosion and should make appropriate management referrals to minimize long-term morbidity and loss of productivity among survivors.

Overly aggressive fluid resuscitation, which may be complicated by failure to recognize transient PBI-induced cardiovascular changes (e.g., hypotension, bradycardia), is an important pitfall. However, concomitant soft tissue injuries and burns requiring intensive fluid resuscitation are common. Therefore, meticulous attention to fluid balance and judicious use of fluid infusions are of paramount importance. Invasive monitoring is considered the standard of care in patients with suspected pulmonary PBI who require fluid management.

The use of positive pressure ventilation in suspected pulmonary PBI is a well-established hazard due to the risk of progressive respiratory failure and air embolism. Patients who have incurred BLI reportedly do not tolerate anesthesia well, so regional or spinal anesthesia should be considered whenever possible.^{7,13,26} Although oxygen administration is indicated in all patients with signs of respiratory distress or air embolism, oxygen toxicity may result. Dilution of the pulmonary vasculature in response to supplemental oxygen may exacerbate pulmonary hemorrhage.⁶

Explosions: Conventional

Robert Partridge

DESCRIPTION OF EVENT

Explosions occur when solid or liquid material is rapidly transformed into a gas with sudden energy release. High explosives, such as trinitrotoluene (TNT) or other nitrate compounds, detonate very rapidly and release large amounts of energy capable of causing blast injuries as well as severe structural damage. Conventional explosions and blasts occur as a result of unintentional civilian incidents (e.g., explosive detonation during ship or truck transport), intentional and unintentional detonation of military ordinance, and terrorist attacks. Powerful explosions have the potential to inflict many different types of traumatic injuries on humans, but such injuries can vary depending on the type and amount of explosive agent, the location of the victims (inside or outside), and whether the blast occurs on air or water.

Conventional explosions cause physical trauma by three mechanisms. *Primary* blast injury (PBI) results from the damage to human tissue from the sudden change in atmospheric pressure that propagates from the explosion (i.e., blast wave). *Secondary* blast injury occurs as debris accelerated by the blast strikes the victim, causing blunt or penetrating trauma. *Tertiary* blast injury occurs as the body of the victim is thrown onto the ground or into fixed objects as a result of the blast. In addition, *quaternary* injury can occur from inhalation of smoke or hot gases, carbon monoxide poisoning, fire, or structural collapse.

The damage caused by PBI is a type of barotrauma that primarily affects gas-containing organs—the lungs, ears, and gastrointestinal tract. The degree of tissue injury is directly related to the magnitude and duration of the maximum overpressure of the blast wave. Most victims of primary blast lung injury are killed immediately, often as a result of massive coronary or cerebral air embolism. Other immediate deaths are attributed to severe multi-system injury due to secondary and tertiary blast injury. The majority of survivors will experience trauma caused by secondary, tertiary, or quaternary blast injury.

PBI must be considered in all victims exposed to an explosion, even if there are no external signs of injury. Severe pulmonary manifestations include hemorrhage, barotrauma, and arterial air embolism, and gastrointestinal manifestations would include hemorrhage and hollow viscous perforation. Of the small number of

survivors with lung PBI, deaths may occur by progressive pulmonary insufficiency. These lesions appear similar to pulmonary contusion, both radiographically and pathologically.^{1,2}

Indoor detonations or explosions within a vehicle appear to cause more severe PBIs than open-air bombings because the blast wave is magnified rather than dissipated as it is reflected off the floor, walls, and ceiling.^{3,4} The type of explosion and victim location at the time of the blast must be considered when managing blast injury.

PREINCIDENT ACTIONS

Conventional explosions can occur anywhere, at any time, with variable numbers of casualties. For these reasons, there is little a person can do to prepare for a conventional explosion. However, communities can be prepared for such an event. Other than safety and law enforcement measures designed to prevent an explosion, the most effective preincident actions involve establishing an effective security, rescue, and medical infrastructure.

One of the major determinants of mortality from conventional bombings is the availability of medical resources at the disaster scene. Explosions occurring in or near major cities with established prehospital systems, emergency departments, and advanced trauma care would be expected to have lower mortality rates than remote areas or areas with less advanced medical systems and longer rescue and transport times. Medical management of blast victims is also enhanced if help is available beyond the community affected and if there is an ability to transfer victims to other medical facilities. In addition, the panic, chaos, and emotional trauma of large conventional explosions can worsen morbidity and mortality. A plan for prompt leadership; coordination of security, rescue, and medical agencies involved in the disaster; and a preexisting plan for rapid rescue, disposition, and treatment of casualties can reduce this risk.^{3,5-8}

POSTINCIDENT ACTIONS

Previous disasters involving conventional explosions have demonstrated that safety and protection of first responders and medical personnel is the most important

initial action. In both terrorist bombings and other non-military explosions, scene safety is the first priority for all responders, because of the risk of being struck by falling or unstable debris or becoming victims of a secondary explosion.⁷ Keeping medical personnel away from the scene of an explosion reduces their risk of injury from such events. Because first responders are trained to rescue and help victims, any secondary explosion and incapacitation of these persons would greatly impair subsequent rescue efforts.⁹

Immediately after a blast, rescue, police, and emergency medical services (EMS) personnel will be the first to care for casualties. Responders should not enter the blast scene until the incident commander has declared the area safe. Most victims will have traumatic injuries resulting from secondary and tertiary blast injury. EMS personnel should observe standard trauma protocols for management of these injuries.

EMS personnel should assess casualties for PBI. A careful assessment of the scene can give clues to the potential for PBI. The presence of a crater or a building collapse are indicators of high blast strength. An assessment of crater size and structural damage and the location and time of the explosion may be useful in estimating the number of casualties and the likelihood of PBI. Blast peak overpressures in unobstructed open-air explosions are directly related to the explosive force of the blast and inversely proportional to the distance from the explosion.¹⁰ The further away a person is from a blast, the less likely he or she is to develop severe PBI. The location and position that victims were in at the time of the blast should be noted. Reflected blast waves are even more likely to cause PBI. Solid surfaces that can reflect blast waves create a zone of very highly pressurized air as the blast wave is reflected back on itself.^{11,12} Rigid shields between a person and an explosion may reduce the risk of secondary blast injury but may not prevent significant PBI.^{13,14} Victims in close proximity to an explosion may have PBI only, and may initially appear uninjured. Because physical activity after PBI can result in a poorer outcome, EMS personnel must ensure that these persons are not physically active until evaluation and observation for PBI is complete.

Injuries sustained from underwater PBI are different than those in open-air blasts. Because blast waves are reflected back underwater from the water-air surface boundary and interact with direct blast waves, greater blast loads are transmitted to the more deeply submerged parts of the victim. If a victim is submerged in a vertical position, particular concern should be raised for the possibility of PBI in the lower segments of the lungs or gastrointestinal tract. PBI to the bowel, including acute or delayed presentations of bowel perforation in addition to lower gastrointestinal bleeding, may occur in partially submerged victims of underwater blasts.^{2,15}

MEDICAL TREATMENT OF CASUALTIES

Management of casualties after a blast event initially involves gathering as much information as possible to

assess the potential for PBI, including the force of the blast, victim location inside or outside, whether the blast took place in air or submerged underwater, and whether there was any postevent strenuous activity. A thorough trauma evaluation is mandatory for all victims of explosive blasts. Standard trauma management for secondary and tertiary injury will be familiar to prehospital personnel, emergency physicians, and traumatologists, so this section will focus on management of PBI and other injuries commonly occurring in blast victims.

The most critically injured patients after an exposure to a conventional blast succumb to their injuries at the scene. For those patients killed immediately after an explosion, death results from head injuries, PBI of the lung, abdominal injuries, or chest injuries.^{16,17} Among survivors, non-life-threatening injuries including fractures, soft tissue injuries, and blast injuries to ears and eyes are common.^{1,5,7,16,18} Of those who survive a conventional explosion, only very few will have severe chest and abdominal injuries, including blast lung. These injuries should be recognized as prognostic markers of severity, and it is important to identify and treat them early because surviving patients with such injuries have a significantly increased mortality rate.

Evaluation of prior blast injuries indicates certain patterns of morbidity and mortality from which conclusions about future events may be drawn. Immediate deaths appear to be related to the strength of the explosion, an associated building collapse, or a blast location that is indoors. The Beirut bombing in 1983 illustrates some important principles of medical management of casualties after an explosion. Most survivors had noncritical injuries, and for those critically injured, death occurred days to weeks later. Most of these deaths (86%) occurred in victims who were rescued and treated more than 6 hours after the blast event. A short interval between blast event and treatment and early aggressive resuscitation are good prognostic factors for survival.^{16,19}

Pulmonary PBI may have an acute or delayed presentation. Patients with acute pulmonary PBI will present with chest pain, dyspnea, and tachypnea with rapid and shallow respirations, dry cough, wheezing, and hemoptysis. Breath sounds will be diminished on the affected side, making the diagnosis of PBI difficult unless pneumothorax, hemothorax, and pulmonary contusion have been excluded. Inspiratory rales, dullness to percussion, and poor chest wall expansion may also be present.¹ A chest radiograph is mandatory for all patients with respiratory difficulty or suspected PBI or chest trauma. Computed tomography (CT) scans of the chest may be useful to detect small pneumothoraces or pulmonary contusions, both of which may not be well visualized on a plain radiograph of the chest.

Massive hemoptysis resulting from PBI can be managed by preferentially intubating the unaffected lung with a cuffed endotracheal tube, thus protecting the function of that side. Patients with PBI of the lung may have concurrent pneumothorax, tension pneumothorax, or hemothorax. Emergent decompression with a tube or needle thoracostomy is indicated.²⁰ Patients with pulmonary PBI who are not having ventilatory problems are

at risk for hypoxemia and should be managed with high-flow oxygen through a non-rebreather mask or continuous positive airway pressure. Patients able to ventilate spontaneously reduce their risk for arterial gas embolism. It has been suggested that patients requiring mechanical ventilation should be managed with low ventilatory pressures and permissive hypercapnia to reduce the risk of air embolism.^{21,22}

Air embolism resulting from PBI may cause coronary vessel occlusion with subsequent myocardial infarction or cerebral infarction with altered mental status or stroke symptoms. Other organ systems may also be affected. Coronary artery air embolism after PBI can be difficult to diagnose but should be suspected in any blast victim who has electrocardiographic evidence of a myocardial infarction or is in shock with all other likely reasons for shock excluded. A head CT scan is mandatory in any patient with altered mental status, seizures, or focal neurologic deficits. Air embolism should be managed with hyperbaric oxygen therapy. Transferring patients to hyperbaric chambers may be problematic, given the risks of worsening the condition during aeromedical transportation and patient deterioration due to worsening pulmonary PBI.

The abdominal evaluation for PBI should focus on the search for perforation and the signs of lower gastrointestinal hemorrhage and shock. The presentation and diagnosis of these conditions as well as diagnosis may be delayed. Diagnostic peritoneal lavage (DPL) is indicated in hemodynamically unstable patients with abdominal findings. Ultrasonography of the abdomen may be considered in patients with suspected intra-abdominal trauma or hypotension and may be especially valuable in managing mass-casualty incidents. Abdominal CT scanning in stable patients to detect abdominal injury due to PBI may be useful in detecting small gastrointestinal perforations or hemorrhage. An abdominal CT scan performed after a DPL may have false-positive results because air and fluid will have been introduced into the peritoneum during the DPL procedure.¹

Tympanic membrane (TM) rupture is a relatively common injury as a result of blast waves. Patients with TM rupture may have acute pulmonary PBI but are unlikely to have delayed-onset pulmonary PBI. The absence of TM rupture is important because such patients are unlikely to develop pulmonary PBI.²³

Patients who appear stable but may be at risk for delayed PBI—including those in close proximity to the blast, knocked unconscious, or who felt the blast wave hit them—should be admitted for observation. Patients who have abdominal pain or tenderness, even if initial studies have normal results, may develop life-threatening bowel complications and should also be admitted.²⁰

Patients can be discharged home if they have no chest complaints, normal chest radiographs, and no evidence of hypoxia, provided they have been observed at least 6 hours. The risk of pulmonary PBI is low in these patients, and onset of any PBI-related complications in such patients should present slowly. These patients can safely return to the hospital for a secondary evaluation. Additionally, patients with TM rupture

only may also be discharged home because they do not appear to be at risk of delayed-onset pulmonary PBI.²⁴ These patients should be given standard instructions on care of ear perforations and provided with otolaryngologic follow-up.

 **CASE PRESENTATION**

There are numerous historical examples of conventional explosions. There were over 12,000 explosive or bombing incidents in the United States between 1980 and 1990.^{25,26}

You are working in the emergency department of a medium-sized port city. A fire aboard a cargo ship on a weekday afternoon results in a massive response by city and regional fire departments. A large crowd of curious onlookers forms, and a major police and security effort is made to cordon off the area. Suddenly, the ship's load of ammonium nitrate fertilizer explodes, destroying the ship, collapsing two nearby buildings, igniting fires, and hurling debris for more than a mile. There are hundreds dead at the scene, including rescue and security personnel, and there are over 1000 survivors.

As the rescue effort begins and victims begin to flood local and regional healthcare centers, the challenge for healthcare providers is to identify and manage those with PBI while also evaluating and managing a larger number with varying degrees of trauma resulting from secondary, tertiary, and quaternary blast injury.

UNIQUE CONSIDERATIONS

Conventional blasts are unique because blast waves can cause PBI in persons physically separated from the epicenter of the explosion. Blast waves travel around walls and can be magnified traveling down corridors. Persons in enclosed spaces frequently have the highest incidence of PBI regardless of whether the explosion occurred within that space or outside it.^{14,21,27} The risk of PBI also increases as the volume of the enclosed space decreases. Persons located next to walls or in corners at the moment of the blast are also more likely to sustain PBI.¹² Persons wearing body protection, such as Kevlar, at the time of the blast, may be protected against secondary blast injury from flying objects but are still at risk for PBI. These garments transmit and may even amplify blast waves, so it should not be assumed that a blast victim wearing body protection has no PBI even if he or she has no secondary blast injury.²⁸

Persons protected from secondary blast injury, either by a physical structure, body armor, or water may have sustained PBI. Because their injuries are not as immediately apparent as those with external injuries from secondary blast injury, they may still be active and helping with the relief effort in the aftermath of the blast. Strenuous activity after PBI may result in poorer outcome. EMS and other medical personnel on the scene must ensure that apparently uninjured persons in close proximity to an explosion do not engage in physical activity.

The most significant pitfall in the evaluation of blast victims is failing to consider PBI in a person exposed to an explosion, whether near or far from the blast, indoors or outdoors, or in air or water.

Explosions: Fireworks

Craig Sisson

DESCRIPTION OF EVENT

This chapter will address the preparation for and response to an explosion involving fireworks. Most formal fireworks displays follow strict safety guidelines meant to predict and prevent major complications. According to the American Pyrotechnics Association, only 3% of all fireworks injuries are related to public fireworks displays. In contrast, it is hard to predict and control the behavior of persons associated with the production and distribution of fireworks. There are multiple reports of large-scale explosions in fireworks factories around the world. This scenario is the focus of the chapter.

Carelessness around fireworks can lead to an explosive event. In Lima, Peru, on Dec. 29, 2001, more than 1100 tons of fireworks were concentrated in the Mesa Redonda shopping area. A fire then developed, resulting in close to 300 deaths and 357 injuries.¹ Chen and colleagues^{2,3} analyzed retrospective data from 339 patients involved in fireworks factory explosions from January 1987 to December 1999. They report a 13% mortality rate among victims, a significant percentage when compared with other causes of burns during the same period.

Black powder, the basic component of fireworks, has not changed much since its invention by the Chinese approximately 1000 years ago. Historically, it is composed of saltpeter, charcoal, sulfur, and small amounts of water.⁴ Black powder is considered a “low explosive” and burns by a process known as deflagration.⁵ Compared with high explosives (e.g., TNT), the chemical reaction is relatively slow and releases energy over a longer period of time. However, if the reaction is enclosed within a contained space, pressure can build rapidly, leading to an explosion. This property makes black powder very useful as a propellant, eventually giving it the nickname *gunpowder*. The current classification system for explosive materials was developed by the U.S. Department of Transportation. Fireworks are included in this classification system under divisions 1.3 and 1.4, which include large display fireworks and “common” publicly available fireworks, respectively.

PREINCIDENT ACTIONS

Perry and Lindell⁶ describe four key steps that a community must take to prepare for a disaster involving a large-scale fireworks explosion: vulnerability analysis, capability assessment, plan development, and coordinated training exercises. The most vulnerable population in a fireworks disaster are those persons working inside the factory or storage facility and those found in close proximity to it. How easily can rescue teams access the site? How much and what kind of material is stored at the site? Where are the nearest first responders located? How far is it to the closest medical facility? Where is the nearest burn center? Are the surrounding buildings residential, commercial, or industrial? Do the citizens, first responders, and medical community know about this facility? How advanced are the safety systems found at the facility? Are the materials being stored properly? Is a protocol in place so that any change at the site is adequately communicated to those who would respond to an event? All of these factors will affect *vulnerability*.

The *capabilities* of the responding parties must be analyzed to determine whether the community is prepared to respond to an event. A hospital may be located close to the potential disaster site but lack personnel and equipment to deal with a large volume of burn victims. Airway control is very important, and responders experienced in recognition of airway compromise and definitive airway management should have priority on the scene and in patient transport.

The *planning* stage requires the collaborative effort of the local government, fire department, police, emergency medical systems, medical community, citizens, and site owners. A *network of communication* must be built so that all parties will be informed of changes in both vulnerability and capability. Finally, organized exercises must be performed to maintain the proper level of preparedness.

POSTINCIDENT ACTIONS

In the immediate aftermath of a fireworks incident, the appropriate medical facilities and response personnel

should be dispatched through predetermined communication pathways. This ensures that information and resources are distributed in the most organized and effective way. Medical facilities must be made aware of potential trauma and burn victims so that space may be allocated and appropriate equipment and personnel made available. In the Mesa Redonda fireworks disaster, the local hospitals lacked adequately experienced personnel and were quickly depleted of intravenous fluids, antibiotics, and analgesics.¹ In 1999, the Jahn Foundry in Springfield, Mass, exploded and within 5 minutes the first victims arrived at Baystate Medical Center. The Baystate emergency department was full at the time, necessitating reorganization.⁷

The initial responders to a fireworks storage facility explosion should be cautious. One should assess the scene immediately for any potential further danger to the victims and rescuers.⁸ The American Pyrotechnics Association instructs that emergency responders should never attempt to fight a fire that involves a building used in the manufacture of fireworks.⁹ The main goal should be removal and treatment of victims and prevention of secondary fires away from the initial site. The surrounding community should be evacuated immediately and triage and treatment areas set up at a safe distance from the disaster site. All nonambulatory patients should be transported to triage areas for evaluation.

MEDICAL TREATMENT OF CASUALTIES

The majority of reports in the medical literature on fireworks injuries involve individual use of class 1.4 fireworks. Reports of large-scale fireworks disasters and the wounds they cause are very rare. The mortality rate associated with fireworks factory explosions is variable and depends on many factors. A study by Navarro-Monzonis and others¹⁰ reports a mortality of 47% in casualties of industrial gunpowder explosions. A 13-year retrospective study by Chen and colleagues^{2,3} demonstrates a 13% overall mortality rate with greater than 50% mortality in those with inhalation injury. The injuries seen in the survivors were a combination of burns, blast injuries, trauma, and inhalation injury.³ In comparison with other blast injury disasters, fireworks disasters have a higher incidence of thermal injury. The burns characteristically involve a large total body surface area, and the majority of the burns are deep dermal or full thickness.^{1-3,10} Wounds found in casualties close to the blast may be severely contaminated with gunpowder residue.³ The primary explosion of gunpowder in combination with smoke generated by secondary fires makes inhalation injury a common finding.¹⁻³

For the initial treatment of burn victims, remove all of the patients' clothing to prevent further thermal or chemical injury. Jewelry and watches should also be removed to prevent a tourniquet effect from tissue swelling. First responders must evaluate the ABCs (i.e., airway, breathing, circulation) of each victim, taking time only to perform interventions that are immediately required on salvageable patients.^{11,12} Airway is a very important aspect of

management given the high incidence of inhalation injury and risk of blast lung injury. Indications for immediate definitive airway management include voice hoarseness, brassy cough, and stridor.¹³ If a patient was in an enclosed space or has facial burns or carbonaceous sputum, early definitive airway management should be considered. Early tracheostomy is the preferred option for long-term management of ventilated patients.²

Intravenous access and aggressive intravenous hydration with normal saline or lactated Ringer's solution should be a priority. These patients will require extensive fluid resuscitation given the frequency of deep dermal and full-thickness burns, large burn surface area, inhalation injury, and potential delays in treatment.¹³⁻¹⁷ The Parkland formula may underestimate the fluid requirement and should only be used as a starting point for resuscitation. A urine output of 0.5–1.0 mL/kg/hour, a heart rate of less than 120 and a clear sensorium can be used as end points for resuscitation in adults.¹⁴ For children, a goal urine output of 1.0 mL/kg/hour and age-appropriate heart rate should be maintained.¹³

To decrease the temperature of the burned skin, cool tap water or a water-soaked towel should be used.¹² Ice should be avoided because it can cause decreased circulation to already damaged tissue. Nguyen and colleagues^{18,19} report that cooling the burn wounds helps prevent progression to deep partial-thickness or full-thickness burns and reduces future complications. Medical providers must use sterile dressings to cover the wounds and wrap blankets around the patient to keep them warm. The principle is to keep the wounds cool and the patient warm.

Primary, secondary, and tertiary blast injuries can be found in fireworks disaster patients.^{3,10} However, there are limited data available on blast injury resulting from large-scale explosion of stored gunpowder. Therefore, many of the treatments recommended in this text will be inferred from similar large-scale events. Primary blast injury is more severe when the victim is exposed to the blast wave overpressurization while inside an enclosed space.²⁰⁻²⁴ Leibovici and others²³ make a specific comparison between open-air and enclosed-space explosions, showing an increased incidence of primary blast injury, more severe injuries, and higher mortality rate in enclosed-space explosions. Intuitively, victims who are located in the collapsed portions of buildings are far more likely to die.^{25,26} Most fireworks today are still made by hand inside enclosed buildings. One can expect a high incidence of immediate death of victims in close proximity to the initial blast.^{23,24}

A rapid and complete secondary survey of all patients will prevent missed associated injuries. Chen and colleagues² report 10% of burn victims to have an associated injury. The most common in decreasing frequency were limb fracture, blast lung injury, fractured rib with hemothorax, and tympanic membrane rupture. The incidence of associated injuries among those who survived versus those who died was 5% and 48%, respectively. Leibovici and colleagues²³ report psychological stress, tinnitus, mild hearing loss, minor penetrating trauma, and simple fractures as associated injuries for patients not requiring hospital admission in open-air bombings.

Patients should be provided with adequate analgesia after initial stabilization, either in the prehospital setting or in the emergency department. Once a patient has reached the hospital, aggressive early debridement of devitalized tissue and topical antimicrobial treatment should begin as soon as possible.^{14,15} Foreign bodies, such as paper fireworks covers and shrapnel from the blast, can increase the risk of infection and should be removed.¹⁰ Chen and others show that 68% of victims required surgery with an average of 2.7 surgeries per patient.³ There is a high risk of barotrauma in blast lung injury patients requiring mechanical ventilation.^{22,24} They also show decreased mortality in patients undergoing early tracheostomy and subsequent mechanical ventilation.² Sepsis, multiple organ failure, hypovolemic shock from inadequate resuscitation, and pulmonary infection were common causes of death in hospitalized patients.² Long-term management of these patients requires an experienced intensive care specialist, preferably within a burn unit setting.

UNIQUE CONSIDERATIONS

Fireworks contain various chemical compounds and elements for the purpose of producing colored spectacles. One of these chemicals is elemental phosphorus. Elemental phosphorus is used in the military in various weapons due to its unique chemical properties. There are three allotropic forms of phosphorus: white, red, and black.²⁷ White phosphorus is sometimes included in the manufacture of fireworks. It burns spontaneously at 34°C, producing a bright greenish light, copious

amounts of white fumes, and a garliclike odor. A wound that is smoking white and exuding a garliclike odor is characteristic of this substance. When placed in contact with oxygen, white phosphorus is oxidized to phosphorus pentoxide, which then combines with water to form phosphoric acid. This chemical sequence releases heat into the environment, causing burns. The phosphoric acid formed lowers the pH of tissues, causing chemical burns.²⁸ This chemical reaction sequence will continue until all of the phosphorus has reacted or until the phosphorus is deprived of its oxygen fuel.

When an explosion occurs with a device containing white phosphorus, immediate steps must be taken to stop the chemical reaction. Treatment should focus on wound irrigation, phosphorus neutralization, and wound debridement.²⁹ The victim's clothing should be removed immediately to prevent any retained phosphorus particles from burning through to the skin or igniting the clothing. Once the clothing has been removed, the wounds should be washed with large amounts of water. This will cut off the oxygen supply and cool the wound to below the ignition temperature, effectively stopping the reaction.^{27,29-31} Before transport, the wounds should be covered with saline-soaked gauze to prevent them from drying and spontaneously igniting again. Oily dressings should not be used because white phosphorus is lipid-soluble and may penetrate into tissues.^{28,29}

Once at the hospital, prompt debridement of all wounds is necessary to remove retained phosphorus particles. A Wood's lamp causes retained phosphorus to fluoresce, aiding in removal.³¹ A second option is to wash the wound with a 1% copper sulfate solution, which reacts with elemental phosphorus and covers the particles with dark-colored copper phosphate. This easily

CASE PRESENTATION

On December 29, 2001, more than 1100 tons of fireworks were being stored in the Mesa Redonda market in Lima, Peru. The market was stocked for a busy sales season during the Christmas and New Year's fireworks celebrations. The streets were coated with a film of gunpowder left from careless transport of packaged fireworks. At 6:30 PM, a vendor ignited a firework for demonstration that in turn ignited nearby displays, leading to a chain of explosions lasting 2 hours.¹ Within minutes, five city blocks were consumed in flame and smoke; nearly 300 people were killed and over 300 more wounded.

The majority of fireworks injuries involve young males. In Mesa Redonda, 70% of the victims were women and children. Many of the bodies were found in groups of 15 to 30, presumably clustering in areas thought to be safe. Gulati and colleagues¹ described the collapse of a high-voltage electrical transformer that crushed 40 people and electrocuted 27 others. Local hospitals treated 357 patients, 263 were treated for burns with 143 admissions for thermal injury.¹ Seventy percent of admitted burn patients had involvement of greater than 20% of their total body surface area. The majority of the burns were second and third degree, and stores of fluids, antibiotics, and analgesics were quickly depleted.¹ Inadequate fluid resuscitation due to fluid shortages led to acute renal failure in a number of patients. The majority of victims suffered some degree of smoke inhalation, and 16% of admitted burn patients had inhalation injury requiring ventilation.

It took 8 hours for firefighters and police officers to bring the blaze and surrounding chaos under control. The stores and houses were built close together and constructed of a highly flammable mix of straw and mud. Combined with the wind and the large amount of gunpowder present, the fire and smoke spread with devastating speed. The streets were very narrow, and many of the buildings lacked windows and emergency exits. The streets were packed with vendors and shoppers at the time of the disaster. Electrical wires were not protected and dangled over the streets, posing another threat to victims and rescue workers. The fire departments were poorly funded, and much of their equipment was old and in need of replacement. There were not enough ambulances available in the area and access to victims was difficult. Most local hospitals were at or near capacity when the disaster occurred. Additionally, patients began arriving at hospitals around 8:00 PM, during staff shift changes, which added to the confusion.

The production, importation, and sale of fireworks was banned by the president of Peru after this disaster.¹

identifies sites that need further debridement and theoretically may slow the oxidation process. One concern is that copper itself is toxic and has never been shown to improve wound healing over normal saline washes alone.²⁸⁻³⁰ As a result of phosphorus absorption, rapid changes in serum calcium and phosphorus levels can occur. Animal models have linked this to cardiac electrical abnormalities with increased risk of sudden death.³² Therefore, continuous telemetry should be initiated for the patient, and his or her serum calcium and phosphorus levels should be monitored. Phosphorus absorption may also damage the kidneys and liver and cause other systemic effects.^{27,33}

Magnesium and aluminum powders and pellets are also used in the production of fireworks. The chemical reactions are similar, producing a brilliant white light, intense heat, and loud noise effects if ignited in the presence of oxygen. Magnesium has an ignition temperature of 623°C and burns at roughly 3600°C. Once the oxygen source is removed, the reaction will stop.³⁴ Magnesium can react with oxygen, nitrogen, carbon dioxide, and water. The reaction with carbon dioxide produces magnesium oxide and carbon, and the reaction with water produces magnesium oxide and hydrogen gas. These reactions are important information for first responders. Applying water to a fire containing magnesium will increase the severity of the fire.³⁵ Hydrogen gas will be liberated and ignite, with the potential for a secondary explosion. Metal-extinguishing powders, such as graphite powder, powdered talc, and powdered sodium chloride present in class D fire extinguishers must be used to fight these fires.

All explosions can spread flaming debris, but fireworks are unique. Many class 1.4 fireworks are designed as self-propelled projectiles. Class 1.4 fireworks, although not at risk of initiating an explosive event, can spread fire throughout the storage facility and surrounding environment. They can also cause a projectile injury during the initial stages of a fire similar to secondary blast injuries but preceding an explosion. This may inhibit a person's ability to evacuate the site and put that person at risk for more severe injury.

PITFALLS

Several potential pitfalls in response to a fireworks disaster exist. These include the following:

- Failure to stop the burning process
- Not performing ABCs with early definitive airway management
- Failure to complete secondary survey; other types of trauma can kill faster than burns
- Failure to remember: fluids, fluids, fluids
- Attempting to extinguish fire in a fireworks warehouse; instead, all persons should be evacuated
- Inadequate pain management
- Failure to establish triage areas a safe distance from primary event site

Suicide Bomber

Jeffrey L. Kashuk and Shamai A. Grossman

DESCRIPTION OF EVENT

An unprecedented wave of terror has captivated world attention for several years, increasing in magnitude with daily warnings.^{1,2} Not unlike other disease outbreaks in world history, this terror epidemic knows no borders and strikes innocent civilians during their most productive years of life. The objective of terrorists is to kill and maim as many citizens as possible; hence, dense population centers and locations where the public congregate are emphasized targets.

Differences have been noted between bombs prepared by terrorists and those of traditional warfare. Operating on more limited budgets, terrorists have discovered methods of packing bombs with nails, metal bolts, and similar objects so as to inflict maximum injury. These bombs are created so as to be easily transportable, usually hidden on the body of the terrorist who carries out the suicide mission. Other bombs are prepared in small, contained, transportable packages or in automobiles.

Blast injury patterns have classically been described based on wartime injuries, with limited survivors requiring medical care.¹⁻⁴ In contrast, civilian urban bomb explosions result in many patients simultaneously arriving at the hospital alive despite the devastating nature of their injuries. These patients may present with an extraordinarily varied constellation of clinical patterns.

Virtually all patients exposed to the blast front will incur primary blast injury. The immediate blast front is dissipated from the explosion center based on forces of spalling, acceleration, and implosion mechanisms. Primary blast injuries classically result in injuries to air-containing structures.⁴ More than 50% of patients exposed to a blast of greater than 50 psi will suffer tympanic membrane perforation. This injury can be used as sign of blast exposure and may be a harbinger of coincident injuries. Primary blast lung injury may not be readily apparent and should be carefully considered in such a scenario. Delayed infiltrates in blast injury are common in primary blast lung injury and may be difficult to differentiate from lacerated lung resulting from secondary blast mechanisms. Primary blast head injury appears to have a higher mortality than other conventional head

injuries, most probably due to the tremendous force of the exposure and associated injuries.

Blast lung versus lacerated lung represents another clinical challenge. Whereas lacerated lung may result from secondary blast injury due to penetrating sheer forces, blast lung injury serves as the classic injury pattern of bomb explosions. Although both mechanisms may commonly manifest as pneumothorax, hemothorax is less common in classic blast lung injury. Both may develop significant respiratory difficulties, with persistent air leaks requiring creative ventilator techniques. However, in the early phase of injury, fluid management may be quite different; blast lung injury requires restrictive management whereas lacerated lung injury requires resuscitative therapy. Repair of a lacerated lung may occasionally require operative therapy—most commonly, tractotomy or oversew for hemorrhage control. In contrast, blast lung injury treatment is physically nonoperative.

The secondary blast effect results from flying shards of glass, metal, and other explosive objects that inflict injury are similar to classic penetrating patterns. Benign-appearing skin wounds may signal underlying severe injury due to the penetration of metal bolts, pellets, and nails.

Terrorists know that maximum death and injury can be accomplished by bringing the explosive content to closed spaces. There is a direct correlation between the location of a blast and survivability. Open, closed, and sealed spaces result in differential injury patterns based on the standard categories of blast injury.⁵ Mortality appears to be highest in super-closed spaces such as buses. Explosions on buses result most commonly in the highly lethal tertiary blast front (i.e., Mach stem effect), where the human body may be propelled via a supercharged blast front against stationary objects, resulting in immediate amputation or death. Such patients typically arrive at the hospital with agonal breathing and extensively burned, mangled extremities. Survival for these persons is rare.

Quaternary blast injuries are burn injuries perpetrated by the highly flammable surrounding area of the explosions. These burn patterns may include all types of classical burn injuries, including inhalation, chemical, and contact burns.

PREINCIDENT ACTIONS

The multidimensional injury pattern, a complex of injuries that occur simultaneously in the same patient, seems unique to bomb explosions.⁵⁻⁷ Patients now arrive at the hospital alive who, in previous war settings, would have died of their extensive blast injuries. Although well-established trauma protocols such as advanced trauma life support remain the gold standard against which one should gauge treatment plans, this injury pattern has resulted in new dilemmas that demand a reassessment of established techniques to improve preparedness, treatment, and survival.

The management of mass-casualty events demands strict adherence to established protocols and superb coordination of available manpower and medical resources, which are commonly stressed to the maximum.^{5,6,8,9} Given recent world events, many protocols are in evolution with plans for a high level of preparedness. Despite this, the sheer volume of injured patients encountered in such events may challenge even the most experienced institution. In addition, refinements in protocols and improvements in techniques are always in evolution as greater experience is gained.⁸⁻¹⁰

Triage protocols for mass-casualty events are different from other trauma situations. Virtually all local and regional hospital facilities are recruited to handle the sheer volume of injured patients.

POSTINCIDENT ACTIONS

Care for the sickest patients should begin immediately. The initial clinical issue in these events is the lack of diagnostic capabilities. Patients who are triaged to smaller facilities for stabilization may require transfer to a trauma center for more definitive care.

MEDICAL TREATMENT OF CASUALTIES

As with all critically ill patients, emergency care of casualties of a suicide bombing begins with evaluation of the ABCs: airway, breathing, and circulation. Once an airway has been secured and breathing and circulation established, the primary and secondary physical examination should proceed.

In evaluating the multidimensional injury pattern with associated abdominal visceral injury, certain patterns have been noted. There appear to be more diffuse and associated injuries necessitating meticulous abdominal exploration. This may be particularly difficult in the midst of a multicasualty event involving other injured patients who are waiting to enter the operating room.^{8,10,11} An intensive and persistent search for injury must be undertaken, with the underlying mechanisms of both blunt and penetrating injuries being kept in mind.

Diagnostic peritoneal lavage (DPL), first described almost 40 years ago, has returned as the most important diagnostic tool in mass-casualty events.^{5,7} It can be rap-

idly performed at the bedside and provides immediate diagnostic information to accompany triage decisions in mass-casualty events. In the absence of other diagnostic maneuvers or bedside ultrasound, this minimally invasive technique is valuable in the acute evaluation of the injured, as well as for follow-up evaluation after the tertiary survey. In patients presenting with delayed injuries, DPL has sometimes been the only test to have positive results. In some cases, these injuries appeared after a computed tomography (CT) scan with initial negative results. A high index of suspicion must be maintained when multiple shrapnel pieces are identified on radiograph or fluoroscopy. Visceral blast injuries may occur from multiple wounding mechanisms. Primary or tertiary blast injury may cause slow dissection along tissue planes, resulting in delayed peritonitis. In contrast, missile trajectory of secondary blast injury may parallel classic penetrating injury that is described in stab or gunshot wounds.⁶ Due to the potential for multiple mechanisms of action, a minimum of 5000 red blood cells/ml as a lower-level threshold for DPL in blast visceral injury has been suggested.⁵

Prioritization of CT scan and ultrasound must be established because these tests must be reserved for immediate, life-threatening, decision-making protocols. Usually, CT scan is available for only the most severe head injuries to support immediate interventional decisions.

Total body fluoroscopy should be used liberally to identify all potential projectiles. Routine mapping of such findings is mandatory for documentation and future reference. Bedside ultrasound is of limited use. An obviously positive examination result may expedite diagnosis of hemothorax or hemoperitoneum; however, in many situations ultrasound may not be available due to the volume of injured patients competing for limited resources. Expert clinical judgment is demanded in such scenarios.

Because of delayed injury presentation, previous negative examination results require careful reevaluation. Blast injuries may develop exponentially over time, resulting in injuries that are missed initially. For this reason, the tertiary survey has assumed a renewed level of importance in these events. If this examination suggests potential missed injury, further tests such as ultrasound or CT may be available and appropriate as soon as the majority of casualties have been admitted and routed through triage.

UNIQUE CONSIDERATIONS

When a complex of injury patterns occur simultaneously in the same patient, as described, this has been termed the *multidimensional injury pattern*.⁵⁻⁷ This subgroup of patients is not predicted adequately by the classic injury severity score system. Parameters such as length of hospital stay, length of stay in the intensive care unit, and mortality appear significantly different than other groups of patients, emphasizing the unique nature of this subgroup.

The management of multidimensional injury can be contrasted with that of other, conventional traumatic injury. Due to the multiple wounding mechanisms, the

CASE PRESENTATION

A 45-year-old man was a bystander in a bus explosion. The patient was triaged to the closest facility along with 45 other multiple-injured patients. The initial emergency department evaluation noted a Glasgow Coma Scale score of 3 with bilateral hemopneumothoraxes. The patient was promptly endotracheally intubated with concomitant placement of bilateral chest tubes and moderate blood return.

An examination of the patient then revealed a perforation of the right eye, a periorbital laceration, peppering of the facial region and scalp, and an extensive laceration of the scalp. The initial abdominal examination revealed a soft and scaphoid abdomen. On closer inspection, a small round wound was noted in the left lower quadrant. A skeletal survey disclosed that the left arm had a comminuted humeral fracture with active bleeding; this was controlled with a pressure dressing. In addition, a 30% body surface area burn encompassing the chest, abdominal wall, and lower extremities was noted, as were multiple lacerations to both legs.

Due to lack of neurosurgical coverage, the patient was prepared for transfer to a level I trauma center (to occur in approximately 40 minutes). Before the transfer, bedside abdominal ultrasound was normal. In addition, CT scan of the head, chest, and abdomen revealed moderate cerebral swelling and multiple shrapnel injuries with metallic spheric balls throughout the body but no penetration of the chest or abdominal cavity.

The patient arrived in the trauma center with stable vital signs. A small spherical ball was noted in the right lower chest area. There was concern that this ball could have traversed the abdominal cavity from the left lower quadrant abdominal wound previously noted. Despite the otherwise normal abdominal examination results, the Focused Assessment with Sonography for Trauma (FAST) examination was repeated. Although this ultrasound had negative results, a DPL was then found to have a positive result of 5000 red blood cells/ml. Further evaluation noted the absence of a pulse in the right hand distal to the injury.

Multiple surgical teams were mobilized. Personnel from the plastic surgery and ophthalmology departments worked on the facial region. The right eye required enucleation. Vascular surgery and orthopedics personnel treated the extremity injuries. A transection of the left brachial artery with comminuted humeral fracture was treated with a temporary arterial shunt. External fixation was placed over the fracture. Abdominal exploration (via the burned abdominal wall) disclosed lacerations of the sigmoid colon, small bowel (mid jejunum), a tear of the right diaphragm, and grade 2 injury of the right lobe of the liver.

An ulnar nerve injury required reconstruction. One week of mechanical ventilation was required for blast lung injuries, and early tracheostomy was performed. Neurosurgical follow-up confirmed resolution of the brain swelling, and the patient regained full neurologic function with rehabilitation.

likelihood that these patients will require some type of surgical intervention is high. Such multiple injuries result in difficult challenges in diagnosis, decision-making, and treatment. Providing care to a patient with multidimen-

sional injury will often require the careful coordination of multiple surgical teams. This translates into the need for a large operating space to accommodate the teams who may need to be working simultaneously.

PITFALLS

Several potential pitfalls in response to a suicide bomber attack exist. These include the following:

- Coordination of manpower and medical resources by protocol are the most important requirements for bombing events.
- The combined clinical scenario of head injury, burns, blast lung, and intra-abdominal or thoracic injury may create extreme difficulties in decision-making for surgery as well as critical care management.
- Due to the vast number of victims, CT scanning equipment may be available only for the most obviously severe injuries.
- Constant clinical vigilance is required to time interventional modalities in the case of combined head and other injuries.
- Healthcare providers must be wary of profound acidosis and hypothermia. Aggressive warming mechanisms must be used, and the potential for developing coagulopathy must be recognized.¹¹

Vehicle-Borne Improvised Explosive Devices

Michael I. Greenberg, Michael Horowitz, and Rachel Haroz

DESCRIPTION OF EVENT

Vehicle-borne improvised explosive devices (VBIEDs) may be used in two general logistical scenarios. They can be used as assassination devices targeting an individual or group of persons or as a weapon intended to damage or destroy a specific target. VBIEDs have been used to attack “high-profile” targets such as specific buildings or targets with symbolic and/or logistical importance. “Soft” targets, or those having inadequate security protection, may also be targeted with the aim of causing substantial casualties in an area where many people are gathered.¹ As an assassination device, VBIEDs may be predeployed with the goal of destroying the occupants of the vehicle in which the device has been installed. As an explosive delivery device, the entire vehicle becomes a bomb that can be used against groups of people, buildings, or other targets. In most instances, a VBIED attack involves a single, high-profile event that cannot be readily predicted. However, detailed preplanning for such an eventuality is essential to maximize the effectiveness of a coordinated medical response. VBIEDs are associated with widely varying casualty and mortality rates. The 1993 World Trade Center bombing resulted in approximately 1000 persons injured, whereas the 1998 bombing of the U.S. Embassy in Nairobi, Kenya, injured more than 4000 persons.^{2,3}

VBIEDs provide a readily available delivery system: the vehicle itself. The explosive devices contained therein may be assembled in a safe and remote location prior to delivery to the intended target. Defense against the deployment of a VBIED is exceedingly difficult because the explosive device is easily concealed and precise target prediction is difficult. Trucks used as VBIEDs may have a dual purpose of being able to carry a very large load of explosive material coupled with the potential mechanical ability and power to penetrate and breach protective barriers. In some cases, separate assault vehicles may be used to break through protective barriers, thus allowing unencumbered access to the vehicle containing the VBEID. VBIEDs may combine a variety of combustible chemicals and explosives as well as radiologic materials and devices.

No specific vehicle type has been associated with VBIEDs; however, terrorists usually choose vehicles that

are common to and widely available in a given geographic region as well as vehicles possessing routine access to the intended target. Vehicles of virtually any size can be used as VBIEDs. However, the size of the vehicle used may depend on the nature and size of the explosive device being used. In the 1993 World Trade Center attack, approximately 1200 lb of improvised explosives were positioned in a rental van reported stolen by one of the perpetrators. Various large vehicles including limousines, sports utility vehicles, small trucks, delivery vehicles, ambulances, and minivans may have special attraction to be used as VBIEDs, based on their relatively large storage capacity. An example of selective vehicle use for specific access to a target is the use of limousines, which may convey the appearance of authority, thus facilitating access to specific locations within buildings or to facilities generally denied to the public.

PREINCIDENT ACTIONS

Although intelligence reports may help to protect against VBIED use in many cases, those who wish to use VBIEDs may often evade preemptive detection. Law enforcement techniques for detection and preemption against VBIEDs are beyond the scope of this discussion. However, response preplanning is a key preincident action and must include coordination between police, firefighters, emergency medical services (EMS) personnel, public works officials, structural engineers, local elected officials, and others. Relationships must be preestablished and roles precoordinated, including who will have overall authority on the scene and who will be the medical authority.

Immediately after a VBIED incident, many competing priorities may emerge. These include rescuing the casualties, securing the area and controlling access, searching for a secondary explosive device, determining whether there is a need for evacuation of the surrounding area, preserving the crime scene, directing traffic to allow easy access/egress to emergency vehicles, and preventing further injury. Something as simple as a passing train could shake already damaged buildings, causing further collapse or fall of debris.^{4,5} Careful preplanning may allow the adverse effects of such factors to be quickly addressed and corrected.

Communication is a key element that requires careful preplanning. The medical authority at the scene must be able to communicate with the scene commander, EMS on-scene (including the EMS dispatcher at the staging area), and local hospitals. The medical commander will need information from all of these sources to properly allocate resources. Information from hospitals regarding patient load and remaining available resources will be vital, allowing the medical commander to direct patients appropriately. Information from the scene commander allows for casualty estimates that will influence the amount and type of personnel that need to be called to the scene. The medical commander must also be provided with constant updates from the triage area at the scene to be aware of needs for resupply. In short, the medical commander will require overall situational awareness to effectively direct medical resources both at the scene and at local hospitals.^{1,6-9}

It is important to remember that, in the event that the major trauma center for an area is a target or is quickly overrun by casualties, a large number of patients may flood some of the smaller surrounding hospitals.^{6,10}

Few factors correlate with patient survival that can be influenced in the case of a car or truck bomb. Factors influencing survival that are not in the medical planner's control include the size of the explosion, the patterns of injury, the number of casualties, and the time of the day of the attack. Some factors important to survival over which a medical planner may have influence include having a well-rehearsed plan, being educated so as to improve triage efficiency, striving to have a minimum interval from injury to treatment, and ensuring that there is a sufficient number of competent medical staff that can be made available if an event occurs.^{11,12} As every car bomb incident will be unique, it is vital that the medical plan allows for contingencies. After the Oklahoma City truck bombing, the medical triage/treatment area needed to be moved three times after it was initially established because of threats of another bombing.⁹

POSTINCIDENT ACTIONS

The overall emergency response will, in most locales, be initiated by police officers, who are usually first on the scene. Firefighters, EMS personnel, and other public safety responders will be expected to follow local response protocols. It is of critical importance that the initial responders survey the overall situation before becoming actively involved in the rescue because the danger of unstable buildings and the potential for the detonation of secondary devices will be high. In addition, the area should be surveyed for the presence of radiation by first responders because the use of radiologic dispersion devices must be considered.¹³ Those on the higher echelons of medical control will need to be made aware of the nature of the event and should receive an initial estimate of the number of casualties. EMS supervisors should alert area hospitals and begin to determine what resources will need to be deployed to the scene of the incident.

Police and/or military bomb units or hazardous materials teams will need to survey the scene to assess the risk for secondary devices while EMS responders initiate rescue efforts and treat casualties. This may engender a variable degree of risk for first responders, as it is likely that the scene will not be completely secured prior to the start of the rescue operation.

Triage and treatment operations should follow local preestablished protocols. A covered and protected area, out of view of the survivors, should be designated as a morgue. Also, a possible air evacuation site can be determined, although there may be substantial amounts of loose debris that could become dangerous during helicopter operations.^{1,4,8}

The flow of casualties from the scene should be as regulated as possible by one medical commander who has a good overall situational awareness both at the scene and at the area hospitals. The goal will be to send less-injured patients to hospitals that are farther from the scene to conserve resources at the closer hospitals for the more seriously injured patients. Real world incidents have demonstrated that the majority of patients bring themselves to the closest hospital by car, by foot, or via public transit.^{1,7,9}

Area hospitals will need to activate individual mass-casualty plans. These plans should include the ability to triage patients away from the emergency unit. It is vital that the typical earlier arrival of less-injured patients not interfere with the later treatment of more critically ill patients. Over-triage (i.e., referring patients for potentially serious injuries when only relatively minor injuries exist) at the scene may also result in a hospital being overwhelmed with less-injured patients.

MEDICAL TREATMENT OF CASUALTIES

The epidemiology of VBIED incidents may be useful in predicting the patterns and numbers of injuries expected in future events. The literature regarding VBIED attacks reveals predictable patterns, including the fact that many injuries in survivors are relatively minor.^{13,14} For example, after the Oklahoma City bombing there were 759 casualties; of these, 167 died, 83 were hospitalized, and 509 were treated and released.¹⁵ The greatest risk for death after the detonation of a VBIED is building collapse. It is estimated that 95% of the deaths associated with the Oklahoma City bombing were secondary to blunt trauma consequent to the collapse of the building.⁹

Other factors influencing the mortality rate include an open versus closed blast environment.¹⁶⁻¹⁸ A closed environment leads to greater overall mortality, increased risk of blast injury, more severe injuries among survivors, and a higher risk of significant burns.¹⁹ Most studies of VBIEDs do not report large numbers of survivors with blast-related injuries. This is likely due to the fact that those close enough to the blast to experience these injuries do not survive the initial explosion. Most survivors therefore sustain injuries from secondary blast effects, including injuries from loose material or frag-

ments propelled by the blast.¹⁶ This epidemiology may be helpful not only during medical preplanning, but also in providing the receiving facility with important predictors of what to expect in the immediate aftermath of an event involving VBIEDs.

The literature is also helpful in planning what supplies are critical in the initial treatment of casualties. The most heavily used supplies in past events were reported to include antibiotics, narcotics, bandages, and tetanus toxoid.^{7,20} The most common injuries observed after a VBIED detonation are soft tissue injuries as well as hearing loss, fractures, and musculoskeletal injuries. The most profound challenge to medical resources of the hospital involves the emergency department, where adequate staffing is essential to ensure a proper flow of casualties.^{7,20} In addition, an increased demand on the radiology services may occur. Thus, in the early hours after an event, the indications for radiology studies may need to be limited to the most critical injuries.²¹

In some cases, the mode of arrival may give a clue as to injury severity, and it is important to remember that the initial group of presenting patients will generally have only minor injuries. This phenomenon was evident after the World Trade Center bombing in 1993, the Oklahoma City bombing, and the Nairobi Embassy bombing. After the 1993 World Trade Center bombing, just 450 of 1040 patients were transported by EMS, and after the Oklahoma City bombing EMS transported only 33% of patients seen in area hospitals.^{1,7} Those patients transported by EMS were much more likely to require hospital admission.⁷

Studies of VBIED events have highlighted the importance of triage both at the scene and at receiving hospitals. It is critical for those performing triage to quickly identify critically injured yet salvageable patients and to initiate treatment. Over-triage is common after VBIED incidents. Even physicians with extensive experience in trauma triage may find it difficult to identify patients with certain blast injuries on initial triage assessment.²¹ Specific clinical findings may be helpful. Tympanic membrane rupture may be a subtle sign of blast injury in some cases. However, the presence of an intact tympanic membrane does not ensure that a patient has not sustained a significant blast injury.¹⁶ Although over-triage places an increased strain on hospital resources, an over-triage rate of 50% is necessary to avoid the less desirable scenario of under-triage (i.e., categorizing a critically injured patient into a delayed treatment category). Frykberg and Tepas¹⁴ evaluated 14 terrorist bombing incidents and found an average over-triage rate of 59%. In general, accurate and efficient triage is an important factor in patient survival.

UNIQUE CONSIDERATIONS

VBIED explosions stand apart from other explosions because they are, unfortunately, relatively common, unpredictable, and frequently perpetrated by terrorist groups. As numerous domestic and international VBIED incidents have demonstrated, morbidity and mortality are

CASE PRESENTATION

At 10:30 AM, a truck carrying approximately 2 tons of explosives detonates in the center of a city's financial district. The explosion results in the collapse of a portion of a 12-story office building and damages buildings in a 24-block radius. Within minutes several EMS units arrive at the scene, and over the next 30 minutes coordination begins between police, fire, and EMS personnel at the scene. Incident command is established per preplanned protocols, and specific areas are designated as casualty treatment and triage sites. The incident area is cordoned off, and rescue efforts begin. Large numbers of people are exiting buildings and police are directing them to safe locations. Hospitals in the immediate vicinity activate their individual disaster plans, and all local emergency departments are quickly inundated with patients. Most victims arrive at area emergency departments on foot or via private vehicle.

Communications from the scene of the explosion to the local hospitals offer limited details of initial casualty estimates. During the course of the day, nearly 700 patients are evaluated at area hospitals as a result of the explosion; of these, 580 patients are treated and released, 12 patients die en route to the hospital or within the first 24 hours, and 115 are admitted to the hospital for further care and/or observation.

high. Another risk to consider with VBIEDs is the potential to use these devices as a dispersal mechanism for various hazardous materials. For example, the bombing of the World Trade Center in 1993 may have involved a cyanide compound, which the perpetrators hoped would be dispersed into the building ventilation system after the explosion. It is not clear whether cyanide was used during this attack; however, it is clear that the terrorists involved possessed cyanide and had plans to use chemicals in conjunction with future explosive devices.²²

PITFALLS

One potential pitfall in responding to a VBIED attack is the failure to consider the risk of a secondary explosion after the initial explosion. Secondary explosive devices may be designed to kill and injure emergency responders both at the scene as well as at the hospital. It is important to note that secondary devices may be located near the epicenter of the original blast as well as at other locations. An example of the use of a secondary device deployed at a location remote from the original blast was the Thiepval barracks bombing incident.¹² In this incident, a second car bomb was deployed and timed to target the local medical treatment facility at a time when arriving patients and medical personnel would be present. Medical treatment facilities must be mindful of this tactic and should have protocols in place to protect against such an eventuality.

A second potential pitfall in responding to such an attack is the failure to consider that a VBIED explosion may be used to disperse hazardous materials.

Rocket-Propelled Grenade Attack*

Marshall Eidenberg

INTRODUCTION

Rocket-propelled grenades (RPGs) have been used in combat since World War II, with the American bazooka and German Panzerfaust. All RPGs share one common element: a shaped charge in the warhead designed to penetrate armor.¹ In one attack in Vietnam, RPGs caused 12% of casualties.² More recently, in Operation Iraqi Freedom, RPGs caused 14.5% of battlefield injuries.³ RPGs have been used to bring down helicopters and have been mass fired, reminiscent of American Civil War battles, to attack armored vehicles. Current examples are the American light antitank weapon (LAW) rocket and AT4 and the Russian-made RPG-7. The RPG-7 has a maximum range of 920 meters, at which time it self-explodes (4.5 seconds from firing). As a result, this weapon is sometimes used as a form of anti-aircraft artillery against slow, low-flying, or hovering helicopters.

There is a second class of weapons that physically resembles RPGs, called enhanced blast weapons (EBWs). They also made their debut in World War II. The Soviet-made Katyusha and German Nebelwerfer were the first. EBWs rely primarily on blast overpressure and secondarily on heat for their effects. Confined spaces intensify the blast effect by reflection of the pressure waves from interior surfaces. Current examples are the Russian TBG-7V (which is fired from the RPG-7 launcher) and the Chinese RPO-A.^{4,5}

DESCRIPTION OF EVENTS

Shaped-charge warheads cause a mix of wound patterns including thermal, blast, and ballistic trauma. The shaped charge forces a jet of super hot material through armor. These wounds have been described as similar to those caused by a blowtorch. The explosion will cause blast injury, discussed in greater detail below, and fragments of the RPG and spall (i.e., fragments of the vehicle or building hit by the RPG) from the target can cause ballistic damage with perforations and lacerations.⁶

*Disclaimer: The opinions or assertions contained herein are solely those of the author and do not represent the views of the Army Medical Department or the Department of Defense.

The EBWs cause injuries from the compressive effects of the shock waves transmitted to the victim (i.e., primary blast injury). The lungs and all air-filled organs are most vulnerable to blast overpressure, and injury to these organs increases the risk of mortality. Internal organs such as the intestines, heart, liver, and kidneys are also susceptible to damage from primary blast injury. The most likely result will be the crushing or rupture of the organ, which can lead to rapid loss of blood, accumulation of body fluids, or eventual peritonitis. Air embolism can also occur in coronary and cerebral vasculature. Pneumothoraces may also result from primary blast injury.

Secondary blast injuries result from limited fragmentation of the warhead as well as the debris displaced by the blast. In open areas this is limited. In enclosed areas like buildings, debris is usually present, which increases the likelihood of these injuries. Typical secondary blast injuries are perforations of the body, fractures, injuries to the eyes (from dirt or dust), and lacerations. Unless a vital organ is damaged, rapid blood loss is the primary danger from this type of injury.

Tertiary blast injury results from the blast throwing the casualty. Typical injuries are blunt trauma, fractures, and amputated limbs. Again, rapid blood loss is the major danger.

PREINCIDENT ACTIONS

Aside from having a well-developed and rehearsed disaster response plan, there are no specific preplanning actions to be taken. Body armor helps cut down on secondary injuries from fragmentation but may enhance primary blast injuries in enclosed spaces.^{4,5}

POSTINCIDENT ACTIONS

Prehospital trauma life support becomes the primary care at the point of wounding. Simple life-saving skills are necessary to treat airway, breathing, and circulatory problems of persons with these types of wounds. Prehospital personnel should document injuries that occurred within an enclosed space to highlight the possibility of blast overpressure injuries when the casualty

reaches the emergency department. Postincident actions include notification of the trauma team and activation of the hospital's mass-casualty plan. Plans should be in place for casualties who may have unexploded ordinance embedded in their bodies, are still alive, and require care. These weapons can be handled relatively safely during removal from patients, but they will need ultimate disposal by the "bomb squad." Police bomb disposal personnel should be involved if there are any unexploded RPGs or EBWs retained in the patient's body. Other considerations consist of mobilization of type O-positive and O-negative blood. The police department and hospital security personnel should be used for crowd control and media control.

MEDICAL TREATMENT OF CASUALTIES

Treatment for both RPGs and EBWs are essentially the same as that of any other injury. The primary survey, airway, breathing, and circulation issues must be addressed first. Traumatic injuries are treated in the same way as any other casualty. Frequently, these patients have a multiple modality injury—burn, blast, and fragmentation (foreign body). Recent information from Operation Iraqi Freedom indicates that RPGs are the leading cause of multiple site injury.³

Blast injuries are relatively difficult to diagnose in the prehospital setting and can take time to reveal themselves, especially in the case of chest and abdominal blast injuries. Injuries to the torso and abdomen may have no external symptoms and may initially be indistinguishable from benign causes of respiratory distress, such as hyperventilation, breathlessness, and agitation due to stress reaction. More subtle signs of primary blast injury include deafness, bleeding from the ears, chest or abdominal pain, confusion, and difficulty breathing. Suspected blast casualties should be transported by stretcher because exercise has been shown to worsen pulmonary problems.⁷

Inappropriate use of intravenous fluids in patients with primary blast injury can cause rapid development of pulmonary problems due to pulmonary contusion (i.e., blast lung). Fluids should not be withheld for

resuscitation but should be used based on clinical parameters such as level of consciousness, urine output, and peripheral pulses. This is slightly different than the current advanced trauma life support guidelines, which recommend the rapid infusion of 2 liters of isotonic crystalloid.⁸

UNIQUE CONSIDERATIONS

Remember that these patients who have been caught in an RPG attack have incurred multiple mechanisms of injury. In addition, these are high-kinetic-energy military weapons, especially compared with civilian modes of wounding, and the amount of energy transfer and tissue damage is likely to be greater.

The RPO-A EBW uses isopropyl nitrate as an energetic material in the warhead. Isopropyl nitrate can be absorbed into the skin, ultimately causing formation of methemoglobin.⁹ Isopropyl nitrate is also a carcinogen. Ordinarily, isopropyl nitrate is a clear fluid, but it may have been dyed pink for ease of identification during maintenance. If a pink fluid is present when the RPO-A malfunctions, avoid contact with this fluid.

PITFALLS

Several potential pitfalls in response to an RPG attack exist. These include the following:

- As with every trauma patient, finding the first injury necessitates the search for the second, third, etc. Responder should not stop looking until the patient has had the tincture of time to unmask the more subtle injuries.
- The anxious patient with no apparent injuries may still have sustained injuries to his or her lungs or abdomen. Rule out the medical causes (e.g., primary blast injury) for this anxiety before obtaining a psychiatry referral.
- Large-volume intravenous fluid resuscitation should be avoided. Healthcare providers should treat for shock, but titrate volumes based on mental status, urine output, and peripheral pulses.

CASE PRESENTATION

While working in an urban emergency department, you see live video on a news channel reporting there is a terrorist situation occurring nearby. Multiple rockets have been launched at buses and buildings, causing multiple casualties and obvious fatalities. You are at the closest facility, and you know from previous experiences with Oklahoma City and the World Trade Center attacks that patients will go to the nearest facility. You have 5 minutes until the patients start arriving. What are you going to do to prepare yourself and your team for these casualties? What information does your team need?

Conventional Explosions at a Mass Gathering

Franklin D. Friedman

DESCRIPTION OF THE EVENT

The magnitude and severity of primary injuries from a blast explosion are determined by proximity, the quantity and type of explosive, and whether the explosion occurs in an open or enclosed space.^{1,2} Naturally, when an explosion occurs in the midst of a large gathering of people, other factors that strongly affect overall morbidity and mortality include access of rescuers to the injured and the personnel and resources available to care for an overwhelming number of victims in the immediate aftermath.

The increasing prevalence of terrorism and insurgency over the last three decades has increased our understanding of the types of injuries caused by blast in the civilian environment—injuries once seen only on the battlefield—as well as the predictors of survival and management techniques for such incidents.³⁻⁵ By the time victims of these injuries reach the hospital, primary blast injuries are uncommon because, so often, they result in immediate death.⁶ Because they are so rare, and because a bombing often results in so many casualties converging on a single institution, many physicians and other healthcare workers with no prior expertise in trauma or disaster management may be pressed into service to care for trauma patients.⁷

Although many articles in the medical literature describe the effects of blast injuries,⁸⁻¹¹ and others describe medical planning and care for mass gatherings¹²⁻¹⁵ (i.e., mass “gatherings of potential patients”¹⁶), few combine both topics.¹⁷⁻²⁰ As late as 2002, a 25-year review of the literature pertaining to mass gatherings did not reference a single article describing a terrorist incident at a mass gathering, or even discuss the topic.¹¹ Most articles concerning healthcare planning for mass gatherings, in fact, ignore the risk of a major traumatic event such as a bombing, instead focusing on environmental or medical emergencies. An incident in which 60,000 spectators are exposed to an exploding bomb demands a different response.

Fortunately, very few incidents of intentional or accidental explosions have occurred, affecting large gatherings such as sporting or entertainment events (e.g., the

Atlanta Olympics in 1996 and Bali in 2002). Many of the terrorist bombings from which we have learned about injury patterns occurred in other settings (e.g., U.S. barracks in Beirut in 1983, the Alfred P. Murrah Federal Building in 1995, the World Trade Center in New York in 1993, the Madrid train in 2004, numerous attacks in Israel). By extrapolating from what is known about the nature of explosion injuries, the outcome of explosions that have affected many victims, and the strategies developed to provide medical care at major events, one can build a workable strategy to care for persons with these injuries.

The *medical usage rate* (generally reported as numbers of patients per 10,000 in attendance) at a mass gathering is rarely greater than 50 at a spectator event, and it is most often related to weather. By stark contrast, one author documents a mortality of 7.8% for open-air and 49% of closed-space bombings, although these do not refer to mass gatherings with several thousand persons in attendance.²

PREINCIDENT ACTIONS

Preparation for conventional explosions at a large gathering is best when it is preventive, rather than reactive. The best preparations depend on making conditions unfavorable for the bomber and designing structures that are fire resistant, are less likely to collapse, and offer easy egress in the event of an explosion. Measures can be taken, as in the London Underground, to remove waste receptacles in which an explosive device may be hidden. Similarly, although inconvenient, inspecting backpacks and the trunks of vehicles for those entering events have become a necessary precaution.

The importance of repeated drilling of all the facets of a hospital and a region’s disaster plan must not be underestimated. After the bombing at the 1996 Atlanta Olympics, Atlanta emergency medical services leaders attributed pre-event training and drills practiced during 5 years leading up to the event as the principal reason why their response went well.¹⁹ All 111 injured patients were evacuated to the area hospitals within just 32 minutes of the explosion.¹⁹ To best prepare for a

conventional bombing at a mass gathering, perform a drill involving a scenario with a large surge of trauma victims, mixing both critically ill and lightly injured victims.

POSTINCIDENT ACTIONS

The potential volume of patients with both critical and noncritical injuries is the greatest risk to successful management of an explosion at a mass gathering. Establishing effective triage, both at the scene and again at the receiving hospitals, will prevent overwhelming limited resources and ensure that the most seriously injured patients are identified rapidly and sent to appropriate medical facilities.

Virtually all civilian bombings constitute a criminal act. Therefore, any material from the explosives found on or inside of victims is evidence that may be useful to investigational authorities in solving the crime. Salvaged clothing may contain identifiable explosive residue. Even corpses may yield important clues; consider performing postmortem radiographs to identify shrapnel. Expect to continue to work with law enforcement personnel after an incident, especially in matters such as evidence collection and serving as witnesses as the examining healthcare providers.

After treatment of casualties is completed, how should outcomes be assessed? Data points of interest include injury severity scores, specific injuries, morbidity, mortality, and location of persons with respect to the explosive device. By publishing data such as these, and lessons learned, it may be possible to improve the response to the next bombing incident.

MEDICAL TREATMENT OF CASUALTIES

When caring for victims of a conventional bombing at a mass gathering, keep in mind the convergence of two types of disaster: injuries unique to conventional explosives and caring for the surge of many simultaneously injured patients. Those close to the actual explosion often will die or suffer serious injuries, but the majority of casualties will receive relatively minor injuries, frequently from flying debris.²¹ The other traumatic injuries likely seen will be those related to stampede from those trying to escape or burns from a resulting fire. Despite the variety of serious injuries unique to blast injuries, the most common injuries among blast survivors involve standard penetrating and blunt trauma.²²

The major medical challenge in caring for the victims of bombs, in addition to the multiple simultaneous casualties, is to identify those who are seriously injured but salvageable and to realize that they will be mixed in with a large number who are lightly injured or psychologically traumatized.¹ Children are particularly at risk for the damages inflicted by bomb explosions, yet the physical clues of injury may be less apparent, particularly to rescuers mainly accustomed to treating adults.²³ Large numbers of children may also be present at certain mass gatherings. Details concerning the nature, type, and care

CASE PRESENTATION: THE BALI BOMBINGS OF OCTOBER 12, 2002

Shortly before midnight in the town of Kuta, Bali, an electronically triggered bomb exploded in Paddy's Bar, driving the patrons outside, where moments later, a powerful car bomb (containing ammonium nitrate) exploded in front of the crowded Sari Club. "The place was packed, and it went up within a millisecond" was the description of a visiting Australian football coach²⁴ (the team was in the club, and half were killed). "A huge, massive flame erupted from the floor like a volcano...Everybody rushed to the back steps, but it was too crowded to get out...everything was on fire."²⁵ Most of the victims were in their 20s and 30s, and most were foreign visitors (primarily from Australia, although at least 22 countries were represented among the deceased).²⁶ The death toll was 202, and several hundred more suffered various injuries including severe burns.

of injuries common to conventional explosions are described in other chapters in this section.

In addition to the actual explosions, the other two principal injury-causing features of this attack were the collapse of the Sari Club (a largely open-sided building), which trapped patrons, and the ignition of a huge fire that was apparently caused by exploding gas cylinders. Care of the injured was compromised by a limited medical infrastructure in Kuta; although it has one of the best hospitals in Bali, the care offered there is still rudimentary.²⁷ Many of the foreign nationals were evacuated to Australia and Singapore. Sixty-one patients were transferred to Royal Darwin Hospital in Australia, 28 of whom had major trauma including "severe burns, missile injuries from shrapnel, limb disruption, and pressure-wave injury to ears, lung, and bowel."²⁸

In Bali, beyond the limitations of caring for so many burned and otherwise injured patients, untrained volunteers performed much of the initial mortuary care. Tourists took on the daily responsibility of bringing ice to a makeshift morgue. Unfortunately, they also combined victims' remains in single bags, commingling DNA and making some identification impossible. Three unidentified bodies were cremated subsequently.²⁶

UNIQUE CONSIDERATIONS

Responding to a conventional explosion at a mass gathering is unlike treating either a small number of victims from an explosion or the typical patients presenting from a large event (usually medical complaints, minor injuries, or environmental-related problems). A carefully placed explosive device at a major indoor event can result in hundreds or potentially thousands of casualties suffering assorted trauma, including burns. Triage, both at the scene and again at the receiving hospitals, is one of the most crucial aspects of the response to prevent

overwhelming limited resources. Keep in mind that, unlike a medical emergency, at a sports event, the EMTs prepositioned in the stadium may be among the victims when a bomb explodes.

Delay of care for those truly in need (i.e., those requiring chest decompression, mechanical ventilation, operative exploration) while methodically evaluating and bandaging every patient with an abrasion will mean lives lost. The effective disaster response, as for any surge of trauma patients, will rely on a variety of caregivers pressed into service to treat minor injuries,⁷ while senior, experienced emergency providers perform rapid triage, directing casualties to appropriate sites for care.

PITFALLS

Several potential pitfalls in responding to an explosion at a mass gathering exist. These include the following:

- Over-triage could rapidly overwhelm hospitals, resulting in the needless death of casualties who otherwise might have been saved.
- Failure to consider the possibility of additional explosive devices after the initial detonation can needlessly result in additional casualties.
- Failure to rapidly institute an orderly means to perform triage, both in the field and at hospitals, will result in unnecessary chaos. A military processing station model should be the ideal.

Conventional Explosion at a Hospital

Donald MacMillan

DESCRIPTION OF EVENT

Although a highly unlikely event, a hospital explosion and its impact on the infrastructure, patients, staff, and the community must be considered. The hospital setting is rich in flammable and toxic materials, making it a potentially hazardous environment. The ever-increasing use of hazardous materials, nuclear agents, and toxic substances makes most medical centers vulnerable to explosions.¹ Although there is a paucity of reports of hospital explosions in the literature, the increasing frequency of terrorist events makes such an event more likely.² The experience gained from damage to healthcare facilities by earthquakes and terrorist incidents provides some insight into how to respond to this type of emergency. This chapter will discuss the types of explosions that may affect a hospital, and the associated injuries will be described. Potential pitfalls and successes from similar events will also be discussed. All will be considered in the context of the Incident Command System (ICS).

Conventional explosions in hospitals are exceedingly rare. When a hazard vulnerability analysis is performed, the probability of such an event would be given a low score; however, the impact of the event on the institution warrants a high score, making the overall score low to intermediate. Explosions can result from either a terrorist event or an internal mishap, such as a ruptured gas line. No matter the source, the result is essentially the same.

A terrorist incident will most likely involve the detonation of an improvised explosive device. These devices come in a variety of shapes and sizes, ranging from small pipe bombs composed of metal pipe and rapidly burning gunpowder to large truck bombs like the one used to destroy the Alfred P. Murrah Federal Building in Oklahoma City in 1995. Secondary devices, which are devices timed to detonate after the primary explosion, must be considered. Although they failed to function as intended, the suspects in the Columbine High School shooting in 1999 had many secondary devices, which were designed to maim and kill emergency responders.³ Secondary devices were also used in the Centennial Park bombing at the 1996 Atlanta Olympics as well as the Atlanta abortion clinic bombing in 1997. Until the source of the explosion can be identified, the presence

of secondary devices must be considered. Unlike terrorist bombings, explosions caused by flammable gases or liquids may continue to burn, resulting in secondary explosions that can cause further damage to the structure. The storage of compressed gases, including oxygen and air, can be the source of an explosion at a healthcare facility.

No matter what the source of the explosion, damage to the building can include the structural components or infrastructural components (e.g., ventilation, water supply, and sprinkler systems). Fires ignited from the initial explosion can generate injured patients, even among those who avoided injury in the initial event. Damage to anything other than a small confined area requires the consideration of a partial or facility-wide evacuation.

PREINCIDENT ACTIONS

An ICS is the foundation of the hospital's emergency operations plan. Repeated drills using the ICS are a must. An ICS is an organized system of command and control that allows the user to employ procedures for organizing personnel, facilities, equipment, and communications during an emergency response. A full discussion of the ICS can be found in Chapter 30. Table 148-1 briefly outlines the immediate tasks of the sector chiefs.

POSTINCIDENT ACTIONS

The Incident Commander will determine when the incident is over or determined to be under control and when to discontinue or contract the ICS. The incident may be turned over to the top-ranking police or fire agency during the investigative phase. The primary function is to restore the hospital to its preincident state. Partial restoration of services may begin as soon as the building is deemed structurally sound and certain patients may be returned to their beds or the hospital can start accepting new patients. The determination of whether severely damaged structures can be repaired or will have to be razed must be addressed. After the 1994 Northridge, Calif, earthquake, four of the eight hospitals that evacuated patients because of that disaster required demolition.⁴

TABLE 148-1 IMMEDIATE TASKS OF SECTOR CHIEFS IN EMERGENCY RESPONSE

TITLE	TASKS TO CONSIDER
Incident Commander	<ol style="list-style-type: none"> 1. Activate Emergency Operations Center. 2. Set agenda for status report by sector chiefs (i.e., operations, logistics, planning and finance). 3. Assign liaisons to coordinate with responding agencies. 4. Assign a public information officer 5. Prepare staff for extended operations. 6. Determine whether patient evacuation will be required.
Logistics Sector Chief	<ol style="list-style-type: none"> 1. Determine the structural integrity of the affected building and advise the Incident Commander. 2. Secure the utilities, including medical gases. 3. Ensure adequate supplies to treatment area. 4. Activate emergency communications plan.
Planning Sector Chief	<ol style="list-style-type: none"> 1. Consider alternative care sites. 2. Secure transportation for patients to alternative care sites. 3. Ensure accurate patient tracking. 4. Develop a plan for convergent volunteerism.
Operations Sector Chief	<ol style="list-style-type: none"> 1. Organize triage and treatment of all casualties. 2. Ensure continued care of all unaffected patients.
Finance Sector Chief	<ol style="list-style-type: none"> 1. Immediately track all costs associated with response, recovery, and mitigation of event.

Immediate real-time cost tracking may become important for reimbursement. The finance officer should work closely with outside agencies, including the institution's insurance carrier, to provide accurate costs. This must include personnel costs as well as replacement costs for material. Determining what types of disaster relief or grant money will be available and how best to access these funds will assist the institution in returning to its preincident condition.

In the event the source of the explosion is unknown and possibly the result of a terrorist attack, the facility also becomes a crime scene. Evidence preservation and limited access to the scene are critical. Jurisdictional issues, particularly with law enforcement agencies, may become complicated. All agencies should understand that safety issues take priority, but responders should try to minimize their impact on the scene. Working with these agencies during drills and appreciating one another's roles and capabilities will greatly enhance the working relationship and allow both missions to be accomplished in overlapping time frames.

Finally, since hospitals have large amounts of hazardous and radioactive material, patient decontamination may be required. Contaminated patients cannot enter the general population without first being decontaminated. Depending on the location of the explosion and the damage sustained, the hospital's own decontamination facility may be unavailable. Even if the facility is undamaged, the

personnel who usually provide decontamination may be unavailable. Contamination with radioactive material has some special considerations. Working closely with the hospital physicist or the radiation safety officer will greatly enhance decontamination efforts. In addition, educating staff about radioactive decontamination will reduce the anxiety of treating these patients.

Although explosions at hospitals are rare, they must be considered during the hazard vulnerability analysis. The best way to prepare for these and all types of events is to implement an Incident Command-based hospital emergency management plan. This plan should be exercised frequently and should involve as many community agencies as possible. This experience will be invaluable no matter what type of emergency disrupts the function of a hospital.

Medical Treatment of Casualties

Victims of a conventional explosion at a hospital will have the myriad of injuries seen in blasts and structure collapse. The care of these victims will follow those guidelines described thoroughly in Chapters 141, 142, and 162. In a hospital setting, however, some casualties may have underlying medical conditions for which they are being hospitalized. The management of such patients should also take into account these underlying conditions.

CASE PRESENTATION

An explosion and fire occurs at 11 PM in the main power plant of a large inner-city hospital, severely damaging that part of the hospital structure. An adjacent building with inpatient wards on seven floors, including the emergency department, operating rooms, and medical and surgical intensive care units, is damaged from the explosion. The backup power supply initiates, then fails after 1 minute and another explosion. Electrical power is lost throughout the hospital. All of the lights as well as some ventilators and monitors turn off, elevators stop, and communications cease. As first responders arrive, one section of the hospital is enveloped in flames, and the remainder of the hospital is in complete darkness. Inside, hospital staff in every unit frantically attempt to locate patients in the dark, rescue patient and staff victims of the explosion and fire, assist those whose ventilators have failed, and begin the evacuation procedure.

UNIQUE CONSIDERATIONS

There are unique considerations with hospital explosions. The first is operating in an oxygen-rich environment. The potential for increase in fire is directly related to the amount of oxygen available from ruptured medical gas lines. It should be an absolute top priority of the operations sector chief to have the oxygen lines shut down as soon as possible. This may mean shutting down the entire facility until the affected area of the building can be isolated.

Whether the explosion is due to a terrorist event or is an accident, there is an increased potential for the dispersal of radioactive material. Contamination will add a level of complexity to the management of the incident because decontamination will have to be executed in consultation with the facility's radiation safety officer. If the explosion is the result of a terrorist event, the involvement of law enforcement personnel adds yet another level of complexity. To ensure that potential radiation contamination is considered, the radiation safety officer should be notified whenever the emergency operations plan is implemented. He or she is a staff officer or liaison to the Incident Commander and needs to be incorporated into the operations plan. The Incident Commander can quickly dismiss him or her if the officer's services are not required, or the officer can be reassigned to the operations sector as needed.

The risk of evacuating patients from a structure that is potentially unstable must be considered. These risks include moving unstable patients through an environment that is immediately dangerous to life and health. If the building is damaged similar to what was seen in Oklahoma City, technical rescue experts will be required and the evacuation will be lengthy. Sheltering in place also has its risks, including turning a potentially stable structure into an unstable one as a result of any secondary explosions. The important point to determine is whether a patient is going to be exposed to greater risk during evacuation than he or she would if sheltered in place.

PITFALLS

Several potential pitfalls exist in responding to an explosion at a hospital. These include the following:

- Lack of an ICS-based emergency operations plan
- Failure to participate with local agencies that will respond in the event of an explosion
- Operating outside the ICS, allowing "freelancing" to occur
- Not incorporating ICS into all facets of drills, tabletop scenarios, and events
- Not getting to know all of the responders' capabilities and limitations before an event occurs

Conventional Explosion in a High-Rise Building

Ryan Friedberg

DESCRIPTION OF EVENT

High-rise buildings are architectural wonders that shape the skylines of many cities across the United States. Explosions in high-rise buildings were essentially unheard of until 1993, when these structures became targets of terrorism. Until then, healthcare workers in the United States had no experience with mass casualties from explosions in high-rise buildings.

There have been three large-scale attacks on high-rise buildings in the United States since 1993. The first was the bombing of the World Trade Center in New York in 1993. This event resulted in six deaths and 1042 injuries.¹ The second attack was in Oklahoma City in 1995, when a truck bomb exploded adjacent to the Alfred P. Murrah Federal Building. This attack killed 167 persons and injured more than 750 persons.² The most recent attack, and the worst single act of terrorism in the history of the United States, was the attack on the World Trade Center towers in New York on Sept. 11, 2001. The actual death toll from this attack is unknown. There have been 1527 identified bodies, but it is believed that the actual death toll is between 2726 and 2742 persons.^{3,4} Thousands of persons suffered injuries from the attack, and 1103 were treated in hospitals for their injuries.⁵ The attack has changed the way people in the United States live and created an urgent need not only to attempt to prevent another such attack, but also to prepare for the possibility of future attacks on high-rise buildings.

There are many different types of explosives that terrorists may attempt to detonate in high-rise buildings. High explosives, including trinitrotoluene (TNT), composite C4, and ammonium nitrate are powerful enough to cause building collapse. However, the explosions and resulting fires from massive amounts of less-explosive aviation fuel in the World Trade Center attack resulted in the greatest structural failure in human history. Trauma after an explosion in a building can be categorized into primary, secondary, and tertiary blast injury. Primary blast injuries are due to the direct effect of the pressure wave on the victim.⁶ The most sensitive organ affected by the primary blast is the ear.⁷ Other systems that are

affected include the respiratory, circulatory, and digestive systems, as well as the eye and orbit.

Secondary blast injuries are incurred due to objects propelled by the blast. These projectiles can be very significant in a high-rise building explosion and may extend far beyond the distance of the initial blast effect. These fragments that become projectiles can be both large and small and can cause both penetrating and blunt injuries.

Tertiary blast injuries occur when a person is propelled by the blast against another structure. These are typically blunt injuries including soft tissue injuries, lacerations, head injuries, and fractures. Less commonly seen are flash burns and thermal injuries.

Crush injuries are common if a building explosion results in structural collapse, and these frequently cause immediate death. In the Oklahoma City bombing, 97% of fatalities were immediate, and most were killed in the building collapse.² This was also true in the World Trade Center attack.³ The risk of building collapse and resultant high fatality rates distinguish explosions in high-rise buildings from other types of explosions. Medical personnel are unlikely to care for victims crushed in a high-rise collapse because survival is rare.

PREINCIDENT ACTIONS

Prevention is the most effective method of reducing morbidity and mortality in the aftermath of an explosion in a high-rise building. In addition to the obvious goal of preventing such an explosion in the first place, constructing high-rise buildings that can withstand an explosion without structural failure should significantly reduce mortality. Other safeguards will help to prevent secondary and tertiary injuries.

Currently, significant focus is being placed on design guidance, including site location, layout, building envelope and interior, and on the mechanical and electrical systems used in high-rise construction. When designing a new building, design guidance is provided for limiting or mitigating the effects of terrorist attacks. It is beyond the scope of this chapter to discuss each of these methods. The U.S. Federal Emergency Management Agency's Web site (<http://www.fema.gov>) extensively describes

each of these strategies in their risk management series as of December 2003.

Another critical element to have in place in the aftermath of a building explosion is a disaster plan that involves all medical and rescue personnel of a given area. Any city or large community must have a well-rehearsed disaster plan in place in case of a mass-casualty event.

POSTINCIDENT ACTIONS

Immediately after a conventional explosion in a high-rise building, there are three phases that need to be addressed. The first is the prehospital management, followed by the emergency department management, and finally, in-patient hospital management of the victims. Each of these will be addressed in this section.

The prehospital management starts with the activation of the mass-casualty alert that makes local, state, and federal agencies as well as all medical personnel aware of a disaster event. The first aspect of the disaster that needs to be addressed is the scene itself. Secondary explosive devices designed to explode on a delay, and directed at the personnel trying to rescue the victims, are unfortunately very common in terrorist attacks.⁸ The safety of the remaining structure must also be assessed. Building collapse is always a significant risk during a bombing, and it is never acceptable to lose rescue workers when attempting to save victims. Once the building is as secure as possible, it is of utmost importance to quickly triage the victims according to standard protocols and determine which of them has life-threatening injuries.

Prehospital and emergency department staff must be prepared to triage patients appropriately, as the more severely injured patients are not usually the first wave of patients seen. Scene triage and separate emergency department triage may be necessary to direct patients to the most appropriate venue for care and maximize use of resources.

Prehospital personnel should expect to see familiar injuries including blunt, penetrating, and thermal injuries. After an explosion, all medical personnel need to maintain a high index of suspicion for primary blast injury. It is very important to evaluate the scene while performing rescue operations. Presence of a crater, injuries to closer victims, and building collapse are important observations regarding blast strength. Likewise, assessment of damaged objects near a casualty situation might yield a gross estimate of the pressures that existed in the vicinity. For example, shock waves able to rupture a tympanic membrane are about the same needed to shatter automobile glass.⁹

It is also important to get a quick history. Phillips and Zajchuk¹⁰ recommend the following questions when evaluating a bombing casualty:

- What type of ordinance was used? How large was the explosion?
- Where was the casualty located with respect to the blast?
- Did the blast occur inside an enclosed space, such as a room or vehicle?

- What was the casualty's activity after exposure?
- Were fires or fumes that might lead to an inhalation injury present?
- What was the orientation of the casualty's head and body in relation to the blast?

Prehospital medical personnel should be ready to perform life-saving interventions, including intubations, resuscitations, field amputations, and chest decompressions, although the most common procedures performed are spinal immobilizations, field dressings, and intravenous fluid administration.¹¹ Prehospital personnel should also be well equipped for the extrication of victims after complete or partial building collapse. Extricating these victims as quickly as possible greatly improves their chance of survival.

The second phase of treatment occurs in the emergency department. It is very important for medical control to direct the prehospital personnel to the most appropriate emergency department. Designated trauma centers should receive the most severely injured patients, even if they are not the closest hospital. Once the patient reaches the emergency department, the emergency staff needs to be prepared for the many types of injuries occurring in a blast. Emergency staff must be prepared for victims to arrive by all modes of transportation, most of whom will have only minor injuries. In the Oklahoma City bombing, Hogan and colleagues¹¹ report that 55% of victims came by private vehicle whereas only 33% came by emergency medical services transport; 80% were discharged that day.

As soon as hospitals are made aware of an explosion, emergency staff must mobilize the equipment necessary to treat numerous victims. This includes wound care trays, tetanus immunizations, antibiotics, fracture care, endotracheal tubes, thoracostomy tubes, cricothyroidotomy trays, and medications for conscious sedation, rapid sequence induction, and advanced cardiac life support. It is also the role of the emergency physician to ensure that the hospital disaster plan goes into effect. This includes making sure trauma teams are aware of any incoming patients and that the hospital is ready to accommodate the many injured patients that will need rapid admission to the hospital. This will improve throughput in the emergency department and create space in the emergency department for incoming wounded. Preparing for this type of disaster includes drilling the plan by hospital staff, and the plan should be well known by all staff members. The importance of adequate communication from the scene and prehospital providers to hospitals and emergency departments about the number of victims and types of injuries cannot be overstated.

MEDICAL TREATMENT OF CASUALTIES

The treatment of casualties after an explosion in a high-rise building can be very challenging due to the different types of injuries seen and the pattern in which injured persons arrive at healthcare facilities. Healthcare professionals should be prepared for all three types of blast

injuries as well as flash injuries, thermal burns, and crush injuries.

It is very important to properly triage patients who arrive from a blast event. The most common injuries are superficial, including abrasions and lacerations, and these patients are often the first group to present for care. The emergency physician must always be aware of the potential for primary blast injury and internal injuries that may present with delayed symptoms. When patients are examined, standard trauma protocols should be followed. For those patients with seemingly minor injuries, it is still necessary to do a thorough examination of the entire body. This will decrease the risk of missing an injury or any sign of an internal injury. Blast injuries differ from many other types of injuries because serious injuries may not manifest themselves immediately, particularly with primary blast injury, and careful observation of the patient is often necessary. Primary blast injury may result after any explosion but is amplified when it occurs in a building due to the enclosed surroundings. The management of primary blast injuries is discussed in more depth in earlier chapters in this section.

Secondary blast injuries are caused from projectiles due to the blast. These types of injuries make high-rise building explosions different from other conventional blasts. With many of the high-rise buildings today made with significant amounts of glass and steel, projectiles traveling at a high speed are very dangerous. It is these types of injuries that are most often seen in the emergency department. This is because the shrapnel that comes from a high-rise building can reach victims well outside the reach of the primary blast zone. During the Oklahoma City bombing, glass laceration injuries occurred as far as 10 blocks from the explosion. The most important thing to remember when treating patients with lacerations is to rule out other more serious injuries. Once more serious injuries have been ruled out, lacerations should be treated as time and resources allow. Delayed closure should be used if resources aren't available to treat both the critically ill and those with minor injuries. Injury to the eye often results from secondary blast injuries and should not be overlooked. Of the surviving victims of the Oklahoma City bombing, 8% sustained eye injuries, including lid lacerations, open globe injuries, orbital fractures, corneal abrasions, retinal detachment, and intraocular foreign bodies.¹²

The most worrisome type of secondary blast injury is the penetrating injury. Every part of the building and its contents has the ability to become shrapnel moving at high velocity. Victims with penetrating injuries should be treated promptly and with the involvement of the surgical trauma team. As with all penetrating injuries, the practitioner should be ready to treat hemorrhagic shock. In a stable patient, deep penetrating shrapnel should only be removed in a safe, controlled environment, usually the operating room.

Penetrating injuries are obvious; however, blunt trauma must not be overlooked. Blunt trauma can occur from secondary or tertiary blast injury after a high-rise explosion. Severe entrapment or crush injuries are rare

in survivors but may be seen in the emergency department. Patients with crush injuries are at risk for amputation, compartment syndrome, and rhabdomyolysis. These patients should be treated according to standard trauma protocols. Flash burns and thermal injuries are usually superficial injuries and should be treated with standard burn care.

CASE PRESENTATION

It is 9:30 AM, and you are the only attending physician working at the only level one trauma center in a small rural city. You receive a call from emergency medical services alerting you that there was just a large explosion from the ground floor of a commercial bank building. The building is made mostly of steel and glass. It is 22 stories high, and there are approximately 650 persons in the building. You are providing medical control for the paramedics.

What do you tell them? What do you need to do immediately with regard to your emergency department and hospital staff? Who else should be notified? What type of injuries do you expect to see, and what special equipment will you need to treat these injuries?

UNIQUE CONSIDERATIONS

Preparing for a conventional bombing in a high-rise building is a difficult task because of the large variety of injuries seen and the great numbers of victims. Unique to these types of attacks is the pattern in which patients arrive. The first wave of patients is usually the furthest from the blast. These are usually secondary blast injuries, most of which are minor. The second wave of patients is usually the most critical. Another consideration in the explosion of a high-rise explosion is the presence of toxic substances, which may necessitate decontamination of victims and rescuers. A final consideration is emergency department patient flow. A triage system needs to be in place that will properly direct the large flow of injured victims.

PITFALLS

Several potential pitfalls in response to an explosion in a high-rise building exist. These include the following:

- Failure to make sure the building is secure and safe for rescue personnel
- Failure to have a rehearsed disaster plan in place for a mass-casualty incident involving an explosion in a high-rise building
- Underestimation of the severity of injuries sustained by victims as a result of a conventional explosion in a high-rise building

Conventional Explosion at a Nuclear Power Plant

Michelle McMahon-Downer

DESCRIPTION OF EVENT

Since the attack on the World Trade Center in New York City on Sept. 11, 2001, there has been increased worldwide concern over the safety of nuclear power plants. In the United States, there are over 100 such plants.¹ Security has been heightened around nuclear power plants. Barricades are in place and armed guards are present.² All commercial nuclear power plants in the United States house the reactor core in a thick stainless steel vessel within a concrete building.³ Nonetheless, studies have shown that if a jet aircraft crashed into a nuclear reactor and only 1% of its fuel ignited after impact, the resulting explosion could compromise the integrity of the reactor core containment building. Thus, these reactor core containment buildings, although designed to withstand impacts, are certainly destructible and vulnerable to large-scale explosions. Nuclear power plants harbor additional radioactive materials in the form of spent fuel pools. The spent fuel pools are housed in corrugated steel buildings, which are much more vulnerable to attack than the reactor core containment structure.⁴

An example of a conventional explosion at a nuclear power plant took place at Chernobyl Nuclear Power Plant in 1986. An accidental steam explosion during a safety test destroyed the reactor core. An atmospheric plume of radioactive substances was released into the environment during the explosion and fire.⁵ Approximately 600 persons were hospitalized within a week due to injuries and ailments linked to the Chernobyl explosion.⁶ Two died the first day as a result of trauma, combined with thermal burns and irradiation.⁷ One hundred thirty-four persons were confirmed to have acute radiation sickness. Twenty-eight of those with acute radiation sickness died within the first 3 months, and 14 died in subsequent years.⁸ Nineteen of the 28 who died in those first 3 months had severe radiation skin injuries that complicated their course of treatment in the hospital.⁷

At the time of the explosion, approximately 100,000 persons lived within a 30-km radius around Chernobyl Nuclear Power Plant. When the explosion occurred, radioactive substances were released into the atmosphere and continued to do so for 10 days, until the fire was

finally contained. Winds and rainfall distributed the radioactive substances throughout the northern hemisphere, with the highest concentration around the power plant in the former U.S.S.R. Contamination of the area around the power plant was patchy in that distribution of the fallout depended largely on where it happened to rain. The volatile radioisotopes of iodine and cesium were the most important in terms of health risk.⁶ Radioactive iodine has a half-life of just 8.05 days, but radioactive cesium has a half-life of approximately 30 years.^{5,7} A total of 350,400 persons were resettled due to concerns over contamination caused by the Chernobyl explosion.⁵

Long-term effects of exposure to radiation, mainly carcinogenesis, are being seen in the population affected by the Chernobyl explosion. A clear association has been made between exposure to radiation and thyroid cancer, especially in children.⁵ An increase in the incidence of leukemia in Russian clean-up workers has been seen, and Ukrainian scientists have indicated that there is an increase in other solid cancers (e.g., breast, lung, urologic) among the inhabitants of contaminated areas and clean-up workers.⁸

PREINCIDENT ACTIONS

Each nuclear power plant is required to have an emergency response plan, as are the local and state government agencies in which the power plant is housed. Some federal agencies have emergency response plans in the event of a power plant explosion.¹ Control and command procedures must be clarified before an incident occurs, as must organizational responsibilities. Assessment of type and quantity of materials and equipment needed, along with decontamination plans and healthcare worker protection, should be addressed. Location of Geiger meters and other radiation survey instruments should be posted along with reference material on what the various readings mean in terms of patient care. An adequate supply of potassium iodide to combat exposure to radioactive iodine should be available for the entire affected population.³

Each community surrounding a nuclear power plant should have a designated person who makes decisions

about evacuation and other issues concerning the potentially exposed population. Communication during the incident is of vital concern, and emergency communication systems must be tested in advance.³ There are two emergency planning zones—the first is within a 10-mile radius of the event, where the threat of direct radiation is highest, and the second is within a 50-mile radius, where the radioactive plume is the biggest threat to residents. A warning system, such as sirens or flashing lights, is required to be provided by the nuclear power plant to alert all inhabitants within a 10-mile radius of an event. Each year, the nuclear power plant is required to distribute emergency information materials to all people who live within a 10-mile radius so that, in the event of an explosion, the public in the vicinity of the plant are prepared.¹

Every hospital, regardless of the proximity to a nuclear power plant, should have a radiation control officer. This officer is responsible for monitoring all patients and medical personnel with radiation counters, supervising clean-up of the potentially radioactive waste, and devising a plan to minimize contamination. Training for physicians to prepare for a disaster involving radiation exposure is offered by the Radiation Emergency Assistance Center/Training Site, which can be contacted by phone at 1-865-576-1005.³

The World Health Organization suggests that the general population, particularly those in the vicinity of nuclear power plants, be prepared for a nuclear incident. One recommendation is that they become aware of possible solid shelter areas in the local area. A second is to have disaster supplies on hand; these include food and water for 3 to 5 days, a first-aid kit, respiration protection, flashlights and batteries, a battery-operated radio with extra batteries, and stable iodine.⁹

POSTINCIDENT ACTIONS

Immediately after a conventional explosion at a nuclear power plant, the local emergency personnel will be activated. The disaster area must be designated as safe for these personnel to enter. Geiger counters and other devices used to detect radiation should be used. If the level is 0.1 Gy/hour or above, emergency personnel should not enter the area and should return to the control point until further notice. Specialized protective equipment is needed to enter the area safely.

As with any mass-casualty event, on-scene triage should be performed. Those with life-threatening injuries are to be taken directly to the hospital.³ For these patients, emergency personnel are to use gloves and gowns, remove the patients' clothes, cover their hair with surgical caps if available, and wrap the patients in sheets for transport. Simply removing the clothes reduces the patient's contamination by approximately 80%.¹⁰ Those who are uninjured or suffering from minor injuries should be relocated upwind, and decontamination should be performed. Decontamination in these situations consists of removing the victim's clothes and placing them in hazardous material bags and washing

the person's skin and hair with soap and warm water.¹¹ All those with nausea, vomiting, diarrhea, or rash should be referred to the emergency department for evaluation of possible acute radiation syndrome.³

In mass-casualty situations, approximately 80% of victims are decontaminated at hospitals; thus, the hospital facility must be prepared to decontaminate patients both inside and outside the emergency department.¹⁰ For those whose conditions are stable, decontamination should be done immediately, and if possible, it should be done outside of the hospital. Those who must be brought into the emergency department immediately should be treated in an area roped off from the rest of the department. Hospital personnel should wear disposable clothing, gowns, gloves, and shoe covers when treating these patients.¹²

The radiation control officer is responsible for monitoring the exposure of hospital staff. Personnel involved with care of contaminated patients should wear dosimeters to monitor radiation exposure.¹⁰ The dose limit for persons providing emergency services other than lifesaving actions is 5 rem per event, whereas for lifesaving activities the recommended maximum dose is 25 rem per event. In the event of a disaster, the recommended limit increases to 150 rem per event.³

The U.S. Federal Bureau of Investigation is the lead federal agency during crisis management, that is, during the period when the focus is on ensuring that there is no further threat and establishing the site of attack as a crime scene. The Federal Emergency Management Agency takes the lead during consequence management, where the focus is on limitation of damage, protection of the public, decontamination, and disposal of the radioactive material. These two agencies will be lead coordinating organizations and should be contacted with questions. Also, the Radiation Emergency Assistance/Training Site should be contacted with any concerns via telephone (1-865-576-1005) or via their interactive Web site (<http://www.orau.gov/reacts>).³

MEDICAL TREATMENT OF CASUALTIES

A conventional explosion at a nuclear power plant will lead to a variety of injuries. Blast, thermal burns, and smoke inhalation will be responsible for most immediate deaths. Radiation injuries will include whole-body or localized exposure (i.e., irradiation) and internal deposition of radioactive substances (i.e., contamination).¹²

Whole-body irradiation by gamma rays can lead to acute radiation syndrome. The most susceptible cells to radiation damage are rapidly dividing cells such as those in the intestinal mucosa and bone marrow.³ However, with massive irradiation, even the central nervous system, with its relatively low cellular turnover rate, will show the effects.¹² The degree of whole-body radiation exposure is estimated using clinical signs and symptoms, the minimal lymphocyte count within the first 48 hours, the severity of thrombocytopenia and reticulocytopenia, and cytogenic studies looking for chromosomal

abnormalities in bone marrow and red blood cells.^{3,12} Lymphocytes are the most radiosensitive cells in the blood, and a substantial dip is apparent within the first 8 to 12 hours.¹³

The faster the fall and the lower the nadir of lymphocytes, the greater the whole-body radiation dose.³ Furthermore, the sooner the onset of signs and symptoms for each phase of radiation illness, the greater the whole-body irradiation.¹ Nausea, vomiting, diarrhea, and rash are the first presentation after gamma irradiation. Later, the clinical manifestations of acute radiation syndrome are related to the level of leukocytes and platelets (Table 150-1). Fever, infections, and hemorrhaging occur. Also, with sloughing of the intestinal mucosal surface, mucositis and enteritis occur.³

In addition to the whole-body, uniform irradiation discussed above, the skin is susceptible to local radiation injury. The distribution tends to be nonuniform, and the skin radiation dosage absorbed is estimated to be 10 to 20 times greater than the bone marrow doses. The signs of a radiation burn are very similar to those of a thermal burn, with the difference being that the signs of radiation burns appear after a period of days in contrast to thermal burns, where the results appear immediately.³ In the Chernobyl explosion, a period of primary erythema was seen in the first few days, followed by a 3- to 4-day period of latency. In severe cases, secondary erythema and the full extent of the burn manifested as early as 5 to 6 days and as late as 3 weeks in milder cases. The most frequent locations early on were the wrists, face, neck, and feet. As time went on, burns were also seen on the chest and back, and later on the knees, hips, and buttocks.¹² Vascular insufficiency can develop at any time after the radiation exposure, even years later, with necrosis occurring. Treatment includes control of pain, vasodilator therapy, and prophylaxis against infection.³ Surgery and plastic surgery consultants should be involved because extensive debridement, skin grafting, and amputation are often required.¹⁴ Burns to the eyelids and eyes are often seen, requiring ophthalmology consultation.

Internal contamination occurs through inhalation, ingestion, and absorption through open wounds. Inhalation can lead to radiation pneumonitis. Early bronchopulmonary lavage may be helpful in removing some of

the radioactive contaminants. Chronic low-level inhalation of radioactive substances is more common and was seen among those involved in the clean-up efforts from the Chernobyl explosion. Radiation fibrosis was seen, and treatment with interferon was of some benefit.¹²

Ingestion of radioactive substances is either treated with specific antidotes and/or general measures to decrease absorption, both of which should be instituted as soon as possible after exposure. Specific antidotes include blocking agents that saturate a tissue with a nonradioactive element, thus reducing the uptake of the radioisotope, and chelating agents that bind metals into complexes, preventing tissue uptake and allowing urinary excretion.¹² As in all poisonings, the local or regional poison control center should be contacted.³

Contaminated wounds should be rinsed with saline until the Geiger meter reads no evidence of radioactive material. If the patient has received a dose of whole-body radiation that leads to decreased lymphocyte count (above 1 to 2 Gy to the bone marrow), the wound should be closed as soon as possible to decrease the chance of the wound serving as a portal of entry for infection.³ Surgical debridement is necessary for the usual indications of dirt and nonviable tissue as well as for continued high readings of radioactive contamination despite saline rinses.¹²

CASE PRESENTATION

The result of a conventional explosion at a nuclear power plant is directly related to the strength and location of the explosion. A large bomb released directly on a nuclear power plant will be tantamount to exploding an atomic bomb. Radioactive contamination will last longer because nuclear power plants house more long-life radioactive substances than do atomic bombs. A smaller explosion, or one that does not hit the structure directly but damages the core or coolant systems, will lead to a core meltdown.² The amount of radiation released into the environment will depend on the severity of damage to the containment structure from the explosion.

TABLE 150-1 CLINICAL MANIFESTATIONS AND TREATMENT OF GAMMA RADIATION EXPOSURE

DOSE (GY)	SYMPTOMS	LYMPHOCYTE NADIR	TREATMENT
>30	Hypotension, high fever, mental status change, syncope, seizures	<100	Palliative
>10	Immediate nausea, vomiting, diarrhea	<100	Palliative
4-10	Delayed (by hours) nausea, vomiting, diarrhea	100-499	Protective isolation, TPN, gut sterilization, hematopoietic growth factors, antimicrobials
2-4	Delayed (by days) nausea, vomiting, or no symptoms	500-999	Antiemetics, pain control, fluids, close monitoring
<1 Gy	Less than 10% with delayed (by days) nausea and vomiting	>1000	Symptomatic care

TPN, Total parenteral nutrition.

UNIQUE CONSIDERATIONS

A conventional explosion at a nuclear power plant differs from all other explosions because of the risk of radiation exposure, illness, and death to large populations. Decontamination is imperative and must be undertaken on a massive scale. Psychosocial issues are very important after the release of radioactive material occurs. The possibility of exposure elicits fear, with common stress reactions. Symptoms can also mimic those of radiation exposure such as nausea, vomiting, and rash. The psychosocial effects can be quelled by communication with the general public in an honest and open manner about the event and the short-term and long-term health risks.³

PITFALLS

Several potential pitfalls in response to an explosion at a nuclear power plant exist. These include the following:

- Many of the victims most severely affected by radiation exposure are emergency personnel and those who were involved in clean-up activities.
- In the event of a conventional explosion at a nuclear power plant, radiation-safe and contaminated areas must be identified. Those with the proper personal protective equipment would be able to enter the designated contaminated area and bring patients to emergency personnel located in the designated radiation-safe areas. Once the patients are removed from the area of high radiation and are decontaminated, they no longer pose a significant risk to healthcare workers using universal precautions.³

Tunnel Explosion

Patrick Zelley

DESCRIPTION OF EVENT

The importance of tunnels in modern travel cannot be overestimated. Multiple uses including transportation across mountainous terrain, under waterways, and through urban areas make tunnels an invaluable component of modern travel. These same aspects also make tunnel disasters a particularly costly event for many reasons, not the least of which are the challenges inherent to providing medical assistance to victims of a tunnel disaster.

Over the years, there have been many documented incidents of tunnel disasters resulting from numerous causes, which illustrate the devastating consequences. In the year 2000, a deadly tunnel fire resulted in the death of 155 passengers on a shuttle train in Kitzsteinhorn, Austria. Another tragic tunnel disaster occurred in Mont Blanc, France, in 1999 with 39 deaths in a 10-car accident. But although these examples demonstrate terrible outcomes of tunnel tragedies, they do not come close to the scale of disaster associated with a large-scale tunnel explosion.

In the changing world we live in, an obvious source of tunnel explosions is the risk related to international terrorism. Traditionally, explosive weapons used by terrorists have been of limited size, usually a few kilograms, resulting in a low mortality rate of approximately 5%. However, due to advanced technology and more elaborate planning, there is the potential for much greater damage. There are three primary factors that increase the risk of morbidity and mortality: larger explosive devices, confined space, and structural collapse. All three of these are possibilities in a tunnel explosion.¹

Although terrorist activity is certainly a realistic possibility, there are many other potential causes of tunnel explosions that must be considered. Construction accidents involving tunnels have occurred. For example, in 1995 a gas explosion in an underground railway in Daegu, South Korea, claimed the lives of 101 people and injured another 143. In 1919, a dynamite explosion in the Baltimore Tunnel, a mining tunnel in Wilkes Barre, Pennsylvania, claimed the lives of 92 people. Other possible causes are tanker truck explosions and multicar accidents.

Tunnel explosions represent a significant challenge to emergency personnel due to many unique characteris-

tics. The purpose of this chapter is to understand the broad scope of preparedness that is essential to a successful emergency response.

PREINCIDENT ACTIONS

In addition to normal disaster preparation, there are some key areas that deserve specific attention when preparing for the possibility of tunnel explosion. Due to the huge variety of tunnel locations, it is common for multiple hospitals and rescue teams to serve the area of a tunnel explosion. An integrated response plan that maximizes the effectiveness of triage, treatment, disposition, and evacuation must be prepared as much as possible in advance. This response plan must be constructed with the ability to adjust from the plan based on actual events. In past mass-casualty incidents, including the bombing of Centennial Park at the Atlanta Olympics in 1996 and the bombing of the World Trade Center in 1993, adhering to a coordinated response plan represented a great challenge. With so many hospitals involved in the recovery process, effective coordination and communication was essential before, during, and after the incidents to effectively make use of all available resources.

There are additional communication challenges associated with tunnel explosions due to the complexities of tunnel design. With multiple entry and exit sites, several control points will be required. Walkie-talkies, cell phones, and landlines should all serve a role in establishing effective communication. In addition, site flags should be used to explain the purpose of each organizational area in both English and Spanish. Translators should be available, both on site and by phone correspondence.

Tunnel explosions are associated with an increased risk of smoke and toxin exposure. Tunnel explosions may involve nuclear, biologic, or chemical toxins in transport for peaceful purposes or criminal acts. Equipment readiness should address the extensive need for respiratory equipment, not only to aid victims suffering from inhalation injuries, but also to prevent similar injuries in the response teams. It is also important for assistance teams to wear proper protective equipment to limit additional injuries, including nuclear, biologic, and chemical

protective gear. Therapeutic agents, including atropine, pralidoxime chloride, oral prophylactic antibiotics, and potassium iodide should be available to treat victims as well as healthcare providers who may be exposed.

Readiness for a possible tunnel explosion includes preparation of site maps to determine the best locations for command posts and triage sites. As was previously stated, multiple entry and exit points increase the need for multiple control points. As a result, it is vital to have accurate maps available in advance of the incident. Finally, transportation plans must include alternative methods of travel due to the high likelihood that a tunnel explosion will result in delays for land travel.

POSTINCIDENT ACTIONS

The effective use of law enforcement is vital for many reasons. Site security is an essential and often overlooked aspect of disaster response planning. A cordoned area should be established as quickly as possible to keep victims from leaving the disaster scene without assessment and to prevent injuries to outsiders who may enter the disaster area. It is also important to set up a release point for equipment and personnel both into and out of the disaster scene. This will help with control of resources. Quick distribution of information concerning the site layout should occur as rapidly as possible among the response team members to prevent improper use of resources. Security should not only be considered at the site of the explosion but also at the receiving hospitals because they are a prime target for secondary explosions when the initial disasters are intentional.

A major post-event challenge that exists with tunnel explosions is related to the multiple access/egress points that may exist. As a result, multiple primary triage points must be established at different sites to limit the obstacles that may exist between different points. For example, a subway explosion would involve multiple underground-to-surface exit stairways that would allow injured passengers to exit at several locations. If triage personnel are not located at or near each of these sites, there is the potential for significant delays in disposition of victims, as well as the increased likelihood that victims will leave the scene without evaluation. This can result in uneven distribution of injured persons to local hospitals and can also increase the risk of morbidity and mortality in those with delayed symptoms. At each of these triage sites, there should also be treatment stations for immediate administration of medical assistance.

A large percentage of patients treated in hospital facilities will arrive at the emergency department by foot, taxi, or other nonemergency transportation method. This results in further administrative difficulties and an exacerbation of over-triage, reducing the effectiveness of hospital resources. For this reason, establishing an external triage site at the receiving facilities is important as an initial triage area for those who have not been previously assessed, and to facilitate secondary triage of patients who have arrived under their own power. Quickly identifying serious injuries in this group is essential because time is of the

essence for those who may suffer from previously unrecognized serious injuries. In addition, these external triage sites should quickly direct victims in need of decontamination to isolated decontamination sites to avoid further exposure to others and contamination of medical facilities.

MEDICAL TREATMENT OF CASUALTIES

Blast injuries are responsible for the majority of the victims after tunnel explosions. The incidence of primary blast injury correlates directly to blast size and proximity to the blast, while correlating indirectly to the amount of open space surrounding the blast.¹ In tunnels, it is important to consider the effects of an explosion in the confined longitudinal space of the tunnel with respect to the frequency and severity of injuries expected. In general, primary blast injuries are most likely to occur with victims located closest to the explosion due to the dissipation of shock waves with progression away from the blast source. However, the confined tunnel space increases reflection of blast forces and, therefore, increases the frequency of primary blast injury. In addition, the reflection of shock waves can increase the destructive potential by 2 to 20 times that of the incident wave, thereby increasing the severity of primary blast injuries.²

Secondary injury is the result of hurled objects causing blunt or penetrating trauma. This involves soft tissue, orthopedic, and head injuries, with traumatic head or limb amputations occurring in those closest to the blast source.³ Tertiary injury is the result of two broad causative factors: the physical displacement of victims (those hurled from the blast source) and the structural collapse of buildings or tunnel walls (crush injuries) as a result of the force of the blast.

Quaternary injury is a collection of other injuries resulting from the blast.¹ This includes thermal injury (hot gases and secondary fires), inhalation injury (dust, smoke, carbon monoxide, and chemicals) and water injury (underwater tunnels).³ Quaternary injuries are likely to be increased in tunnel explosions because the length of the confined space may make it difficult to escape, prolonging exposure, and persons in the tunnel far from the explosion may still be exposed to smoke and gases that vent from the tunnel.

Primary blast injury to the lung or gastrointestinal (GI) blast injury may occur as a result of a tunnel explosion. GI blast injury is more common when victims are submerged or partially submerged in water. A secondary underwater explosion in an underwater tunnel that flooded from the primary blast raises the possibility of underwater blast waves striking victims while submerged and may result in GI blast injury. Blast injury to the GI system can result in hemorrhage and shock or perforation. Because it is the major site of intestinal gas accumulation, the colon is the most common site of GI blast injury.³ Physical evidence of GI blast injury includes absent bowel sounds, bright red blood from the rectum, guarding, rebound tenderness, abdominal pain, nausea, vomiting, diarrhea, and tenesmus.⁴ This

nonspecific presentation makes it necessary to maintain a high index of suspicion for GI blast injury.

The risk of extensive bleeding makes fluid and blood transfusions vital to maintenance of cardiovascular stability before definitive surgical care. Due to the limitations of computed tomography scans in the recognition of hollow viscous injury, judicious use of more invasive diagnostic procedures, including diagnostic peritoneal lavage and laparotomy, should be used to maximize treatment success.⁴

Secondary and tertiary blast injuries include a huge variety of typical and atypical traumatic injuries. Due to the large amount of fragmented materials projected from the blast site in tunnels, a large number of soft tissue injuries, penetrating injuries, head injuries, and traumatic amputations are to be expected. Secondary, tertiary, and quaternary injuries resulting from tunnel explosions should be managed according to standard treatment protocols.

CASE PRESENTATION

It's rush hour in the city of Boston and the Ted Williams Tunnel is bumper to bumper across the entire 1.6-mile span of the underwater passageway. In the middle of the tunnel sits a yellow rental truck that is packed to capacity with high-explosive materials, waiting for ignition at the hands of the driver. As the stop-and-go traffic proceeds, he nears the halfway point that was the planned marker for detonation. He takes his foot off the break and advances 15 feet before the traffic stops him again. The truck comes to a halt, he puts his head down as his last thoughts go through his mind, and then he pushes the button. The contents of his vehicle are blown in all directions, creating a shock wave that passes abruptly through the length of the tunnel to both its front and its rear. The cars surrounding the explosion are launched violently in opposite directions toward the nearest exit point from the tunnel. As if chasing the pressure wave, a rush of flames covers the distance at a slower pace with thick, black smoke furling closely behind it.

As those surviving the initial blast come staggering out of their vehicles, they face the first of their many challenges—smoke is everywhere. It is pitch black, and they struggle to find enough oxygen to breathe. Chaos ensues as people attempt to determine the direction toward help. As the first rescue vehicles converge on the exit points, hundreds of people—some appearing well, others obviously injured—struggle for safety and assistance.

UNIQUE CONSIDERATIONS

Tunnel explosions increase the risk of primary blast injury because the explosion occurs within a confined space, which magnifies the intensity of the blast wave. Tunnel explosions also increase the risk of quaternary injury. Thermal injuries and toxic inhalations are common, with increased incidence in direct proportion to proximity to the blast source. The extent and severity of these injuries

depends greatly on the explosives, chemicals, and materials present at the site of the blast, as well as each victim's proximity to the blast and duration of exposure.³

Multiple triage sites must be established because there are often many different ways out of a tunnel, including stairs to the surface, ventilation shafts, connections to separate tunnels for traffic moving in the other direction, and the obvious entrance and exit points.

Body armor increases the severity of primary blast injuries. A high index of suspicion for severe primary blast injury should be maintained when caring for injured tunnel or subway security personnel.⁴

PITFALLS

Several potential pitfalls in response to a tunnel explosion exist. These include the following:

- As with other explosions, the major pitfall after a tunnel explosion is failure to recognize primary blast injury in victims who are asymptomatic or have only mild symptoms. Victims of primary blast injury who sustain minimal secondary and tertiary injuries may be inappropriately triaged based on initial evaluation.
- Due to the often delayed symptoms of blast injuries, it is important to recognize associated physical examination findings which may signify otherwise occult injury. These findings include tympanic membrane rupture, hypopharyngeal petechiae or ecchymosis, retinal artery air emboli, and subcutaneous emphysema.⁴
- Because the explosion occurs in a confined space, the risk of blast lung is greater in tunnel explosions than in open-air explosions. In addition, the risk of gastrointestinal injury is greater in underwater tunnels due to the risk of secondary explosions occurring after the influx of significant volumes of water.

Liquefied Natural Gas Explosion

Michael I. Greenberg

DESCRIPTION OF EVENT

Natural gas is composed primarily of methane, with small quantities of other hydrocarbons, as well as water, carbon dioxide-, nitrogen-, oxygen-, and sulfur-containing compounds.¹⁻⁵ If natural gas is cooled to less than -259°F , most impurities present are removed and the natural gas is transformed into a clear liquid. This colorless and odorless material is known as *liquefied natural gas* (LNG). LNG is a cryogenic material. That is to say, it will remain in the liquid state if kept at adequately low temperatures. This liquid form of natural gas, in itself, is a noncorrosive and relatively harmless substance. It is important to note that LNG is lighter than water and thus will float on the surface if spilled in water.

LNG in itself is not an explosive material and when properly stored will not combust spontaneously. However, if converted to a vapor, LNG can become suddenly explosive, especially if it is released into a closed space. However, it is explosive only if it exists within a specific “flammable range” of 5% to 15% of an air mixture.¹⁻⁵ Similarly, LNG may be combustible if LNG vapor in the same concentration range (5% to 15%) contacts air that is relatively warm in temperature. If a large volume of LNG is spilled into water at a rapid rate, a so-called rapid phase transition may occur, and heat is rapidly transferred from the water to the much colder LNG. This results in very rapid transformation of LNG from its liquid state to a gaseous state. This transformation may result in the release of a large amount of energy and a substantial risk of explosion may develop. Obviously, if such an explosion were to occur, it could pose a serious hazard to buildings and people in areas near the explosion. If such a scenario took place in a port area in relative proximity to populated areas, a major disaster threatening life and property could result.

Under certain circumstances, LNG is considered to be a potentially hazardous material that embodies a few important safety concerns including cold-related skin injury, the creation of oxygen-poor environments, and explosion/incendiary risks.¹⁻⁵ The extremely cold temperatures at which LNG must be stored makes it a direct cryogenic hazard. Although the results of fleeting contact between LNG and human skin may be relatively benign, more extended contact may cause serious local

cold injury to the skin. An LNG vapor cloud may facilitate the formation of an oxygen-poor environment with the potential for asphyxia by virtue of its ability to displace oxygen. This may be a special hazard if LNG is released into a closed or relatively closed space. Finally, LNG vapor clouds may ignite within the portions of the cloud where the flammability characteristics necessary (concentrations of 5% to 15%) are present. However, even under these circumstances, a source of ignition is required for a conflagration to take place.

Of special concern with regard to LNG as a potential hazard is a spill or release of LNG on a large body of water such as a lake or the ocean (as opposed to land). Under these circumstances, effective containment of the spill would be difficult or impossible, and LNG would evaporate rapidly, forming a vapor cloud with the potential for explosion and fire. This situation could result from a terrorist attack against an LNG tanker at or near a port or harbor. If attacked in a manner that resulted in the spill of a large quantity of LNG with a source for ignition (e.g., the detonation of an improvised explosive device, bomb blast, or air attack against a tanker hull), the results could be devastating.

PREINCIDENT ACTIONS

The most important preincident actions with regard to LNG transport are the protection of LNG tankers and LNG storage facilities from terrorist attack.

LNG is typically transported by double-hulled tanker ships. These vessels are specifically designed to accommodate the very low storage temperatures necessary to maintain LNG in its liquid state. In addition, all LNG transport tankers are required to be compliant with rigorous federal and international regulations promulgated by such agencies as the U.S. Coast Guard, the U.S. Department of Transportation, and the International Maritime Organization.⁶⁻⁸

On land, LNG is usually stored at fixed facility receiving terminals. There are currently only four LNG receiving terminals in the continental United States, and only three of these terminals (Boston, Savannah, Ga, and Lake Charles, La) are operational.⁵ The U.S. Coast Guard regulations require that a 2-mile “moving safety

zone” surround any LNG tanker ship entering Boston Harbor. This regulation mandates that Boston’s Logan Airport be shut down whenever an LNG tanker enters or leaves the harbor. Coast Guardsmen board all LNG tankers before their arrival in Boston Harbor and provide continuous monitoring of cargo transfers from these LNG tankers during off-loading operations.⁵⁻⁹ These are examples of extraordinary measures that have been implemented due to concern for the destructive potential that an explosion and fire involving an LNG tanker would cause.

Although the majority of all LNG transport is done by tanker ships, some lesser amounts of LNG are transported over ground in tanker trucks. LNG is also transported from Canada and within the United States via pipeline. The transport of LNG over land engenders some of the same concerns as those described for waterborne transport of this material.

Catastrophic accidents involving LNG receiving terminals have been modeled.⁴ These simulations provided conservative estimates of the projection of downwind effects after the catastrophic loss of a four-tank LNG storage vessel and predicted a downwind spread of intense heat.⁴ These models emphasize the potential damage involved in an LNG catastrophe.

First responders working in areas that may store, receive, or transport LNG should be aware of the potential hazards and should train for hazardous materials incidents that may involve LNG.

POSTINCIDENT ACTIONS

Actions following an explosion and conflagration resulting from an accident or terrorist attack depend, in part, on the location of the incident. If an incident involved an LNG tanker on the high seas, damage and loss of life would probably be limited to the ship itself and its crew. However, if an incident occurred in or near a port or at a fixed storage facility, the degree of property destruction, human injury, and death could be considerable. A fire resulting from the explosion and ignition of LNG could be extremely difficult to control, particularly in cases involving the phenomenon known as *burn back*, in which the entire transported load of LNG combusts. In this situation, the resultant fire may burn uncontrolled until the supply of LNG that was fueling the fire was fully consumed by the burning process.^{8,10,11}

MEDICAL TREATMENT OF CASUALTIES

As in virtually all hazardous materials incidents, removal of victims or potential victims from the scene is of paramount importance. In the event of skin contact with LNG, treatment requires immediate removal of the material from the skin and the initiation of standard therapies for cold injury, including immediate rewarming of cold-injured skin or digits by immersion in warm water. Persons exposed to oxygen-poor environments induced by the creation of an LNG vapor cloud may require cardiopulmonary resuscitation after removal from the envi-

ronment. First responders entering such environments must use adequate respiratory protection with external supplied air. Persons who may be injured or burned in an explosion involving LNG should be evaluated and treated using standard trauma and burn protocols.

CASE PRESENTATION

A double-hulled tanker ship transporting LNG collides with a smaller cruise ship carrying 1500 passengers in a fog-laden port just after dusk. For reasons that are unclear, all navigational aids on the tanker failed and the U.S. Coast Guard was not accompanying the vessel as it made its way into port, as regulations require. The collision takes place less than a mile from the harbor of a large east coast city. A large tear in the hull of the tanker develops and LNG leaks out, vaporizing soon after contact with sea water. Reports indicate that people are in the water and the cruise ship is aflame. Shortly after the initial reports of the collision, a large explosion occurs in the harbor, and early reports indicate that a fireball has enveloped both ships. There are buildings ashore that have been destroyed by the blast. Substantial loss of life and property is predicted based on the earliest reports from the scene of the incident.

A large-scale disaster is declared and federal, state, county, and city medical, hazardous material, law enforcement, military, and public service personnel and resources are mobilized. Prearranged protocols are launched in response to the disaster, including the curtailing of all sea and air transport within 500 miles of the incident. The response to this incident lasts 10 days and the multilevel legal, sociologic, and medical ramifications extend for many years.

UNIQUE CONSIDERATIONS

The excellent safety record for LNG is somewhat unique among potentially hazardous materials. International transport of LNG via tanker ship began in 1959, and since that time there have been no reports of serious explosions at sea or in port.⁵ However, since 1944 approximately 13 important incidents at onshore LNG terminals have been documented. One accident occurring in Algeria in 1977 and another at Cove Point, Maryland, in 1979 each resulted in at least one fatality.⁵ In 2004, a fire at the LNG processing facility in Skikda, Algeria, resulted in the death of approximately 27 workers with injuries sustained by an additional 74 persons.⁹ Although these data illustrate an excellent safety record for the LNG industry, they also emphasize that LNG is a potentially hazardous material that can cause a major disaster.

PITFALLS

Confusing LNG with liquefied petroleum gas (LPG) or compressed natural gas (CNG) is a common mistake.⁵ LPG is a mixture of propane and butane in a liquid state at room temperatures and moderate pressures. LPG is

highly flammable and requires storage away from sources of ignition and in a well-ventilated area, so that any leak may disperse safely away from populated areas. An additive, mercaptan, is usually mixed in to give LPG a distinctive and unpleasant smell, making leaks readily detectable. The concentration of the added mercaptans is such that an LPG leak can be detected when the concentration is below the lower limit of flammability.

LNG also differs from the material known as CNG.⁵ CNG is a form of pressurized natural gas and is usually the same composition as pipeline-quality natural gas. CNG is often misrepresented as the only form of natural gas that can be used as vehicle fuel. However, LPG and LNG may also be used as transport fuels.

Liquefied Natural Gas Tanker Truck Explosion

Jonathan M. Rubin

DESCRIPTION OF EVENT

The explosion of a liquid natural gas tanker is a boiling liquid expanding vapor explosion (BLEVE). A BLEVE occurs when a pressurized liquid evaporates rapidly, leading to explosion of the tank containing the liquid. Either mechanical damage to the tank shell or intense heat from a fire outside the tank causes the liquid to evaporate. In the case of fire, the extreme heat weakens the walls of the tank, the tank is unable to withstand the rising pressure within, and the tank fails.¹ In either case, the resulting explosion leads to a blast wave, fireball, and flying tank fragments. BLEVEs typically occur within 8 to 30 minutes of the start of a fire, with an average of 15 minutes.² This time can be significantly shorter inside a tunnel.³ Damage to the tank (as with impact in a traffic crash) usually results in immediate BLEVE. Relief valves that are located on the top of the tanker truck are designed to vent vapor to reduce pressure in the vapor space of the tank but may not function properly if the tanker is on its side, as in a traffic crash. In this situation, the valves will vent liquefied natural gas (LNG) and will not reduce the pressure inside the tank.

PREINCIDENT ACTIONS

Safety standards and codes related to LNG and propane have been established by the American National Standards Institute, the National Fire Protection Association (NFPA), and the American Society of Mechanical Engineers. These standards address safety issues related to tank design and manufacturing, relief valves, transportation, and fire and hazardous materials response. In addition, federal agencies such as the U.S. Department of Labor and the U.S. Department of Transportation have established rules and regulations pertaining to the transportation of LNG and other flammable gases. Educational programs sponsored by the National Propane Gas Association and the NFPA have also raised the awareness of emergency responders about appropriate decisions in managing LNG incidents. These efforts are all intended to enhance the safe transport of LNG and to ensure the enactment of the appropriate emergency response to an incident involving an LNG

tanker. In fact, since 1993 only three significant BLEVE incidents have occurred in the United States and Canada⁴ (Table 153-1).

At the incident scene, truck placards and color schemes can be used to identify tanker contents. The type of flammable gas as well as the size of the tank are important considerations for the Incident Commander. The size of a BLEVE depends on the weight of the container pieces and how much liquid vaporizes when the container fails.² The condition of the tank must also be evaluated; structural damage and the presence of fire are essential considerations. Besides the type of fuel present, an additional consideration during scene assessment is the incident location. A BLEVE inside a tunnel or other closed space results in more devastating effects than one occurring in an open area. If fire is present at the incident scene, the decision to evacuate the scene may be more prudent than committing firefighting personnel to extinguish the fire. This decision must be based on the length of time the fire has been burning and knowledge of the usual time course for BLEVE occurrence. The potential for a BLEVE should be considered any time there is direct flame impingement on an LNG tank, when venting through relief valves is not adequate to relieve the rising pressure.²

POSTINCIDENT ACTIONS

Once a BLEVE occurs, the resulting explosion typically burns up the fuel source, causing a large fireball. At this point the fire usually burns itself out as the fuel source is consumed, but extinguishing the fire may be necessary. The containment and clean-up of leaked, unburned fuel may also be required, although LNG typically evaporates quickly. Casualties with burns and/or explosion injuries will necessitate field triage and treatment as well as transport to the hospital.

MEDICAL TREATMENT OF CASUALTIES

Injuries occurring in conjunction with a BLEVE fall into two categories: burns and thermal injuries, and trauma

TABLE 153-1 SIGNIFICANT NORTH AMERICAN BLEVE INCIDENTS, 1993–2004

DATE	LOCATION	DESCRIPTION	CASUALTIES
June 27, 1993	Ste. Elizabeth de Warwick Quebec, Canada	1055-gallon propane storage tank	4 fatalities, 7 injured
October 2, 1997	Burnside, Ill	1000-gallon propane storage tank	2 fatalities, 2 injured
April 9, 1998	Albert City, Ia	18,000-gallon propane storage tank	2 fatalities, 7 injured

from fragments thrown from the explosion. Standard medical care for these injuries is appropriate. The potential for exposure to a leaking fuel source before the BLEVE also exists. In this case, patients will require decontamination and evaluation for potential toxic effects.

CASE PRESENTATION

At 5:00 PM, a fully loaded tanker truck carrying LNG jackknives on an interstate highway and is struck by two vehicles traveling at a high rate of speed in the adjoining lanes. One of the vehicles crashes into the midsection of the tanker and bursts into flames. The fire subsequently engulfs the tanker and 12 minutes later it explodes, creating a large fireball and sending multiple large fragments up to 200 feet from the crash site. The driver of the tanker truck is able to escape unharmed, but multiple casualties result from the fire and projectiles.

UNIQUE CONSIDERATIONS

Projectiles from a BLEVE are a major hazard. A Queens University study showed that projectiles are dispersed more than 300 feet away from an exploding tank.² Failure to take this into consideration can greatly increase the number of casualties and fatalities at the incident scene.

PITFALLS

Past practice was based on the belief that debris fragments only come from the ends of the tank. BLEVE research and experience have shown that this is not accurate: any part of the tank can break and become a projectile. The U.S. Department of Transportation now recommends that emergency responders stay away from tanks engulfed in fire.⁵

Petroleum Distillation/Processing Facility Explosion

David C. Lee and Henry C. Chang

DESCRIPTION OF EVENT

The petroleum industry concentrates on the process of obtaining and refining crude oil into usable compounds (i.e., gasoline or petrol, other fuel oil, plastics, polymers). Crude oil or crude petroleum is a liquid or semisolid mixture of mainly hydrocarbons that often contain sulfur, nitrogen, and oxygen, as well as metals such as iron, vanadium, nickel, and chromium. As crude oil is refined into fuels and gasoline, other useful products that are not fuels can also be manufactured (e.g., lubricants and asphalt for road paving). There are more than 4000 different petrochemical products, but those that are considered as basic products include ethylene, propylene, butadiene, benzene, ammonia, and methanol. The main groups of petrochemical end products are plastics, synthetic fibers, synthetic rubbers, detergents, and chemical fertilizers.

The chemical constitution of crude oil varies widely, and they can also vary in consistency from a light volatile fluid to a semisolid substance. Crude oil can be classified into three broad chemical groups: aliphatic/paraffin compounds with saturated hydrocarbon chemical structures, naphthalene-type compounds with saturated cyclic chemical structure, and aromatic compounds. Crude oil may also be categorized as asphalt base, paraffin base, or mixed base. Crude oil may be a sweet crude or a sour crude. Sweet crude oils have less than 5 ppm of hydrogen sulfide, and sour crude oils have significantly more hydrogen sulfide; drilling site wellhead concentrations of hydrogen sulfide may range from 50,000 to 180,000 ppm.^{1,2}

Refining crude oil can be grouped by several stages, each with certain characteristics, and disasters have occurred in all stages:

1. Obtaining and extracting crude oil, often by heavy machinery drilling and pumping, usually in an isolated area.
2. Transporting crude oil, often involving large volumes.
3. Refining, usually requiring heat and multiple other potentially toxic chemicals.
4. Transporting end products of refinement, usually through populated centers.

In the extraction phase, subterranean crude oil must be obtained by means of wells. Typically, an exploratory well, known as the wildcat, is dug. Once oil is located, full-scale drilling commences. Oil drilling is a complex and risky process involving exposure to high temperatures and pressurized systems. Usually, the petroleum from a new well will come to the surface under its own pressure. Later, the crude oil must be pumped out or forced to the surface by injecting water, gas, or air into the deposits. Many of these wells are located in isolated areas of extreme environmental conditions that challenge the most modern transportation systems. Additionally, exposures to toxic gases released from the initial contact with oil field deposits frequently occur.^{3,4}

In the second stage of transportation, crude oil must be transported from extraction site to refineries. The main methods of transporting crude oil and natural gas from the oil fields to refineries are usually by ocean tanker or by pipelines.

Thirdly, the processes involved in petroleum refining consist of three basic steps: distillation, conversion, and treatment. Fractional distillation involves using the difference in boiling point to separate the hydrocarbons in crude oil, and the process typically occurs in a vacuum distillation column. A large amount of heat is expended during this stage. As the distillate exits the column, it often requires further processing to make other fractions and to convert crude into basic petrol and other useful chemicals.

Conversion involves three main processes: cracking, unification, and alteration. Cracking is the most widely used conversion method and is the process for breaking down larger molecules into smaller ones. Unification is the process of combining smaller molecules to make larger ones. Finally, alteration is the process of rearranging various molecules to make the desired hydrocarbon product. These processes typically involve the use of significant amounts of heat, as well as additional hydrogen source and a catalytic unit.

Finally, the distillate undergoes finishing treatments to make it into products that meet specific requirements. Such processes can include solvent extraction, dewaxing, and hydrogenation. Distilled and chemically processed fractions are further treated to remove impu-

rities, such as organic compounds containing sulfur, nitrogen, oxygen, water, dissolved metals, and inorganic salts. Treating is usually done by passing the fractions through the following methods:

1. A column of sulfuric acid removes unsaturated hydrocarbons (those with carbon-carbon double bonds), nitrogen compounds, oxygen compounds, and residual solids (e.g., tars, asphalt).
2. An absorption column filled with drying agents removes water.
3. Sulfur treatment and hydrogen-sulfide scrubbers remove sulfur and sulfur compounds.

Finally, the refined products are transported to the consumer. Because of this, many refineries are located near large-population centers. Large customers, like airports, are supplied directly from the refinery by pipelines. A disaster at a refinery may involve a nearby high-volume consumer like a petrochemical plant or a power station. Smaller consumers, like gasoline stations, are supplied by a road tanker originating from terminals, which act as storage depots and distribution centers. The terminals are supplied by rail or pipeline if they are inland or by coastal tanker if they are on the coast or a river estuary.

POTENTIAL HAZARDS

The main process of the petroleum industry is to obtain and convert a relatively flammable product to a highly flammable one. Thus, the majority of deaths reported in the petroleum industry disasters are caused by explosive blast injuries and burns (see Table 154-1 and Chapters 141 and 155).

EXPOSURES

The petroleum industry makes use of various chemicals in the process of refining crude oil. These include chlorine, chromium-containing corrosion inhibitors, and biologic additives. Byproducts of the refining process can also cause significant toxicity. These include carcinogenic polyaromatic hydrocarbons such as benzene. Hydrogen sulfide is another byproduct that can cause significant injury and is produced in the drilling and refining processes. Hydrogen sulfide gas has been reported to be a significant problem of oil fields in Alberta, Canada, due to its high concentration of sulfur.⁵

PREINCIDENT ACTIONS

The first order of action is to confirm the site of the disaster. Although the majority of disasters reported are from explosions and burns, various parts of the petrochemical refining process are susceptible to specific scenarios. Disasters occurring in the process of obtaining crude oil often occur when an oil well ignites. Oil wells are often distant from major population centers. On the

other hand, refineries are often close to major population centers. In the former scenario, healthcare workers may have to deal with getting to a remote location such as an offshore oil rig.⁴ In the latter situation, healthcare workers must address the demands of the local community.

The materials involved in an explosion must also be identified. Many refineries use and store toxic compounds. Hydrofluoric acid is a compound found ubiquitously in the refining process. It is a lethal substance and is toxic on contact to the lungs, skin, and eye. It is often in liquid form but turns into gas quickly. In significant releases of hydrofluoric acid, prehospital care providers will require personal protective devices (see Chapter 36). Treatment of injuries caused by hydrofluoric acid exposure often requires unique antidotes, such as calcium-containing dermal, inhalational, and intravenous treatments.^{6,7}

Another order of business is to identify blast-resistant portable buildings. These buildings are structures developed to provide temporary safe haven to personnel from the potential hazards associated with the petroleum industry. They are designed to resist the explosive forces that cause sliding and overturning of buildings during a blast. They are also designed to be easily sealed and airtight to provide a shelter during a toxic gas release. They are often the size and shape of shipping containers and are positioned to be easily accessed by personnel. During disasters, healthcare personnel should identify and seek out these structures to locate potential victims and also to provide shelter if secondary incidents occur.⁸

POSTINCIDENT ACTIONS

After the explosion of a petroleum distillation or processing facility, possible contaminants must be identified. A disaster at an eastern European oil storage depot was reported to cause significant environmental contamination of heavy metals (e.g., lead, arsenic, cadmium, nickel, chromium, and copper), polyaromatic hydrocarbons, and polychlorinated biphenyls.⁹⁻¹¹

Identify and address psychological issues of victims, healthcare workers, and the community. Many of the reported disasters in the oil industry have involved a significant number of patients with burns, and there are multiple documented reports of significant effects on the mental health of healthcare workers.^{7,12-20}

MEDICAL TREATMENT OF CASUALTIES

Disasters at petroleum facilities typically involve exposure to blast injuries and high-temperature burns (see Chapters 141 and 155). Additionally, exposures to toxic chemical fumes via inhalation or dermal contact are also common.

TOXIC CHEMICAL EXPOSURES

Chemical exposures in a petroleum refinery are common. Hydrofluoric acid is a relatively common toxic

TABLE 154-1 MAJOR DISASTERS IN THE PETROLEUM INDUSTRY SINCE 1970 AS REPORTED BY THE UNITED NATIONS ENVIRONMENT PROGRAMME

CAUSE OF ACCIDENT	YEAR	LOCATION	PRODUCTS INVOLVED	NUMBER OF FATALITIES	NUMBER OF INJURED	NUMBER OF EVACUATED

chemical that requires specific treatments and antidotes. Patients should be immediately removed from the area and be evaluated for signs of respiratory decompensation as a result of pulmonary edema, pneumonitis, pul-

monary hemorrhage, or systemic toxicity. Administering 2.5% or 3% calcium gluconate inhalational solution by nebulizer as a therapy has been suggested for respiratory exposures. Treatment of hydrofluoric acid dermal

injury consists of immediate irrigation with copious amounts of water for at least 15 to 30 minutes, removal of all blisters because they may harbor fluoride ions, and calcium gluconate (2.5%) gel applied to the debrided skin surface. Systemic toxicity from hydrofluoric acid exposure can cause dysrhythmias and hypocalcemia, thus warranting cardiac and electrolyte monitoring. A 10% calcium gluconate solution should be administered intravenously or intra-arterially in patients exhibiting significant hydrofluoric acid systemic toxicity.

Ammonia is another compound that is found throughout the refining process. Ammonia is widely used as a cleaning agent and as a coolant. The release of ammonia causes injury to the patient in two ways: (1) because of its low freezing point (-33°C), frostbite injury occurs to any skin in direct contact; and (2) ammonia vapors readily dissolve in the moisture of the skin, eyes, and mucosa, causing chemical burns through liquefaction necrosis. Exposures require prompt irrigation of the eyes and skin with water and management of inhalation injury.

CASE PRESENTATION

A mist develops after a pipe rupture at an oil refinery. Multiple workers at the plant begin complaining of cough, sore throat, and difficulty breathing. Disaster plan management is implemented, and emergency medical services are called into action. Plant supervisors notify personnel that the pipe delivers hydrofluoric acid. Prehospital healthcare workers are notified to use personal protective equipment. Patients are treated with nebulized calcium gluconate solutions, and the evacuation of potential personnel and the surrounding community is initiated.

The pipe is later repaired, and the hydrofluoric acid spill is contained and dissipates.

UNIQUE CONSIDERATIONS

A common scenario in a petroleum industry disaster is the explosion of oil and gasoline drums. Bak and colleagues²¹ reported a series of incidents where these containers were inappropriately handled. The typical scenario was that in which a worker attempted to divide or cut through a presumably empty 55-gallon drum with a grinder or a blowtorch. These drums often contain residual quantities of flammable material in liquid or vapor form. Once the container is penetrated, the metal drum explodes. Nearby workers suffer from significant trauma from projectiles, the blast force, and burns.

PITFALLS

Many different and potentially toxic chemicals are used throughout a petrochemical refinery. When a refining column is damaged as in an explosion, lighter components are released. These hydrocarbons composed of

fewer carbon and hydrogen atoms vaporize, leaving behind a heavier, less volatile fraction. Gasoline contains relatively high proportions of toxic and volatile hydrocarbons, such as benzene (which is known to cause cancer in humans) and hexane (which can affect the nervous system). Gasoline and kerosene releases are exceptionally hazardous due to their high flammability. Crude oils and semirefined products such as diesel and bunkering oils may contain cancer-causing polycyclic aromatic hydrocarbons and other toxic substances. These differing chemicals have various thresholds for combustion, and multiple explosions can occur at differing times. This poses a serious threat to healthcare workers who arrive on the scene after the initial incidents.

chapter 155

Introduction to Fires and Burns

Marianne E. Cinat and Victoria M. Vanderkam

Burn injuries are commonly seen in disasters. In addition to being associated with structure fires, they may also occur in conjunction with explosions; wild land fires; plane, train, or automobile crashes; or other serious events. Injuries may be the result of flame, flash, chemicals, or electricity. More recently, there has been increased concern about nuclear, biologic, and chemical warfare disaster management, all of which can result in significant burn injury to a large number of victims. Burn injury can involve only the skin or may have an inhalational component resulting from heat exposure to the face and upper airway or from smoke inhalation causing damage to the distal airways and bronchial tree. Burn injury with inhalation may result in rapid loss of airway and shock. Immediate triage and resuscitation are essential to survival and optimal outcomes. Many authors have described burn injuries associated with major disaster. Recent events and lessons learned will be reviewed.

CURRENT PRACTICE

Preincident Action: Disaster Planning

Firefighters, rescue workers, and emergency medical personnel should have a good working knowledge of the treatment of burns. Disaster preparedness in a specific geographic area should include a plan to triage burn victims to burn centers in the area that are equipped for and experienced in handling critically injured patients. Burn care should be prioritized as a curriculum item for instruction to emergency medical services (EMS) workers including emergency medical technicians, paramedics, and firefighters. All EMS responders should be aware of the nearest burn center as well as nearest receiving centers. Collaboration among burn centers should be proactive. Working relationships among centers with specific plans and transfer agreements will be effective in ensuring the triage and early care of burn victims. Burn centers must be prepared to receive multiple burn patients that may have other associated injuries.

Prehospital Management of the Incident

The American Burn Association (ABA) endorses the Advanced Burn Life Support course curriculum. A section

of this course is devoted to the management of multi-casualty burn incidents as well as scene safety with fire hazards.¹ Excerpts of this course are provided in Boxes 155-1, 155-2, and 155-3. Organizational components for incident management by all responding units are listed in Box 155-1.

The triage area should have adequate lighting and be located in an area where the triage officer can visualize the entire scene. It should be located away from hazards, at a site between the scene of the incident and transport vehicles. Four treatment categories are recommended and are summarized in Box 155-2.

Stabilization in the field is managed by EMS using protocols and communication with base hospitals. Airway control is the top priority. The airway should be established and maintained with endotracheal intubation based on local protocols. In general, burn patients without other injuries typically do not go into shock within 60 minutes from the time of injury, even if no treatment is provided.¹ Therefore, a burn victim who develops shock soon after an incident should be evaluated immediately for underlying injury, occult hemorrhage, respiratory failure, or other causes of shock (e.g., cardiac, neurologic).

Masellis and others² provide guidelines for the general public regarding immediate first aid in the care of burn victims. They are as follows:

1. Maintain self-control—don't panic.
2. Protect yourself.
3. Reduce the activity of the fire.
4. Extract and transfer victims to open air if possible.
5. Extinguish burning clothing.
6. Remove burning clothing.
7. Provide emergency treatment of burns.
 - a. Thermal burns: Leave blisters intact. Cool the burn for up to 10 minutes. Avoid hypothermia. Cover body with dry, clean sheet. Avoid ointments or other medications.
 - b. Chemical burns: Flush the exposed area with water thoroughly. Collect detailed information about the chemical agent, and be prepared to provide this information to the emergency medical personnel.
 - c. Electrical burns: Remove the source of electricity and protect the airway.

BOX 155-1 BURN DISASTER MANAGEMENT

- A. The medical command post should:
 1. Be established in a safe area.
 2. Serve as the communication center for dispatch and medical control.
- B. Security and hazard control:
 1. Should minimize risks of injury to rescuers and onlookers.
 2. Is coordinated at the medical command post.
 3. Are the responsibility of all members of the rescue team.
 4. Should ensure crowd and hazard control.
- C. A communication center at the medical command post should:
 1. Communicate patient information to incident managers, including the number of victims and their condition.
 2. Ensure casualty distribution to appropriate facilities.
 3. Communicate to the receiving facility the number of casualties and treatment provided.

Reproduced from *Advanced Burn Life Support-Pre-Hospital Course Manual*. Chicago:American Burn Association; 2001:19-20, with permission.

BOX 155-2 TRIAGE TREATMENT CATEGORIES

1. Immediate care (red)
 - a. Burns >20% TBSA in patients aged 10 to 50 years
 - b. Burns >10% TBSA in patients aged <10 or >50 years
 - c. Inhalation injury
 - d. Chemical injury
 - e. Electrical injury
 - f. Associated, life-threatening injuries
2. Delayed care (yellow)
 - a. Burns <20% TBSA in patients aged 10 to 50 years
 - b. Full-thickness burns of <5% TBSA
 - c. Sunburn or first-degree burn
3. Minor category (green)
 - a. Minor injuries; no emergency care required
4. Deceased (black)
 - a. Survival unlikely

Reproduced from *Advanced Burn Life Support-Pre-Hospital Course Manual*. Chicago:American Burn Association; 2001:20-1, with permission.

Masellis and colleagues² also recommend guidelines for trained personnel regarding the initial management of burn victims. They are as follows:

1. Immediate triage of seriously ill victims
2. Inspection of the upper airway
3. Qualitative assessment of the burns
4. Quantitative assessment of the burns
5. Intravenous resuscitative therapy
6. Analgesic therapy
7. Hospital transfer

To appropriately triage burn victims in a mass-casualty incident, emergency medical personnel must be able to accurately assess the severity and extent of the burns along with the signs of inhalation injury. Outcomes

BOX 155-3 PRINCIPLES OF SCENE SAFETY WITH FIRE HAZARDS

1. In the presence of a major fire, the emergency vehicles should be located a safe distance from the scene. The safe area may vary depending on the type of incident and scene assessment.
2. Before entering a burning structure, rescue personnel should have proper knowledge of and training in the following:
 - a. the utilization of approved protective clothing
 - b. the use of self-contained breathing apparatus
3. The rescuer must be knowledgeable and skilled in rescue techniques from a burning structure.

Reproduced from *Advanced Burn Life Support-Pre-Hospital Course Manual*. Chicago:American Burn Association; 2001:17, with permission.

after burn injury are negatively affected when care is delayed. Rapid triage and treatment are essential to survival. Specific parameters that should be measured in the field and reported to the hospital include the following:

- Severity of burns
- Extent of burns (total body surface area [TBSA])
- Status of inhalation injury
- Etiology of injury
- Symptoms of shock

Assessing the Severity of Burns

Burn wounds have classically been described as being first, second, third, or fourth degree. Recently, however, this classification has changed to reflect the anatomic thickness of the skin layer involved. Specifically, wounds are now classified as superficial, partial-thickness, or full-thickness burns.

First-degree burns, or *superficial burns*, involve only the epidermis. They are not included when calculating the TBSA burned for use in fluid resuscitation. This category of burn is usually caused by a brief exposure to heat or ultraviolet radiation from the sun (i.e., sunburn). First-degree burns are painful and appear as reddened skin without blistering.

Second-degree burns, or *partial-thickness burns*, involve the entire epidermis and part of the dermis. Superficial partial-thickness burns appear bright red with blister formation and a moist surface. They are extremely painful to touch, especially once blisters are broken, and they blanch with pressure, demonstrating brisk capillary refill.

Third-degree burns, or *full-thickness burns*, involve all layers of the skin (i.e., epidermis, dermis, and dermal appendages). They may appear charred, mottled, pale, waxy, yellow, brown, or nonblanching red. They are firm, dry, and leathery.

Fourth-degree burns, or *subdermal burns*, extend through the skin into the subcutaneous tissues and may involve underlying, bone, muscle, and associated structures. Tissue appears charred, firm, dry, and leathery; mummification may also be apparent. These wounds are insensate.

Assessing Extent of Burn

The extent of burn wounds is reported as the percentage of TBSA burned. When calculating TBSA burn for fluid resuscitation, only second-, third-, and fourth-degree burns are used in the calculation.

The “rule of nines” is the classic way of calculating the TBSA³ (Figure 155-1). The body surface is divided into areas that equal 9%. When all the body areas are summed they equal 99%, with the remaining 1% attributed to the genitalia and perineum. This is an efficient method of calculating the extent of a burn, but is less accurate in children under the age of 10 years, especially infants, due to the difference in body proportions.

For small or irregular burns, the TBSA can be calculated by using the patient’s palm (including the fingers) to represent approximately 1% of his or her TBSA.⁴

Identifying Inhalation Injury

The likelihood of inhalation injury is increased in patients with facial burns, soot in the oropharynx, or singed nasal hairs. Inhalation injuries can be divided into supraglottic and infraglottic categories. Supraglottic inhalation injury is the most common. It can result from thermal or chemical sources and causes injury to the upper air passages and supraglottic structures. Rapid airway edema and occlusion can occur.¹ Signs and symptoms of supraglottic inhalation injury include hoarseness, a change in phonation, stridor, and difficulty breathing. In unresuscitated patients, supraglottic edema may be delayed until fluid resuscitation is well under way. Because of this risk of delayed airway obstruction, early intubation is recom-

mended to prevent airway occlusion and the need for a surgical airway.

Infraglottic inhalation injury almost always occurs due to chemical injury of the airways and lung parenchyma. Direct damage to the epithelium of the airways occurs because of inhaled noxious chemicals (e.g., aldehydes, sulfur oxides, and phosgenes). The factors that increase the extent of injury are prolonged exposure to such chemical gases (seen in patients found unconscious at the scene) and smaller size of gas particles. These factors cause the smaller airways and terminal bronchi to be affected. This toxin inhalation can lead to respiratory failure with prolonged intubation and ventilatory support. Inhalation injury leading to pulmonary failure should be anticipated in a victim with a history of smoke exposure in an enclosed space and with subsequent loss of consciousness.

Etiology of Injury

Information regarding the cause of the fire and subsequent burn are helpful to the treating physician. Information should be obtained at the scene and then communicated to the receiving hospital personnel. Information that is pertinent to treatment includes whether the incident occurred indoors or outdoors. Indoor incidents are very likely to result in inhalation injury. Treatment of the burn wound may vary depending on the cause or agent involved (e.g., flame, electrical, chemical).

Symptoms of Shock

Decreased level of consciousness, decreased blood pressure, increased heart rate, and decreased peripheral perfusion are all classic indicators of shock. In patient with burns, adequate blood pressure may be maintained for some time due to release of catecholamine after the burn occurs. These substances constrict blood vessel and act to maintain the blood pressure.

Emergency Department Assessment and Treatment

Initial assessment of a burn victim follows the same priorities as for any injured patient. Airway management is the top priority in a major burn with inhalation injury and is the first priority in the emergency department (ED) triage area. Respiratory support and fluid resuscitation must take place concurrently. Although intravenous access through unburned skin is preferred, access through burned skin is acceptable if necessary. Central lines or femoral access may be required. Circulatory compromise must be identified early. Any jewelry or circumferential devices should be immediately removed because profound swelling during burn resuscitation can result in these devices functioning as tourniquets, leading to circulatory compromise. Escharotomies may be required for circumferential full-thickness burns to the chest or extremities but should be performed at a burn center under the supervision of a burn surgeon. Neurologic deficits and mental status should be accu-

FIGURE 155-1. The rule of nines.

rately assessed and recorded. The patient should be fully exposed to allow appropriate assessment of burn depth and extent. However, the patient should then be immediately covered with a warm dry sheet to prevent hypothermia. During assessment and resuscitation, it is important to avoid hypothermia and maintain the patient's body temperature. This can be accomplished by liberal use of warm blankets, increasing the temperature of the room, warming intravenous fluids, and warming the ventilator circuit for intubated patients.

Fluid resuscitation should be initiated using the burn consensus formula of 2 to 4 cc/kg/%TBSA burned.¹ Once calculated, half of this volume is given in the first 8 hours after the burn injury; the second half is given in the next 16 hours. This formula should only be used as a guide for initial volume resuscitation rates. Rates can be adjusted hourly to maintain a urine output of 0.5 cc/kg/hour in adults and 1.0 cc/kg/hour in children.

Analgesia and sedation are needed, and the patient should be monitored on an ongoing basis. Once the initial priorities are managed and the patient's condition is stabilized, he or she is moved to an intensive care unit for ongoing care.

UNIQUE CONSIDERATIONS

Arturson⁵ analyzes a series of 14 fire disasters that occurred between 1973 and 1990. Details of these disasters are summarized in Table 155-1. This study demonstrates that indoor fires result in fewer survivors than outdoor fires, with six times more injuries reported from the latter. In the study, actual hospital admissions were 20 times higher after outdoor incidents. Indoor fires are more likely to result in the rapid death of those who cannot escape, due to hypoxia and inhalation of toxic chemicals. Relatively few admissions were seen

after indoor fire disasters in the Arturson study. Survivors of indoor disasters were typically a result of less severe burns (i.e., <30%) or inhalation injury. Outdoor incidents resulted in larger numbers of hospital admission with more severe injuries. Patients with large TBSA burns (>70%) are more likely to be encountered in outdoor disasters. Triage should involve getting the most severely burned persons to specialized burns beds. Minor burns can be triaged to medical personnel in nonburn facilities if necessary. The outcomes noted in this review are attributed to inhalation of smoke and poisonous compounds.

PITFALLS

Leslie and colleagues⁶ provide an informative report of management of a multiburn casualty at an ED in Massachusetts without a burn unit that provided insight into potential problems. In this disaster, 11 burn victims were brought to Baystate Medical Center after a foundry explosion.

Their retrospective review of this event resulted in a number of recommendations for both field triage and for hospitals. In respect to triage, it is recommended that the first ambulance to arrive at the scene become the dedicated triage unit. A method of triage should be preplanned by the EMS and hospital systems in each particular geographic area. A proactive plan maximizes assessment and allows for rapid relay of information to the receiving hospital. This in turn allows hospital personnel to make early decisions regarding staffing and allocation of resources. The importance of providing as much information as possible regarding the causative agents was stressed. In this example, the causative agent was phenolic resin. There was a delayed recognition of the possibility of toxic exposure to the

resin. While the possibility was remote, the real potential for contamination of the entire treatment area remained.

Lessons learned in the ED included the need for a clearly demarcated command center with a large whiteboard to be used for patient documentation. Information including patient identification, injuries, and transfer status should be made readily accessible in this format. A team captain who will make all important decisions should be designated. Further, the need for large amounts of warm intravenous fluids, humidified gases for inhalation, warming blankets, and radiant heat sources are absolutely necessary; this was not appreciated early on. Hospital personnel reported difficulty in controlling ambient temperatures in the ED where rooms could not be enclosed, and this made core body temperatures difficult to maintain.

Dunbar⁷ reports on the Rhode Island nightclub fire that resulted in 200 injuries and 100 deaths. The author, an emergency room nurse, was present at the receiving ED in a hospital with a burn center. Activation of the Hospital Emergency Incident Command System allowed an orchestrated response that enabled the staff to meet their goals of providing life-sustaining procedures and comfort measures. They received 67 victims, admitted 43 patients, and intubated 22 of them in a matter of hours. Areas they identified for improvement were family support and control of traffic congestion around the ED. They are currently working on a system to better support families during a disaster. Traffic congestion will be minimized in future disasters by implementation of an alternate route for employees returning to the hospital.

Several authors have reviewed the September 11, 2001, World Trade Center disaster in New York City as it pertains to burns and disaster planning.⁸⁻¹⁰ These reports cite the importance of having a hospital incident command center and proactive disaster plan in place. Other factors that had a positive impact on outcomes were early mobilization and organization of the workforce and consistent methods of patient care among all practitioners.⁹ Several important issues were identified. Medical teams were dispatched to the scene within hours of the attack. This placed these persons at risk for illness and injury. Secondly, the hospital was not equipped to handle nuclear, biologic, or chemical weapon casualties. Finally, many volunteers responded to the hospital to assist, but there was no system in place to verify the credentials of these people. These issues have resulted in the reassessment of disaster planning. It is interesting to note that Kirschenbaum and others⁸ found that the mix of injuries corroborated the findings of Arturson described earlier. A large number of victims were seen, but there were a small percentage of victims who had severe injuries.

The increased incidence of large disasters with multiple casualties has initiated the discussion of how best to manage these types of events and the resulting patient populations. Mackie¹¹ has suggested that medical personnel should not be dispatched to the disaster scene. Doing so puts healthcare workers at risk of personal

injury. Similar opinions were documented by reviewers of the 2001 World Trade Center disaster.⁸ While this is a debated issue, it seems that there is growing consensus that burn assessment teams should be hospital based versus scene based. He further recommends that national associations should work to develop and refine disaster plans that are appropriate to their regions.

To this end, the ABA has made major strides following the New York City World Trade Center attack in developing a national response to fire/burn disasters. The ABA has identified burn centers and burn beds across the country. Via e-mail, this system can be activated as necessary to respond to major burn disasters. It is estimated that 350 to 500 beds could be filled during a disaster. This system would require movement of patients to verified regional burn centers from the burn center nearest the disaster rather than the movement of trained personnel. Consensus of the ABA board after an evaluation of the Sept. 11, 2001, disaster response is that local burn nursing corps will yield greater efficiency when remaining stationary, rather than transferring personnel to overloaded burn centers.¹²

SUMMARY

In summary, the effective management of a fire disaster involving multiple burn victims requires quick action on the part of the EMS. Expert triage with clear communication to the base is essential to the rapid movement of patients that is so critical to the positive outcome for the burn patient. Hospital EDs that are prepared for disaster with efficient means of communication and prioritization will optimize the outcome of the victims of a multi-casualty disaster.

Structure Fire

Deborah Gutman

DESCRIPTION OF EVENT

Each year, 2 million fires are reported to U.S. fire departments. Based on 2000 data from the National Fire Incident Reporting System, fires in structures account for approximately 30% of all fires, but they cause nearly 76% of property loss, approximately 72% of fatalities (3500 annually), and nearly 82% of injuries (19,600 annually) resulting from fires. Structure fires occur in homes, assembly buildings, office buildings, schools, stores, businesses, manufacturing facilities and plants, and many other structures. Almost all *fatal* structure fires occur in residential structures.

In residential structures, kitchens are the most common fire location, with bedrooms being the second. Among nonresidential structures, the majority of fires occur in storage facilities (30.9%), followed by businesses (19.8%), assembly structures (14.1%), and manufacturing (9.9%), with the leading cause being arson.¹ Although there is no seasonal pattern for fires in general, more structure fires take place in the winter, with the lowest percentage taking place in the summer. The highest percentage of structure fires occur between 5:00 and 6:00 PM.

The fire and subsequent collapse of the World Trade Center in New York City on September 11, 2001, has raised consciousness regarding high-rise fires and fire-fighting tactics. High-rise fires are inherently more difficult for the fire service. By nature of the buildings' height, smoke movement in high-rise structures is very different than those in other structures. Temperature gradients result in varying pressures throughout the structures and allow for uncontrolled movement of smoke and flame (known as the *stack effect*).² The air-conditioning and heating vents and other utilities in some high-rise structures service multiple levels and can facilitate the spread of smoke and flame through a building, injuring occupants who are floors away from the fire itself. Elevators stall or shut down (elevators failed at 59 of 179 major high-rise fires), fire radios don't function above certain floors because the structural steel interferes with radio communication, fire ladders are too short, and civilians may jump to their death.³ In an emergency, the movement of people out of the building is particularly difficult.

A high-rise structure fire is usually defined as a fire in a structure that is five stories or taller, although this defi-

inition may vary by jurisdiction. Unlike the World Trade Center fire, the majority of high-rise fires occur in apartment buildings; 6% occur in hospitals, 4% in hotels, 3% in dormitories, and 3% in offices. Three-quarters of high-rise fires take place in residential structures. However, residential high-rise death rates are half as common as those of residential structures in general. More people are available in a high-rise building than in a single-family home to alert residents of a fire and to assist with an evacuation. Also, most building codes require hardwired smoke alarms in high-rise buildings. A smoke alarm activates in 69% of residential high-rise fires compared with 38% of all residential structure fires. Similar to other residential fires, the leading cause of all high-rise fires is cooking (38%), but cause patterns vary by property type.

PREINCIDENT CONSIDERATION

The United States has made significant progress in reducing the number of fire deaths through the widespread use of smoke detectors, fire sprinkler systems, stricter fire codes, and changes in lifestyle, including decreased smoking.⁴ However, three-quarters of fire deaths and nearly 60% of fire injuries occur in structure fires where no alarm is present, or where an alarm was present but failed to operate.⁵ Preventive measures are usually lacking in all investigated fires and training of personnel is rare, in particular, with regards to communications. Fire safety plans should be in place and inspections kept up to date. Firefighters must be familiar with the construction of local buildings and have access to the layout of local buildings. People should also learn the emergency evacuation procedures of the office buildings they work in and the stores and businesses they frequent.

Experience with burn disasters has suggested that one of the most important features early in a burn disaster is effective communication between prehospital personnel, local hospitals, and specialized burn centers allowing for expert triage of the severely burned patient. Appropriate patient triage involves both promptness of care as well as level of care and appropriate hospital destination. Triage becomes essential to the use of limited resources such as air evacuation, burn beds, ventilators, and operating rooms. Expert triage may even reduce the

need for burn beds. In one review of 14 severe fire disasters, they found that victims from structure fires had less severe burns and more significant risk from inhalation injuries.^{6,7}

There is often a very small time window for establishment of effective communication between the scene and all area hospitals to accomplish this triage. In the Coconut Grove fire in Boston in 1942, the first casualties arrived 15 minutes after the fire started. It is estimated that one casualty arrived at Boston City Hospital every 11 seconds for a total of more than 300 patients in 2 hours.⁸ The time elapsed between notification and arrival of patients after a burn disaster is brief for most hospitals, and some reviews have suggested that numbers of victims are often underestimated. Many large structural fires or high-rise fires occur in major cities, and there is a major response from city rescue agencies with most victims evacuated from the site within 30 minutes. Apart from ambulances, many patients will be transported by private cars, taxis, and even buses and will simultaneously arrive to the emergency department, overloading its capacity. In fire disasters, the massive arrival of burn patients in a specialized burn unit will quickly paralyze its capacity to accept and care for patients.

A central command center at the site would assist with the assessment of available burn beds and resources (e.g., ventilators) at each of the area hospitals and match the distribution of patient types and severity to each hospital, thereby shifting the major burden for triage away from nearby hospitals. The disaster system needs to establish, in advance, procedures for prioritizing and coordinating both ground and air medical evacuation of patients to specialized burn centers to prevent the need for many interhospital transfers and competition for limited air flight services to burn centers.

This emphasizes the need for the development of improved information systems/networks as part of disaster planning. For example, in New York State after the September 11, 2001, World Trade Center attack, the State Department of Health implemented an enhanced statewide system known as the Hospital Emergency Response Data system that allows hospitals to communicate over a Web-based secure system during a crisis.⁹ The U.S. Army has developed an automated e-mail system that queries participating burn centers each morning regarding bed and resource capacity. These types of systems would facilitate appropriate triage and use of specialized burn centers.

POSTINCIDENT CONSIDERATIONS

Fire causes panic in its victims, and their actions then may serve to worsen the damages. Some people trapped in a burning high-rise building who cannot be reached will leap to their deaths. It can be anticipated that persons who are not trapped will try to go to the aid of trapped victims, putting themselves in harm's way. In the 1911 fire at the Triangle Shirtwaist Company in New York, some trapped victims chose to leap to their deaths from windows on the eighth and ninth floors. One hundred forty-six people leapt to their deaths, were burned, or crushed

to death in the panic. The potential for secondary traumatic injuries in survivors who leap to safety or reenter burning buildings should be taken into account.

MEDICAL TREATMENT OF CASUALTIES

The first 72 hours of burn care constitutes the resuscitation phase. The actions composing appropriate medical treatment follow:

1. Remove the victim from the source of the burn, taking care not to become a victim yourself. Rescuers must assess the situation and must be able to protect themselves from flames, fumes, toxic gases, falling masonry, and other hazards to their personal safety. All rescuers at the scene of a fire should use protective clothing and devices. Ventilation and cooling systems must be turned off, and any fixed extinguishing equipment should be turned on. To extinguish a victim's clothing, throw the person to the ground and wrap him or her in a blanket. Cut away belts, sleeves, and tight clothing with care; remove rings, bracelets, and other constricting items. Do not violently tear off clothing that may adhere to burned skin.
2. Check the patient's vital signs, check for other associated trauma, and stop any bleeding.
3. Evaluate the patient's airway. Involvement of the upper airways should be suspected in the presence of face and neck burns. Look for carbonaceous sputum and singed nasal hairs. The more serious the thermal damage, the more rapidly the patient needs airway management. Treat with oxygen and orotracheal intubation as necessary. Have a high suspicion for inhalational injuries. In structure fires, many new synthetic polymers are used for furniture, upholstery, carpets, bedding, and curtains, and these yield combustion products such as carbon monoxide, cyanide, phosgene, hydrogen chloride, and nitrogen oxides. These noxious gases may be additive. Autopsies after the Stardust nightclub fire in Dublin, which killed 48 people, showed that 80% of victims had a carbon monoxide level higher than 50%. In the 1990 Nagasakiya supermarket fire in Osaka, Japan, the dead bodies were covered with soot but not badly burned. Of 14 blood specimens, 8 showed carbon monoxide levels over 50%, and in 10 cases the cyanide level was higher than 3.0 $\mu\text{g}/\text{mL}$, which is believed to be a lethal concentration. Hyperlacticacidemia is an excellent indicator of cyanide intoxication, and an initial plasma lactate greater than 10 mmol/L is a sure indication of toxicity. The use of amyl nitrite pearls in unconscious patients with inhalation injury should be seriously considered in the prehospital setting. In the hospital, serum should be sent for measurement of carbon monoxide, lactate, and cyanide levels.
4. Make a qualitative and quantitative assessment of victim's burns. Use the rule of nines for adults (9% for each upper limb and for the head, 18% for each lower limb and for the front and back of the thorax) or the rule of palms (size of patient's palm is equal to 1% of the body surface area [BSA]). In children, the head is 20% of BSA.

5. Start intravenous resuscitation therapy if the burned surface exceeds 15% to 20% BSA in an adult or 15% in a child. Use physiologic fluids such as normal saline or Ringer's lactate solution. If intravenous therapy is impossible, the victim should sip water containing a little salt. If there are no veins visible, a venous cutdown may be necessary. The fluid requirements for the first 4 hours can be calculated as 0.5 cc/kg for each percent of BSA.
6. Use analgesia therapy liberally. For severe pain, intravenous morphine can be titrated to effect.
7. Perform bladder catheterization to monitor urine output.
8. Institute burn treatment. Cover burned tissue with clean sterilized wet sheets. Cooling reduces burn depth, edema, and pain. If more than 2 hours have elapsed since the accident, it may be necessary to perform emergency escharotomy for deep circumferential burns that involve the neck, thorax, or limbs and hands. Do not burst blisters or remove the epidermis. Do not cool for longer than 20 minutes, and stop if patient begins to shiver. Use care with cooling children and the elderly. Use clean plastic bags to wrap burned hands and feet, and do not apply any constrictive dressings.
9. Reexamine the patient. Detection of additional injuries may have to be delayed until this point.
10. Make decisions regarding hospital transfer. Basic resuscitative measures should be taken before secondary air transport. If smoke inhalation is suspected, a preflight chest radiograph and an arterial blood gas should be done. If a pneumothorax is diagnosed or suspected, a chest tube must be placed prior to flight, nasogastric and urinary catheters must be placed and the balloon filled with fluid, not air. Plastic bottles must be used for fluids and blood, and parenteral infusions must be provided through a large-bore catheter.

CASE PRESENTATION

It is 2 AM on a winter morning. You are the attending physician on duty in a level I trauma center, and you receive a call from a local EMS personnel notifying you of 100 potential burn victims from an ongoing fire at a local nightclub.

What else do you need to know? What do you do to prepare?

UNIQUE CONSIDERATIONS

There are certain populations and fire situations that deserve additional discussion. In the case of structure fire fatalities, 25% of deaths occur in persons older than 64 years, and 16% of deaths occur in children under the age of 10 years. Children may not respond appropriately to fire; they may hide or not tell adults about the situation. Even in the presence of working smoke detectors, children may not react properly and usually need adult

rescuers to help them get out of a burning building. From ages 3 to 5 years, children are more likely to play with matches, lighters, or candles and start fires if left unsupervised. Nationally, among children younger than the age of 6 years who die in residential fires, one-third are due to children playing with matches or fire. Efforts to teach match and lighter safety to children and parental education regarding child supervision would be worthwhile in preventing child fire deaths.¹⁰

Older Americans also represent a high-risk group. Over the age of 65 years, fire death rate exceeds that of the national average.¹¹ Smoking is the leading cause of fire deaths among older adults, and cooking is the leading cause of injuries. Cooking injuries occur due to accidental igniting of loose-fitting clothes or forgetting to turn off a burner or leaving food on the stove. Disabilities including vision, hearing loss, and impaired mobility impair their ability to escape a fire.

Among all structure fires, nightclub fires in the United States are proportionately few in number (0.3%). However, over-capacity crowds at nightclubs create the potential for high numbers of casualties in the event of a fire; therefore, when these types of fires occur, they attract national media attention. Local jurisdictions that do not routinely inspect nightclubs or do not enforce existing safety regulations, coupled with the exemption of small clubs from installing sprinkler systems, increase the potential for a fatal nightclub fire. Oftentimes, the exits are locked or blocked. The detection of the fire is slowed, and alarms are often delayed. Nightclubs pose a challenge for fire prevention and public safety.

PITFALLS

Several potential pitfalls in response to a structure fire exist. These include the following:

- Not instituting strict fire prevention codes and inspections and not implementing public safety campaigns can result in unnecessary injury. Fire disasters are preventable and avoidable, and most of them are man-made.
- If no on-scene triage officer is designated, a “scoop and run” practice will put significant burden on receiving hospitals for secondary triage of burn patients to specialized burn units and will create competition for limited aeromedical resources.
- Inadequate advance planning for use of limited resources such as aeromedical transport and specialized burn facilities is another potential pitfall.
- Not suspecting and treating for toxic inhalants and associated trauma in an unconscious fire victim can lead to avoidable exacerbation of injury from fire disaster.

Wilderness/Forest Fire

John Moloney

DESCRIPTION OF EVENT

Fire is a natural phenomenon that has been a part of our ecosystem for millions of years.¹ Fire in an area not inhabited may have environmental and ecologic consequences, but the fire per se does not have health and medical consequences. These only arise when there is an interaction between the fire and the infrastructure of human civilization.

Prior to the ability of the human race to light fires, most forest fires were due to lightning strikes. Lightning strikes the earth an average of 100 times per second, or over 3 billion times per year.² Fires caused by lightning are, on average, less severe than human-caused fires. Lightning tends to strike at the tops or ridges, where there is often higher humidity, lower temperatures, and less fuel.

Naturally occurring fires cannot occur in all environments. Some parts of the globe are too wet or too sparsely vegetated.⁴ Due to the importance of fire in agriculture, humans have historically chosen to live in fire-prone areas. Burning kills the local flora and soil microfauna, leaving a cleared space in which to plant crops. Farmers would allow a field to lie fallow for a season, after which they burn it to regenerate the area.⁴ A recent study has identified a substance in smoke that stimulates the germination of many plant species.⁵

As greater proportions of the population began to live in towns and cities, fire began to be seen as an enemy. Fire could easily spread from forest to town, and then from house to house. There have been a number of large fires involving the interface between forest and urbanization that have had large costs in terms of lives lost and economic costs. Federal agencies of the U.S. government spent \$3 billion suppressing 170,000 fires over the 2-year period from 2002 to 2003.⁶

More and more people are choosing to live in forested areas that are susceptible to fire. The qualities that people value in this environment (e.g., dense forests providing a sense of seclusion and screening from the neighbors) are the same qualities putting them at risk.⁷

Ninety percent of fires in the United States are caused by humans and their activities.³ Accidental causes include the use of faulty machinery (e.g., chain saws), which release sparks. Other causes include discarded cigarettes, burning of leaves and other garden debris, and chil-

dren playing with matches. Loss of control of an intentionally lit fire can be another contributor. This may include campfires or fires used for fuel reduction of fire-break formation. A certain percentage of fires are deliberately lit for various reasons. The South Wales Fire and Rescue Service estimated that 98% of the 5239 grass and forest fires it attended in 2001–2002 were deliberately lit.³ In May 2000, the U.S. Park Service deliberately lit a fire to clear brush at the Bandelier National Monument. After getting out of control, the fire burned for 2 weeks, destroying 200 homes and 47,000 acres of forest.⁸

PREINCIDENT ACTIONS

Management of forest resources can reduce the likelihood and impact of fire. Controlled burning can be used to reduce fuel levels or to create buffer strips or firebreaks. These controlled burns should be carried out in low-hazard periods, such as the cooler months of the year.

Local communities in areas at risk for forest fires need to take preventive action to minimize the risk of fire involving their properties. Long-term issues include setting up firebreaks around housing and other buildings and prohibiting vegetation from growing up to the edge of structures. Potential fuel for fires (e.g., fuel for farm machinery, piles of dry firewood) should not be stored next to housing. Buildings should be kept in a good state of repair, with the guttering clear of leaves and other flammable debris. Local governments can designate areas to be used as fire refuges (e.g., sporting grounds), to which residents can evacuate if needed. In the time prior to the fire season, fuel loads can be assessed and reduced if appropriate.

Visibility on the roads can be impaired by smoke, roads may be blocked by fire or falling trees, and there may be high numbers of emergency vehicles on the road. The lack of effective traffic management during the Berkeley Hills Tunnel Fire in California in 1991 is said to have directly contributed to loss of life.⁹ In contrast, 26,000 people were evacuated in 2 hours from the Laguna Beach area in 1993. This evacuation included planning for separate fire service access and civilian egress.

Communities and individuals in areas of high fire risk should develop a personal fire plan. These plans should

include a considered opinion about whether, in high-risk conditions, to stay in the area to defend the house or to leave the area early. The decision to evacuate when the fire is very close can be a deadly decision. The plan should include notification of relatives of where you will be and a plan for children and pets. The plan could also include neighbors who, due to age or illness, are less able to care for themselves. At times of high risk, such as hot dry summer days with winds from dangerous areas predicted, fire action plans should be invoked. An example of a fire plan can be accessed at: <http://www.cfa.vic.gov.au/residents/living/index.htm>.

If fire does invade an area, actions can be taken to further minimize risk to life and property. Appropriate clothing will reduce the risk from radiant heat. As a fire approaches, people should move to the inner parts of the house away from windows and the radiant heat. Garden hoses, which may be used to put out small fires after the main fire front has passed, may be damaged by the main fire front, so these should be protected.

Michael Rhode⁹ undertook a review of incident command of fires at the interface between wild land and the urban environment. He noted that command decisions and actions could and should be preplanned, both for firefighter safety and efficiency. He reviewed the response to six fires in California between 1990 and 1996. The initial command post locations were inadequate. Command posts burned in three of the six fires. In all fires, public volunteerism proved unmanageable. Communications centers and fire radio systems were overwhelmed. Before an incident, local emergency managers can develop and communicate strategies and tactics for managing the incident. Planning of evacuation routes and fire refuges should be communicated to the local population as well as emergency managers.

POSTINCIDENT ACTIONS

In many emergency situations, the postincident actions aim to gain control of the incident, and then to safely and effectively respond to it. With wilderness fires, effective control of the fire may not be possible for days or weeks. During this time, effective and efficient incident management must occur.

As is often seen in emergency situations, maintenance of command can be difficult. This is especially so if the incident is spread geographically and there are impaired communications. In the 1993 fires around Malibu, 20 separate entrapments of firefighters occurred. These resulted from actions independent of command.⁹

Forest fires may cause displacement of people from their homes or even from their areas of residence, often with minimal time to prepare for the evacuation. Other areas may become isolated due to road closures. This may affect the ability to provide routine medical care and pharmaceuticals, regardless of any increase in requirements related to the fire. Local plans should include methods for provision of this routine care to isolated communities or people.

Persons managing healthcare facilities and prehospital medical services may not be able to access extra staff because these staff may either be protecting their homes¹⁰ or unable to safely travel to their place of work. Because most wilderness fires will continue for hours, days, or weeks, provision of adequate staffing levels, with adequate rest breaks, will stretch the personnel resources of many institutions.

Management of the media in the postincident phase is crucial. Media, particularly the radio and television, can provide up-to-date information to communities over a large area. In the case of radio, this can also include members of the community who are not at home, as they are moving, or after they have reached a refuge.

MEDICAL TREATMENT OF CASUALTIES

Common medical complaints in patients who have been involved in forest fires include smoke inhalation, bronchospasm, heat-related injuries, and burns. After the fires around Canberra, Australia, in 2003, there were 233 presentations to the emergency department of The Canberra Hospital (Table 157-1).

Poor air quality was a major contributing factor for the increase in patients presenting for healthcare after the San Diego fires in 2003.¹⁰

Important in the initial management of burns is the decision about where patients should be managed. Patients with burns can be managed in an ambulatory setting, a general hospital, or a specialized burns unit. Factors affecting this decision include the size and thickness of the burn, location of burns (e.g., face, perineum), comorbidities, and extremes of age.

TABLE 157-1 PRESENTING COMPLAINTS OF EMERGENCY DEPARTMENT PATIENTS FOLLOWING THE CANBERRA, AUSTRALIA FIRE OF 2003

CONDITION	PRESENTATIONS	ADMISSIONS
Breathing problems/ smoke inhalation	65	10
Eye problems (irritation, ulcer, foreign bodies)	43	0
Trauma (falls and motor vehicle)	45	6
Burns	24	10
Medication issues*	21	0
Accommodation and chronic disease†	5	5
Other	30	5
Total	233	36

* Supply of usual medications required by people unable to return home. These included insulin, antipsychotics, antihypertensives, and home oxygen.

† Persons with chronic disease requiring emergency accommodation.

CASE PRESENTATION

It is Christmas Day, 2001, and 5000 firefighters are fighting more than 70 fires in the area around Sydney, Australia. Winds at speeds of 90 kph make control difficult. Major highways are closed, stranding motorists, many of whom are holidaymakers commencing their summer vacation. Three thousand people are evacuated from the Royal National Park. Conditions deteriorate over the next few days, with fierce winds and temperatures of 39°C (102°F).

More than 1.2 million acres of bushland burned over the next week. This is approximately 50% larger than Rhode Island. Half of the fires were suspected to be the result of arson. Many of the arsonists were aged 9 to 16 years.^{11,12}

The NSW Health Counter Disaster Unit managed the health response. One thousand five hundred clients were evacuated from 9 aged-care facilities. More than 10,000 persons evacuated from their homes received assistance. Ten disaster medical teams were deployed, and some of these went into communities isolated by road closures. There were two reported deaths.¹³

- Failure to consider unavailability of staff to respond due to personal involvement in an incident or restricted ability to travel
- Failure to prepare adequate systems to deliver commonly used pharmaceuticals to members of the population displaced from their homes or communities
- Failure to consider that health facilities may be directly threatened by the fire or smoke
- Failure to appreciate that wilderness fires are an ongoing incident that may last for days to weeks and that may change rapidly
- Failure to appreciate the extent of a burn injury; this may result in inadequate fluid resuscitation, or triage to an appropriate facility

UNIQUE CONSIDERATIONS

Wilderness fires are unique among disasters. It is possible to predict, in most cases, when the conditions are suitable for a fire to develop. Preventive actions, such as fuel reduction, can reduce the impact of a fire on the population.

Wilderness fires are ongoing events, with the potential to continue to spread to adjacent areas or to commence somewhere else. Most other disasters that cause “trauma,” with the exception of war-like activities, have a beginning and an end to “new” injuries. They also have a well-localized geography.

Another unique consideration of wilderness fires is their ability to destroy or threaten healthcare facilities at a time when these facilities are needed to manage casualties.

PITFALLS

Several potential pitfalls in response to a wilderness fire exist. These include the following:

- Failure to prepare adequate systems to respond to large numbers of low-acuity patients (e.g., those with smoke inhalation or ocular foreign bodies)

Tunnel Fire

Daniel L. Lemkin and Wade Gaasch*

DESCRIPTION OF EVENT

People have been constructing tunnels for thousands of years. Tunnels have been created under rivers, through mountains, and beneath cities. Engineering marvels, they displace huge amounts of earth and still support enormous weight above them.

Society has become dependent on tunnels as a vital component of our transportation system, allowing movement of vehicular traffic, subways, and rail cars. The volume of traffic in major U.S. metropolitan areas is enormous. For example, more than 42 million people traveled through Baltimore's Fort McHenry tunnel in 2003.¹ Subway systems weave a complex network of tunnels beneath most large metropolitan areas. Although less visible to the public, rail systems are still very active and use many tunnels in both urban and rural settings. Freight train tunnels lack hazardous materials restrictions, and in many cases, adequate ventilation or fire-suppression systems.² Train fires have much greater destructive potential, which is made worse by absent safety systems.³ Persistently high levels of traffic combined with flammable and hazardous materials cargo make tunnel fires almost inevitable. The increasing threat of terrorism makes an intentional tunnel fire or explosion even more likely and potentially more disastrous than an accidental event.

One of the greatest challenges in coping with tunnel fires is early recognition that every tunnel's construction and features are substantially different. Technology and materials have changed appreciably over the years, so crews that respond to tunnel emergencies face a wide range of possible scenarios. Most older tunnels were excavated using drills, dynamite, and substantial manual labor. Many were constructed using horseshoe geometry and lined with brick and mortar. Modern tunnels are generally round and lined with steel and concrete. They are carved from the earth using enormous hydraulic tunnel-boring machines, which create clean cylindrical tubes in which reinforced liners have been placed. These variances in construction materials and geometry

call for different types of systems for evacuation, ventilation, and fire suppression.

After ensuring responder safety, the first priority during a tunnel fire is to evacuate all of the people trapped inside. In large roadway tunnels and subway systems, this could mean the evacuation of hundreds or thousands of people.⁴ Rail tunnels used for passenger trains may rival or supersede subway passenger levels. If used strictly for freight, trains commonly travel with only a two- or three-person crew. Because construction varies greatly, so do escape routes and protocols.

Many older tunnels consist of single-tube construction, whereas most modern roadway tunnels are built in connected pairs. Lengthy single-tube tunnels constructed for passenger traffic often have escape route stairways that provide access to the surface. Paired tunnels usually contain cross-tunnel adits,⁵ that is, air-tight passageways connecting the two tubes. The adits are usually recognized as doorways lining one side of a tunnel spaced at regular intervals. Sometimes labeled, sometimes not, these doorways provide essential refuge to motorists from rapidly expanding smoke and heat. If these doorways are left closed, the paired tunnel serves as a parallel escape route with a separate air supply and shielding from heat. If left open, the adits will permit contamination of the unaffected tunnel.

Subway tunnels may be single or paired and vary with regard to cross-tunnel ventilation. They also contain an additional hazard for escaping passengers—the electrified third rail. These rails generally operate on direct current at around 750 volts. During an emergency, electrified rails should be shut off. There are many separate segments of electrified rail, however, and the possibility of failing to remove power from an occupied portion of track is certainly plausible. This presents a significant danger to both passengers and rescuers. Rescuers should be provided with “hotsticks” (voltage detectors) and trained in their use to ensure track is de-energized before working in close proximity. The track should be rechecked repeatedly and always treated as if energized to minimize the chance of electrocution. If staffing permits, dedicated personnel should be assigned to continuously monitor tracks for electricity. This provides a greater level of safety for crews and evacuating passengers.

*Technical consultants for this chapter were William Shives, Battalion Commander, Baltimore City Fire Department, and Scott C. Gorton, Assistant Director, Field Services, Hazardous Materials Systems, CSX.

Once fires ignite, large plumes of smoke and superheated gas rapidly fill a tunnel's confined spaces.⁶ Within minutes, victims could be overcome with smoke at temperatures over 1000°F. To provide a safe environment for escaping motorists and passengers, tunnel engineers have designed and instituted various types of ventilation systems. The most simple is a longitudinal system. Air is injected into a tunnel at one end, where it travels within the same compartment as passenger traffic, exiting the other end. Depending on the system, air flow is driven by supply fans or pulled by exhaust fans. In most systems, a combination of both types operates in a push-pull fashion. When a fire is identified, manual or automated systems activate the fans to direct plumes of smoke and heat away from the majority of people. If these systems can generate adequate air velocities in the tunnel, they provide a temporary safe environment on the supply side of the fire. However, the exhaust side becomes significantly more dangerous because of a "burner effect"⁵ generated by winds blowing past fires with superheated exhaust fumes. People trapped on the exhaust side of a fire in a longitudinal ventilated tunnel will succumb rapidly from intense heat and smoke exposure. In systems of this type, the fans can generally be reversed to direct exhaust in either direction.

However, this feature may not be effective. Tunnels have a natural air flow perpetuated by the flow of traffic. As vehicles travel through a tunnel, air is pushed along with them. This creates a "piston-effect" that can take several minutes to diminish, even after traffic stops. Depending on the capacity and location of supply and exhaust fans, the natural air flow may be too strong to overcome. Attempts to do so would result in an increase in turbulent flow within the tunnel and dispersion of superheated gases and smoke. Testing of such systems is imperative to prevent disastrous results during a real fire. Longitudinal ventilation systems are used in many older tunnels, as well as subway, rail, and smaller vehicular tunnels.

Another method, the transverse-ventilation system, is used in many large metropolitan vehicular tunnels. In these systems, the circular tunnel tube is divided into three horizontal sections. The portion used by commuters occupies the center section. Two large semicircular sections remain hidden from sight but serve several important purposes. Contained in these sections are communications antennae, a water-drainage system, and a supply and exhaust ventilation system. Large buildings stationed near both entrances house enormous fans that funnel air through the tunnels via large cement conduits. The Holland tunnel is ventilated with 84 such fans. The Fort McHenry tunnel's 4 tubes are ventilated with 24 much larger fans. The supply of air is generally delivered at curb level through vents placed along either side of the traffic lanes. Exhaust fumes are suctioned through vents in the steel-plate ceiling and blown out of stacks located in the ventilation buildings. These systems generally have much greater air flow capacity and have been shown to function quite effectively in real fire situations. Unlike longitudinal flow systems, transverse-flow ventilation has not been shown to exacerbate fires or create dangerous conditions for escaping motorists. Modern systems are incorporating adjustable dampers that focus

exhaust air flow over or surrounding a fire to further speed evacuation of smoke and superheated gases.

Once ventilation is addressed and evacuation is ensured, fire suppression activities take precedence. The decision of whether to enter a tunnel to attack a fire is neither a simple one nor one that should be made hastily. There is no way to know with certainty what hazards exist at the source of a tunnel fire. Hazardous materials restrictions exist for most vehicular tunnels, but the same restrictions do not apply to most rail tunnels. Although laws are in place, it is quite possible that trucks may knowingly or unknowingly transport hazardous materials through restricted tunnels. The threat of terrorism brings with it unpredictability and the potential for intentional secondary explosive devices. While tunnels are designed to withstand fires of great intensity, most are not designed to withstand large explosions. Great care should be exercised when entering a tunnel with the intent of suppression. If available, material safety data sheets carried by all carriers should be inspected. All freight train conductors carry a "consist," which contains a detailed accounting of all rail car locations on the train, their contents, hazard potential, and specific instructions on suppression.

Not all flammable materials respond well to water. Powdered sodium, for example, when exposed to water, will combust spontaneously in a massive exothermic reaction. The rail industry has many hazardous materials specialists on staff. Their expertise and that of local and regional experts should be requested for evaluating hazards before blindly attacking a fire. At a minimum, all responders should have access to and familiarity with the Department of Transportation's *Emergency Response Guidebook*, which lists most industrial hazards, their placard identification numbers, and suppression information.

Although tunnels are confined spaces, they affect a much broader area. As the fire burns, smoke accompanied by possibly toxic gases will be released out of the tunnel ends or ventilation buildings. This should be monitored continuously for possible community hazards. If the potential for toxic releases is recognized, early consideration and planning for resident evacuation should be undertaken. There are many other less emergent but significant consequences of tunnel fires. Closure of major vehicular or subway routes can cause major traffic delays. These delays could be prolonged if significant damage has occurred and requires repair. Prolonged rail disruption could significantly affect a region's industrial and commercial viability. In addition, tunnels are often lined with communications and Internet data cables. Fires often destroy these lines and can cause significant disruption of telecommunications traffic on a regional or national scale.⁷

PREINCIDENT ACTIONS

Prior to an incident, all emergency operations plans should be amended to address specific hazards associated with fires and explosions. They should specifically address evacuation, ventilation, and fire suppression for all tunnels located in a given jurisdiction. Because each

tunnel's construction is different, it is imperative that emergency operations personnel become familiar with each tunnel's infrastructure. Site visits and training operations should be coordinated with tunnel officials. These training sessions serve many purposes, including hazard analysis, validating operating procedures, identifying and correcting flaws, testing communications equipment, and improving relationships between agencies. Ventilation systems and water-delivery systems should be tested on a regular basis. Because of the hazardous materials potential, a network of specialists who can respond to any significant event should be formed. Personnel and agencies that should be included are the Department of the Environment, the Environmental Protection Agency, railroads, industrial hygienists, toxicologists, structural tunnel engineers, and the Department of Public Works. This list is not all inclusive and will likely vary by jurisdiction and local risk potential.

POSTINCIDENT ACTIONS

The primary goal after recognition of a tunnel fire is evacuation of trapped passengers or motorists. Rapid coordination with tunnel control center officials can help locate the fire and direct appropriate application of ventilation to provide a safe environment for evacuating people. Rapid identification of possible hazardous materials should be sought before the initiation of conventional fire-suppression activities. Most tunnel fires involve single vehicles and do not represent a significant threat to other motorists or the tunnel; larger trucks and fires involving flammable liquids can present a much greater hazard. A rapid but informed and methodical approach is warranted when dealing with unknown hazards in a confined space such as a tunnel. If the fire represents anything other than a simple event, the pre-arranged emergency hazardous materials network should be activated and involved in decision-making.

MEDICAL TREATMENT OF CASUALTIES

Most injuries occurring as a result of a tunnel fire will be related to smoke inhalation. If people are able to escape the fire by crossing over to an adjacent tube, they may avoid potentially fatal exposure to smoke and superheated gases. Any people trapped on the exhaust side of a substantial fire once longitudinal ventilation has been initiated will likely not survive. Rescuers should concentrate on rapid evacuation of motorists and passengers to a safe location outside the tunnel. Rescue operations should focus on checking abandoned vehicles and subway cars for people unable to ambulate to safety. Depending on the size of the tunnel and the number of casualties, a mass-casualty incident may be declared. Emergency medical services personnel should follow standard Incident Command System protocols for triage and transportation of the injured. Burn centers and centers with hyperbaric capabilities may be warranted in some circumstances.

CASE PRESENTATION

A call comes over the radio that smoke is coming from the mouth of a local railroad tunnel⁸. On arrival, the firefighters see copious amounts of black smoke rising from the tunnel. They don self-contained breathing apparatus and walk into the tunnel carrying 2 1/2-inch dry lines. The railroad engineer and conductor run up to the fire officer and recommend they not enter until reviewing the consist. Several hazardous rail cars are identified, including sulfuric acid, ethylene oxide, tripropylene, and anhydrous ammonia. All suppression activities are halted and personnel removed from the tunnel. The hazardous materials team is notified and arrives with gas-sampling devices. The railroad dispatches its hazardous material experts, and a team of industrial hygienists, toxicologists, and engineers is consulted.

Smoke is seen emanating from the other end of the tunnel, which is located in a heavily populated area. A major highway bridge is located within 1/8 mile from the tunnel entrance. Rush hour traffic is starting to build. Initial sampling notes no toxic gas release. The mayor shows up and asks, "What is going on?" What are you going to tell him?

UNIQUE CONSIDERATIONS

Tunnel fires present numerous unique challenges that make emergency response dangerous and, at times, frustrating. Access to the fire is often hampered by several factors. Because of the confined space and dense smoke, visibility will likely be nonexistent. Many tunnels are quite long, and depending on the tunnel, a reliable water supply may not be available close to the fire. Once a fire breaks out, people will abandon their vehicles, obstructing the tunnel and making access by any means other than walking impossible. Firefighters will have great distances to cover by foot, reducing their available air from self-contained breathing apparatuses once they reach the fire.

Other conditions make suppression activities very dangerous. The confined space makes rapid evacuation impossible, and usually there are no areas of refuge should the fire flash over or explode. If flammable liquids are extinguished, their vapors remain volatile and could saturate the tunnel, creating a dangerous explosive condition. In Swiss tunnel fire simulations using an abandoned rail tunnel, a gasoline fire spontaneously exploded 19 minutes after it was initially extinguished by sprinklers.² Another factor complicating suppression activities is the development of dangerous steam clouds within the tunnel. Without effective means of escape, application of water to intensely burning fires can create a hazard to firefighters and evacuating people far greater than the fire itself.

PITFALLS

Several potential pitfalls in response to a tunnel fire exist. These include the following:

- Failure to familiarize operations personnel with specific tunnel features, systems, and hazards
 - Inappropriate application of the ventilation system, which can endanger evacuating people and complicate suppression activities
 - Failure to test the capacity of ventilation and stand-pipe systems prior to a fire
 - Failure to coordinate a network of hazardous materials specialists who can respond and aid in hazard analysis, mitigation, and clean-up
 - Premature suppression activities before potential hazards are identified
 - Delay in the application of appropriate ventilation and fire suppression
 - Delay in the recognition of hazardous condition and public notification or evacuation
 - Failure to verify that abandoned vehicles are empty and do not contain viable nonambulatory patients.

Gunshot Attack: Mass Casualties

Leon D. Sanchez and Jason Imperato

DESCRIPTION OF EVENT

In 2001 there were 20,308 homicides in the United States, 11,348 of which involved firearms.¹ Gunshot injuries include violence-related, accidental, and self-inflicted injuries.² The majority of these injuries are caused by handguns. Although most gunshot attacks involve only one victim, there have been several well-publicized cases in which multiple persons were killed and injured in a single event.

Firearms include two basic types: rifled firearms and shotguns. A rifled firearm (i.e., pistol or rifle) has spiral grooves in its barrel. When the cartridge is fired, the burning of the powder generates gas in a contained space, and the pressure generated by the gas propels the bullet forward. The bullet accelerates while inside the barrel, reaches its maximum speed upon exit (muzzle velocity), and heads toward its target. As the bullet enters tissue, it will begin to tumble and deform. Depending on the makeup of the bullet and the properties of the tissue through which it travels, it may expand, fragment, or remain in one piece.³⁻⁶

Shotguns differ from rifles and pistols in that they have a smooth barrel that discharges hot gases, wad, and either multiple projectiles or a single projectile (rifled slug). Shot charges containing multiple projectiles spread out from the muzzle in a conelike pattern. The distance from the muzzle of the shotgun to the point of impact of the projectiles is a key determinant of the magnitude of injury. At short range (less than 6 m), the shot charge containing multiple projectiles results predominantly in a single-hole wound (diameter of less than or equal to 6 cm) that communicates with a deep underlying wound with massive tissue destruction. At this short range, soft tissue impact deforms the individual pellets, increasing their original cross section with a concomitant increase in tissue crush or hole size. The multiple pellets result in severe disruption between the multiple wound channels. A gradual decrease in the amount of pellet deformation and tissue destruction occurs as the distance of the impact range increases. When the impact range exceeds 7 m, the multiple projectiles result in numerous discrete wounds that are not associated with underlying massive tissue destruction.³

Shotguns also can discharge rifled slugs that are designed for killing larger animals. The muzzle velocity of rifled slugs (487 m/sec) is approximately half that of nonexpanding, fully jacketed rifle projectiles. The rifled slug does not hold the point orientation that it has as it is propelled from the muzzle of the gun, but drifts toward a sideways orientation as it moves toward the target. The rifled slugs experience a 25% decrease in velocity as the impact range increases from 5 to 45 m. At short range (less than or equal to 45 m), the slug deforms on striking the tissue, thereby enhancing the size of the permanent and temporary cavities.

PREINCIDENT ACTIONS

Hospital, emergency department, and outpatient facilities should all have general disaster plans in place in the event of an attack. Mass-casualty events require coordination of local, state, and federal public safety resources. Both emergency medical service (EMS)- and hospital-based triage systems may need to be altered in the event of a large number of patients seeking medical care within a brief period of time. Healthcare providers should practice universal precautions. In the event of multiple casualties, triaging of the victims at the scene and on arrival to the hospital will be necessary. Protocols for the triaging of the victims are part of a properly prepared disaster plan. Disaster plans should be in place and personnel should be familiar with the plans so that when an event does occur, a minimum of confusion will ensue.

POSTINCIDENT ACTIONS

First responders and EMS personnel should confirm the scene is safe before evaluating casualties at the site of the event. If a large number of casualties are identified and a disaster needs to be declared, the proper channels must be notified and triage protocols instituted. Receiving hospitals should be given as much advance notice as possible to ensure that hospital personnel will be ready to handle the influx of patients. The need for psychological

help for victims, bystanders, and personnel responding to the scene should not be forgotten.

CLINICAL PRESENTATION

Tissue is injured by a bullet via two mechanisms: tissue crush and tissue stretch. These two mechanisms correspond to the permanent and temporary cavities created by passage of the projectile.^{4,7} As the bullet travels through tissue, it will crush tissue that is directly in its path. This is the primary method of injury from gunshot wounds. The most important determinant of injury is the tissue the bullet crushes. The tissue that is crushed corresponds to the permanent cavity formed by the bullet. Injury created by the temporary cavity becomes more important with higher-energy bullets (see Chapter 160).

MEDICAL TREATMENT OF CASUALTIES

Initial evaluation of persons with gunshot wounds is similar to that of any multiple-trauma victim, with initial evaluation of the ABCs (i.e., airway, breathing, circulation), followed by the secondary survey and ongoing monitoring, including vital signs, electrocardiographic monitoring, and pulse oximetry. The focus of the examination is the detection of penetrating or perforating injuries. A careful examination of the patient including the back, under the hair, the axillae, and the gluteal fold will help identify injuries. Radiographs of the areas the bullet is thought to have traversed are indicated to identify the position of the projectiles. Laboratory studies should be ordered as clinically indicated.

Evaluation, resuscitation, and ongoing management should proceed as for any other multitrauma victim in both the prehospital setting and the emergency department. The management of gunshot wounds is best conducted in consultation with a trauma surgeon. If adequate resources are unavailable, the decision to transfer the patient should be made early in the course of treatment.

Wounds that may have crossed the mediastinum require a thorough evaluation, even in the stable patient. In this setting, injury to the aorta, heart, pericardium, and esophagus must be ruled out. Patients who present with unstable vital signs or become unstable during evaluation should receive bilateral chest tubes. The presence of pericardial tamponade should also be considered; using bedside ultrasound is a fast way to identify cardiac tamponade. Surgical exploration is often indicated in these patients.⁵

Patients with penetrating gunshot wounds to the abdomen require exploratory laparotomy, even in the presence of stable vital signs. Stable patients with back or flank wounds can be evaluated by computed tomography and observation, but these patients may also benefit from surgical exploration. This decision must be made in conjunction with the trauma surgeon.

Injuries to the extremities require evaluation of the distal neurovascular status. A bullet does not need to transect a vessel to cause injury. The development of compartment syndrome resulting from swelling of the

injured area should be considered. Angiography is indicated if arterial injury is suspected. Fractures from a gunshot wound should be treated as open fractures with early administration of antibiotics. Debridement of devitalized soft tissue is often necessary.⁵

Penetrating gunshot wounds to the head are often not survivable. For patients with this type of injury who arrive at the hospital alive, consultation with a neurosurgeon is indicated. Injuries to the spine can occur even when the bullet does not actually pass through the vertebral canal. Use of steroids is not indicated for penetrating cord injuries. Additionally, the presence of a central nervous system injury should not delay assessment for the presence of thoracoabdominal injuries that can be rapidly fatal.

CASE PRESENTATION

On a sunny afternoon at 11:10 AM on Tuesday, April 20, 1999, Dylan Klebold and Eric Harris arrived in separate vehicles at Columbine High School in Littleton, Colorado. Although the arrival of these students may not have been unusual, the events that followed would shock the nation.

Around 11:14 AM, the boys carried two 20-lb propane bombs in duffel bags and placed them near tables in the school cafeteria, then returned to their cars. When the bombs failed to ignite, the pair began to prepare for the next stage of their attack.

Klebold, wearing cargo pants and a black T-shirt with the word "wrath" written on the front, was armed with a 9-mm semiautomatic handgun and a 12-gauge double-barrel sawed-off shotgun. Harris, wearing dark pants and a white T-shirt that read "natural selection" was armed with a 9-mm carbine rifle and a 12-gauge pump sawed-off shotgun. Both wore black trench coats to conceal their weapons and their utility belts filled with ammunition. They also carried a backpack and duffel bag full of homemade bombs.

At 11:19 AM, Klebold and Harris entered the school and started firing at students outside the school cafeteria. The students continued to fire at their peers in the cafeteria, the hallways, and later in the school library. Local, state, and federal authorities including police, healthcare workers, and SWAT teams were dispatched to the scene. From 12:02 to 12:05 PM, the two students fired toward the police and paramedics who had arrived at the scene and waited outside the school as students frantically fled the dangers from inside the school. Finally, the Columbine massacre ended at 12:08 PM when Klebold and Harris pointed their guns to their heads and shot themselves.

In the most devastating school shooting in U.S. history, a total of 12 students, 1 teacher, and the 2 killers were dead, and 21 others were injured.

UNIQUE CONSIDERATIONS

Gunshot wounds must be reported to the appropriate authorities. In most cases, shootings become the subject of a criminal investigation by law enforcement authorities. Therefore, the medical record and patient property should be preserved as evidence. If patient clothing is cut, care should be used to avoid cutting through por-

tions a bullet might have gone through. Any material that needs to be saved for law enforcement authorities should be placed in paper bags because plastic bags will trap moisture, and this can degrade evidence. The location of all wounds identified should be recorded in the medical record, including comments on the presence of any powder residue observed surrounding the wound. It is often difficult to differentiate entrance from exit wounds. Although it is often thought that the smaller wound must be the entrance wound, this is not always true. If a bullet is recovered, avoid making any markings on the sides of the bullet because this will interfere with forensic evaluation of rifling patterns.³ Any marking of recovered bullets that may be necessary for the preservation of chain of custody should be at the nose or base.

PITFALLS

Several potential pitfalls in response to a gunshot attack exist. These include the following:

- Allowing EMS personnel to enter the scene before it is secured
 - Failure to have a disaster plan in place prior to the event
- Failure to involve a trauma surgeon early in the management of the patient
 - Failure to consider transfer of the patient to another facility
 - Delays in the evaluation of stable patients with thoracoabdominal injuries

Sniper Attack

Jennifer E. DeLaPena and Leon D. Sanchez

DESCRIPTION OF EVENT

A sniper is a concealed, usually skilled shooter who fires at exposed persons. These attacks typically occur using powerful high-energy, military-style assault rifles. These rifles have the capability of being fired semiautomatically or automatically. Semiautomatic weapons fire as quickly as one can pull the trigger, whereas automatic weapons continue to fire until the trigger is released. Assault rifles are becoming more available to the public.¹

Rifles are the most powerful of the three main types of firearms: rifles, shotguns, and handguns.¹ When a cartridge is fired, the burning of the powder generates gas in a contained space, which generates the pressure that propels the bullet forward. The bullet accelerates while inside the barrel and reaches its maximum speed upon exit (known as *muzzle velocity*). Military-style rifles have long barrels and are therefore able to accelerate to higher muzzle velocities.¹⁻⁵

The majority of bullets in use today are at least partially jacketed. The jacket is a layer of harder metal that surrounds what is typically a lead core. This allows bullets to reach greater muzzle velocities; without the jacket the lead bullet would be stripped at higher velocities, quickly fouling up the firearm's barrel.⁵ Military-style bullets are fully jacketed, whereas bullets for sale to civilians usually have the lead core exposed at the tip (soft point), which can be modified into different varieties of hollow-point bullets. The exposure of lead at the tip will cause the softer lead to deform much more than a fully jacketed bullet on entry into tissue. Hollow-point bullets are designed so as to expand as they penetrate tissue. The injury patterns of fully jacketed and hollow-point bullets will be different, although the claims that soft or hollow-point bullets cause more tissue destruction are not consistently borne out.

PREINCIDENT ACTIONS

In light of the recent sniper attacks in the Washington, D.C. area, confusion and panic may ensue if a sniper attack were to occur. Emergency departments should have disaster plans and protocols in place to handle such events. Personnel should be familiar with the plans in

order to minimize confusion. This may require coordination of local, state, and federal public safety resources.

Healthcare providers should always practice universal precautions. In the event of multiple victims and casualties, protocols for triaging victims must be used. These protocols are an important part of the disaster plan, and hospital personnel should be familiar with them.

POSTINCIDENT ACTIONS

For prehospital personnel and first responders, it is important that the scene be secured and declared safe before the victims are approached and the casualties evaluated. If patients are awake, they should be asked how many shots they heard and any other information they have relating to the event, such as their position and that of the assailant and the weapon or weapons used. Gunshot wounds must be reported to the appropriate authorities.

There should be close communication with emergency medical services personnel and the receiving hospitals to give as much lead time as possible for healthcare facilities to prepare for casualties. It is also important to be prepared to offer psychological help for victims and their families.

CLINICAL PRESENTATION

Injuries from a gunshot are the product of two mechanisms: tissue crush and tissue stretch. As the bullet travels through tissue, it will crush tissue that is directly in its path, and this results in a permanent cavity. This is the primary method of injury from most gunshot wounds. Passage of the projectile at a high rate of speed also displaces tissue surrounding the direct path away from the path of the projectile. As this tissue stretches away from the path, a temporary tissue cavity is formed. This is a more significant mechanism of injury with higher-velocity bullets, such as those encountered in a sniper attack.^{3,6}

The degree of tissue stretch and the size of the temporary cavity that is formed vary depending on the elastic properties of the injured tissue. Elastic tissues such as muscle, skin, and lung are good energy absorbers. Their elastic properties allow them to maintain a lot of their structure and function, even after temporary cavi-

tation. Inelastic tissue, including liver, heart, and brain, will be fractured and rendered nonviable to a much greater degree by a temporary cavity.⁵

Since the brain is encased in a solid container (the skull), brain tissue is even more susceptible to injury from temporary cavitation than other inelastic tissue. The solid container prevents tissue displacement during tissue cavitation, resulting in increased pressure inside the skull as a bullet penetrates. This pressure can only be relieved either through the entrance or exit wounds. The brain is also very sensitive to structural disruption. This combination makes high-velocity gunshots to the head very destructive.

MEDICAL TREATMENT OF CASUALTIES

Initial evaluation of persons with gunshot wounds in the prehospital setting and the emergency department is similar to that of any trauma victim. Initial assessment of the ABCs (i.e., airway, breathing, circulation) should be followed by the secondary survey and ongoing monitoring of vital signs. The focus of the examination is the detection of penetrating or perforating injuries. All clothing should be removed, and careful examination for entrance and exit wounds must include the back, under the hair, the axillae, the perineum, and the gluteal fold. Radiographs can be useful to identify the position of bullets. Radiographs and laboratory studies should be ordered when clinically indicated. Evaluation and treatment of gunshot wounds are best conducted in consultation with a trauma surgeon. Patients should be stabilized and transferred as quickly as possible if appropriate resources are unavailable where they are being treated.

Injury to the aorta, heart, pericardium, and esophagus must be suspected when wounds cross the mediastinum. These wounds require a thorough evaluation, even in stable patients. Surgical exploration is often indicated in these patients. Those who present with unstable vital signs or who become unstable during evaluation should receive bilateral chest tubes, and the presence of pericardial tamponade should be considered. Ultrasound is a fast way of identifying cardiac tamponade.⁴

Patients with gunshot wounds to the flank or back can be evaluated by computed tomography and observed if their conditions are stable. The decision to observe a patient must be made in conjunction with a trauma surgeon because these patients may benefit from surgical exploration. Patients with gunshot wounds to the abdomen require exploratory laparotomy.

Gunshot wounds to the extremities may cause neurovascular damage and fractures. Neurovascular function should be assessed carefully. There should be close monitoring for the development of compartment syndrome from swelling of the injured area. Angiography is indicated whenever arterial damage is suspected. High-velocity wounds should be debrided and closed secondarily. Fractures from a gunshot wound are considered open fractures, and early antibiotics should be instituted.⁴

Evaluation of gunshot wounds to the head should be done in consultation with a neurosurgeon. These

injuries are often not survivable. Spinal cord injuries can result from direct penetrating injuries, but the spine can be injured by temporary cavitation even in the absence of direct passage of the bullet through the vertebral canal. Steroids are not indicated in direct penetrating injury to the spinal cord. Although injuries to the central nervous system can be distracting to the physician, it is important not to delay the assessment and treatment of thoracoabdominal injuries.

CASE PRESENTATION

The Beltway Sniper attacks took place during 3 weeks of October 2002 in the eastern United States. Ten persons were killed and three others critically injured in and around the Baltimore-Washington, D.C. metropolitan area. The attacks were carried out with a Bushmaster XM-15 semiautomatic .223 caliber rifle, the civilian equivalent of the U.S. military's M-16 assault rifle, at a range of 50 to over 100 yards.

The sniper attacks began October 2, 2002, with a series of five fatal shootings in 15 hours in Montgomery County, Maryland, a suburban county north of Washington. The attacks continued for the next 3 weeks in the Washington, D.C., metropolitan area, filling residents of the region with fear. The shootings occurred at gas stations, supermarkets, restaurants, and schools in a rough circular pattern around Washington. The victims were apparently selected at random, crossing racial, gender, and socioeconomic categories.

During the period of the attacks, the North American media devoted enormous amounts of airtime and newspaper space to news of each new attack. By the middle of October 2002, all-news television networks were providing live, ongoing coverage of each new attack.

On October 24, 2002, John Allen Muhammad and Lee Boyd Malvo were found sleeping in their car, a blue 1990 Chevrolet Caprice, at a Maryland rest stop, and were arrested on federal weapons charges. A 223-caliber weapon and tripod were found in a bag in Mr. Muhammad's car. Ballistics tests later conclusively linked the seized rifle to 11 of the 14 bullets recovered from earlier attacks. In March 2004, Muhammad was sentenced to death and Malvo to life imprisonment for the attacks.

UNIQUE CONSIDERATIONS

Gunshot wounds must be reported to the appropriate authorities. Special care must be taken because the medical record and patient property often become evidence. Paper bags should be used to collect material to be saved for law enforcement because plastic bags can trap moisture, resulting in damage to the evidence. If a bullet is recovered and it must be marked, this should be done at the nose or base rather than the side. Marking the side will interfere with the evaluation of rifling patterns. Care should be taken during clothing removal to avoid cutting through portions of clothing that a bullet might have gone through. The location of all wounds identified should be recorded in the medical record, with comment on the presence of any powder residue

observed surrounding the wound. Attempts to differentiate between entrance and exit wounds are often an educated guess. The smaller wound is often thought to be the entrance wound, but this is not always the case.²

PITFALLS

Several potential pitfalls in response to a sniper attack exist. These include the following:

- Failure to ensure that a scene is secure prior to approaching victims
- Failure to fully examine the patient and identify multiple injuries
- Failure to consult a surgeon early in the management of the patient
- Failure to consider transfer to another facility
- Failure to fully evaluate stable patients with thoracoabdominal injuries

Grenade and Pipe Bomb Injuries

Charles Stewart

DESCRIPTION OF EVENT

Recent terrorist events have featured an increasing use of explosives. The weapon of choice of these terrorists is often the grenade, pipe bomb, or explosive-containing vest. Other terrorists will use a rocket-propelled grenade that was originally designed to cheaply defeat armor.

Pipe Bombs

The design of a pipe bomb is quite simple: it consists of a piece of pipe that is filled with explosives. The end caps for the pipe are used to contain the explosives and the force of the explosion. The fragments of the exploding pipe are propelled by the explosion and can cause lethal injury at a considerable distance. Since pipe comes in many sizes and materials, the shape and size of the pipe bomb is quite variable. These devices often either contain scrap metal or may be wrapped in scrap metal to increase the number of fragments and consequent injuries.

Pipe bombs can be carried in a satchel, briefcase, or backpack. The Centennial Park terrorist explosive device activated during the 1996 Olympics in Atlanta was a backpack containing pipe bombs.

Grenades

In World War II, the grenade was a cast-iron segmented oval shape designed to fit the thrower's hand. This is often called the "pineapple" grenade because of its shape. After the Vietnam War, the U.S. army deployed an egg-shaped grenade that was created by wrapping scored steel wire around a high-explosive core. This wire would fragment much more reliably and in smaller pieces than the older cast-iron bodies. This design has been copied and improved and is widely available throughout the world. The U.S. M26 grenade weighs 425 g and has a fuse delay of 5 seconds. The average throwing distance is about 40 m. Its blast radius is 10 m, with a killing distance of 5 m and a wounding distance of up to 25 m. Other countries have developed a cylinder-shaped grenade with attached handle, "the potato masher"

design. These are similar in performance and specifications to the US grenade.

Two special forms of grenade have evolved that are now widely dispersed, and an emergency physician may encounter casualties produced by their effects. These are the rifle grenades designed to project the grenade beyond the soldier's ability to throw and the antitank grenade, which has evolved into the rocket-propelled grenade discussed below.

Other types of grenades are also produced, but most of these have lesser wounding potential. These include concussion grenades (i.e., flash-bang grenades), illuminating grenades, smoke grenades, incendiary grenades, and chemical or gas grenades. These are often cylinder-shaped containers.

Rifle Grenades

The grenade launcher has evolved into a weapon that projects a grenade with good accuracy for about 200 m. First used during the Vietnam War, the M79 grenade launcher resembles a short, fat (40 mm), breech-loading, break-open, single-shot shotgun. The military also designed a grenade launcher that clamps onto the infantryman's M16 rifle that uses exactly the same ammunition as the M79 weapon. Numerous similar designs for these weapons are used by military forces of both North Atlantic Treaty Organisation and former Warsaw Pact nations. Comparable devices are often used by police forces to project riot-control agents, "nonlethal" beanbag rounds, and smoke. Multiple different rounds exist for both military and civilian grenade-launching weapons, and an emergency physician may well encounter patients injured by these devices. The grenade rounds contain about as much explosive and cause as much damage as the more common baseball grenade.

Rocket-Propelled Grenades

The need for an antitank weapon that could reliably penetrate enemy armor has been present since the tank was first used in World War I. One solution to this problem was to upsize the grenade and to mount it atop a

rocket, creating the rocket-propelled grenade (RPG). Many countries manufactured these devices by the millions and sold the inexpensive RPG to hundreds of rebel and terrorist groups. The former Soviet RPG launcher is reloadable. The United States distributes a similar light antitank weapon (the M72 LAW or the M136 AT4) that is not reloadable. The RPG is designed to defeat the armor on a tank and carries substantially more explosive material than any other device discussed in this chapter. See Chapter 146 for a more detailed discussion of RPGs.

Clinical Presentation

Trauma caused by explosions traditionally has been divided into the injury caused by the direct effect of the blast wave (primary injuries), the effects caused by other objects that are accelerated by the explosive wave (secondary injuries), the effects caused by movement of the victim (tertiary injuries), and miscellaneous effects caused by the explosion or explosives.

The victims of primary blast injury almost always have other types of injury, such as penetrating wounds from flying debris or blunt trauma from impact on immovable objects.¹ The number of victims of primary blast injury due to a grenade, pipe bomb, or suicide vest will likely not be large since the quantities of explosives contained are small. (A suicide vest is an improvised explosive device to be worn as a vest, a waist belt, or a backpack. Suicide bombs are covered in detail in Chapter 144.) The topic of primary blast injury is covered in Chapters 141 and 142.

With both grenades and pipe bombs, secondary blast injuries are both the most common and the intended injury mechanism. Terrorist devices often have additional objects such as nails, nuts, and bolts added to the explosive mixture to increase the effects of secondary blast injury. Military devices such as grenades are designed in such a way as to increase the number of fragments flung by the explosion. The penetrating injuries occur most often in the exposed areas such as the head, neck, and extremities.

Tertiary blast injuries are caused when the victim's body is propelled into another object by blast winds.^{2,3} This is unlikely to occur from the relatively small amounts of explosives found in a grenade. It may be possible to note these effects with the larger amount of explosive in an RPG, pipe bomb, or suicide vest.

PREINCIDENT ACTIONS

It is difficult, indeed, to plan for the consequences of an explosive device that can be carried in a backpack, briefcase, or even in a pocket. The use of these devices in the United States has not been common, but given the evolving worldwide political climate, such events could occur. Emergency physicians are increasingly likely to see the effects of these devices and must be prepared to treat the victims of these explosive hazards.

POSTINCIDENT ACTIONS

The predominant injury found after an explosion of a grenade or pipe bomb will be penetrating trauma from fragment wounds. Those who are quite close to the blast may sustain either primary blast injury or traumatic amputations. An explosion that occurs in a confined space (e.g., vehicles, mines, buildings, subways) is associated with greater morbidity and mortality.

Field Medical Care

The following are important points regarding appropriate field medical care of patients sustaining injuries from a grenade or pipe bomb explosion.

- Appropriate initial care is similar to regular trauma care.
- Rapid evacuation increases the chance of survival.
- Do not attempt definitive care in triage.
- Arterial bleeding from traumatic amputations should be controlled with tourniquets until the area is entirely safe and the patient can have definitive care.
- Do not attempt extensive resuscitation in the field.
- Cardiopulmonary resuscitation at the scene of a mass-casualty event is not indicated.

MEDICAL TREATMENT OF CASUALTIES

Most of the injuries seen after the explosive in a grenade or pipe bomb detonates are blunt, penetrating, and thermal trauma that is well known to prehospital providers, emergency physicians, and trauma surgeons.⁴ Much of this trauma involves soft tissue, orthopedic, or head injuries.⁵⁻⁷ The appropriate approach to the patient with blast-related injury from grenades or pipe bombs is therefore the same as any other trauma victim.

The first and most important step of management is to assess life support needs and ensure that the patient has an adequate airway, appropriate ventilation, and adequate circulation. As noted above, use of tourniquets can buy time to evacuate the victim to a safe area where appropriate care can be rendered.

A thorough physical examination should be then performed. Most of the wounds will have been caused by fragments from the device or metal surrounding the device.

There are few screening studies that are of any benefit in the casualty with primary blast injury. Indeed, for these smaller devices, studies should be directed toward the effects of multiple penetrating fragments. A seemingly small abrasion or wound may mask the entrance wound for a substantial fragment. The physician should also remember that blast fragments may be traveling up to five times as fast as a military bullet.

A chest radiograph should be obtained in all patients who have been near a significant explosion. If the patient is not wearing body armor, presume there are

fragments in the chest until a chest radiograph proves to be negative for both pneumothorax and intrathoracic fragments. A chest radiograph may also show fragments or free air under the diaphragm, signifying hollow viscus rupture in the abdomen. Long-bone films are indicated in traumatic amputation or if wounds are found in a patient's extremities.

A computed tomography (CT) scan of the head, chest, or abdomen should be obtained if the history or physical examination suggests pathology in these areas. If the patient is unconscious, these CT studies are not optional. There is about an 80% rate of infection when fragment wounds are sutured. All debris that is flung by the explosion is not radiopaque, and the wise provider should carefully explore injuries and consider CT, ultrasound, or magnetic resonance imaging of wounds to evaluate for radiolucent foreign bodies.

The only laboratory study that is useful is serial hemoglobin determinations. These appear to be of use in evaluating patients who have severe bleeding. The data can be used as a guide for blood transfusion requirements.

Hypotension in blast injury victims can be due to several mechanisms:

- blood loss due to wounds (otherwise not related to the cardiovascular system); this is particularly common with traumatic amputations and the multiple fragments sustained at close range from a modern fragmentation grenade
- blood loss due to gastrointestinal hemorrhage
- blood loss due to intraabdominal solid organ rupture
- hypotension from compression of vessels and heart by pneumothorax
- hypotension due to the cardiovascular effects of an air embolism
- hypotension due to vagal reflexes

The disposition of these patients depends on the injury sustained by each victim. Those who were close to the center of the explosion should be considered for observation for at least 24 hours, even if they have no obvious injuries.

CASE PRESENTATION

You are listening to a professional football game in your emergency department. A newscaster reports a loud explosion at about the 50-yard line. Cameras show an RPG that streaked over them and impacted in the crowd on the other side of the field. You realize, as an employee of the closest hospital to the event, that your facility is going to be receiving substantial casualties in the next few minutes. You activate your disaster plan and prepare for the casualties that you will be getting.

The television shows emergency medical services (EMS) providers moving to the area to provide care to the victims as you make your first phone calls contacting the hospital supervisor and administrator. Horrified, you watch as a hot dog vendor pulls out a second RPG and aims it at the ambulance rally point. The casualties will now include EMS providers.

UNIQUE CONSIDERATIONS

Expect that the most severely injured patients will arrive after those who are less injured. The less injured often skip emergency medical services and proceed directly to the closest hospitals. For a rough prediction of the "first wave" of casualties, double the first hour's casualty count.

Ensure that physical activity of the victims is minimized after the blast explosion; exertion after the blast explosion can increase the severity of primary blast injury. This was seen in World War II in cases of some blast casualties who appeared well but died after vigorous exercise.⁸

PITFALLS

Secondary Devices

Remember to check all victims for weapons, booby traps, and explosives. It is quite common for a bomber to become a victim of his own device. It is also common for a secondary device to be concealed under a casualty. Frequently, this secondary device is a grenade with the pin removed, so that disturbing the body will allow the spoon to fly off and the grenade to arm and explode.

Abrupt Decompen-sation

If a patient with a blast lung injury abruptly decompensates, the clinician should presume that the patient has a tension pneumothorax and treat accordingly. This is particularly true when the patient has thoracic fragment wounds from a grenade or pipe bomb.

Blast Lung

If the clinician does not consider the possibility of primary blast injury, it may further complicate the patient's care. This entity is covered elsewhere in another chapter.

Air Transportation

The potential from pneumothorax that results from grenade or pipe bomb explosion can be exacerbated by evacuation. Regardless of the altitude and distance of the flight, casualties with evidence of pneumothorax must have a chest tube placed. Evacuation aircraft should fly at the lowest possible altitude.

Introduction to Structural Collapse (Crush Injury and Crush Syndrome)

Pier Luigi Ingrassia, Alessandro Geddo, Francesca Lombardi,
and Francesco Della Corte

DESCRIPTION OF EVENT

Crush injuries are commonly seen in disasters and they are often found in victims of collapsed structures, which may result from earthquakes, hurricanes, tornados, bombings, and other large-scale events. Crush syndrome is the systemic manifestation of rhabdomyolysis caused by prolonged continuous pressure on muscular tissue^{1,2}; in particular, it is a reperfusion injury as a result of traumatic rhabdomyolysis.

Crush syndrome was first described in the English literature by Bywaters and Beall.³ They described several patients who were trapped under the rubble of buildings bombed in the United Kingdom and who subsequently died of acute renal failure (ARF). The clinical features typically seen with crush syndrome are predominantly a result of traumatic rhabdomyolysis and subsequent release of muscle cell contents. The mechanism behind crush syndrome is increased permeability of the sarcolemmal membrane resulting from pressure or stretching. As the sarcolemmal membrane is stretched, sodium, calcium, and water leak into the sarcoplasm, trapping extracellular fluid inside the muscle cells. In addition to the influx of these elements, the cell releases potassium and other toxic substances such as myoglobin, phosphate, and urate into the circulation.⁴⁻⁶ Injury to other cells may release: lactic acid, histamine, leukotrienes, peroxides, free radicals of oxygen, superoxides, lysozymes, and enzymes (such as like creatine phosphokinase).

These events may result in hypovolemic shock, hyperkalemia, metabolic acidosis, compartment syndrome, and ARF. The ARF is caused by a combination of hypovolemia with subsequent renal vasoconstriction, metabolic acidosis, and the insult of nephrotoxic substances such as myoglobin, urate, and phosphate. Compartment syndrome occurs when injured skeletal muscle contained within fascia-bound compartments develops swelling due to increased fluid uptake by

injured muscle cells. Once the compartment pressure exceeds capillary perfusion pressure (at about 30 mm Hg), the tissue inside the compartment become ischemic and compartment syndrome develops.

Major earthquakes often result in a substantial number of crush syndrome injuries, the victim of which develop rhabdomyolysis and pigment-induced ARF. The incidence of crush syndrome has been estimated at a minimum of 2% to 5%. Approximately 50% of patients with crush syndrome will develop ARF, and of these, 50% will need dialysis.⁵

PREINCIDENT ACTION

Emergency physicians, general practitioners, surgeons, and pediatricians should be familiar with the diagnosis and management of crush injuries and crush syndrome. As part of disaster preparedness to treat these patients, simple portable medical kits for on-scene treatment of patients with crush injury should be organized. These kits should contain materials and means to treat at least five critically ill patients and also maps and telephone numbers of all medical-aid centers in the region to which patients should be moved as soon as possible, theoretically within the first hour.⁷

The medical-aid centers would be identified at no more than an hour's walk from any location to ensure accessibility even if the road transportation system failed. Sites might include schools, gymnasiums, fire stations, and hospitals and should be located near potential helicopter landing zones for patient evacuation and delivery of supplies and equipment.

Since crush syndrome is a common cause of death in large-scale events, hemodialysis facilities and their capacity should be identified in advance.

After a disaster, challenges in communication should be anticipated. Therefore, one of the first priorities must be to establish an independently powered short-wave

communication network. The hospitals, especially emergency departments and intensive care units, must be prepared to receive multiple critically ill patients.

Triage practices are of vital importance during a mass-casualty disaster. The Simple Triage and Rapid Treatment system is internationally suggested to categorize patients according to the severity of their illness and priority to evacuation.⁸

POSTINCIDENT ACTION

It is critically important that medical and rescue personnel coordinate their efforts in caring for victims of crush injury. Serious morbidity and mortality can occur with delay in treatment of a crush victim. Aggressive medical treatment of patients before and during extrication will help prevent renal and cardiac complications of crush injury.

Since the crush syndrome is the second most important reason for increasing morbidity and mortality, triage guidelines must incorporate this into patient assessments to facilitate the strategic use of hemodialysis resources.

In the field, disaster medical personnel can obtain relevant physiologic parameters from crush victims that do not require any specific devices. An initial field triage model for determining which patients may require early intervention for crush syndrome could consist of the following three factors:

- pulse rate
- delay of response activity (>3 hours)
- macroscopic urine findings

A second triage model, applied in healthcare facilities, could be composed of other parameters, including the following laboratory tests:

- Tachycardia (> 120/minute)
- Macroscopic abnormal urine findings
- White blood cell count
- Hyperkalemia

Hemodialysis machines and filters, together with nephrologists, nurses, and technicians, should arrive within 24 to 36 hours as national and international resources are mobilized. Emergency dialysis units should be set up in easily accessible areas to avoid problems of transportation for those patients who may have other serious injuries requiring major surgery. On-scene doctors treating disaster victims can consult with remote renal experts using telemedicine or Internet linkages for advice on treating particularly complex cases. Decisions about which type of dialysis modalities to use should take into account the hypercatabolic state of the victims, the degree of electrolyte disturbances, the presence of polytrauma and bleeding tendency, as well as specific geographic and local conditions, transport problems, and other logistic difficulties. Conventional hemodialysis allows for efficient solute removal, treatment of multiple patients, and application without anticoagulants.

Peritoneal dialysis is difficult to administer in patients with abdominal trauma and often is inefficient for

removal of potassium and other catabolic metabolites. It might offer temporary help, however, especially during disaster scenarios where conventional hemodialysis equipment is not ready available.⁹

MEDICAL TREATMENT OF CASUALTIES

The treatment of crushed casualties should begin as soon as they are discovered. Attention should be given to the possibility of concomitant injury such as fractures, solid organ damage, or spinal injury. Intravenous access should be obtained with large-bore intravenous catheters, and the patient should receive fluid as soon as possible.¹⁰⁻¹² Multiple intravenous lines are necessary because these patients require large fluid volumes and individual intravenous lines may be dislodged during extrication. Normal saline is an appropriate initial choice for intravenous fluid resuscitation. A saline infusion of 1000 to 1500 mL/hour should be initiated during extrication. When a urine flow has been established, a forced mannitol-alkaline diuresis up to 8 L/day should be maintained (urine pH > 6.5). Once the patient reaches the hospital, 5% dextrose should be alternated with normal saline to reduce the potential sodium load. Since large volume of intravenous fluids may not be available in the first 2 days after a major incident, it is reported that hypertonic saline is also safe and effective in a variety of trauma patients.¹³ Placement of a Foley catheter is also recommended to have accurate measurements of urine output.

Alkalinization increases the urine solubility of acid hematin and aids in its excretion. This may protect against renal failure and should be continued until myoglobin is no longer detectable in the urine. In addition to its protective effect as an osmotic diuretic, mannitol also is an effective scavenger of oxygen free radicals and may help reduce the reperfusion-related components of this injury by this mechanism.^{4,6}

At hospital admission, electrolytes, arterial blood gases, and muscle enzymes should be measured. Performing a simple dipstick test on the urine for hemopositivity in the mildly injured patients can diagnose subclinical rhabdomyolysis and can be useful in identifying this critical condition. If these patients are discharged because of a limitation of facilities, they should be advised to check the color and the volume of their urine daily and to watch for other symptoms of ARF such as weight gain and edema.¹

The outcome of the renal victims of catastrophic earthquakes is influenced by the type of trauma, concomitant events, and complications observed during the clinical course as well as epidemiologic features such as age, distance to reference hospitals, and time elapsed between disaster and admission to reference hospitals.¹⁴ The earlier one starts intravenous therapy, the better the chance of preventing ARF. When fluid therapy is delayed for 6 hours after extrication, ARF is almost ensured. If the desired urinary output cannot be achieved, the use of diuretics, preferably furosemide, should be considered. The majority of crush injury victims who do not receive intravenous therapy early enough and who do not

respond to forced alkaline diuresis go on to develop renal failure and the requirement for hemodialysis.¹⁵

There are case reports of hyperbaric oxygen improving the outcome of victims of crush injury.^{16,17} The use of this modality is obviously limited in disaster situations because of lack of access to hyperbaric chambers.

CASE PRESENTATION

You are the physician of an emergency medical services ambulance. You are attending a victim of building collapse. You have already assessed the patient's airway, breathing, and circulation, and you are coordinating with rescue personnel. Which is your next priority?

- Notify 9-1-1 dispatch center and obtain directions.
- Consider amputation as soon as possible.
- Use tourniquets as a treatment of wounds.
- Obtain multiple intravenous lines and start fluid infusion.
- Perform field fasciotomy.

Note: To obtain multiple intravenous lines, reduce the possibility of the lack of intravenous access during extrication procedures and allow intravenous effusion of larger amounts of normal saline to prevent ARF and hemodialysis.

UNIQUE CONSIDERATIONS

There is no doubt that the majority of deaths occur immediately after structural collapse or a catastrophic event, such as an earthquake.¹⁸ And among those still alive, short-term mortality dramatically increases as the time the persons are buried under the rubble lengthens. During the first few hours, a not inconsiderable number are still alive. After 24 hours the survival curve starts to fall more steeply, and after 5 days all those not recovered are dead. Disaster medical plans should comprise a medical care chain in which casualties receive life-supporting measures at the accident scene, with subsequent transport to hospital for more definitive care within a few hours of their rescue. The development of crush syndrome after crush injury is preventable and treatable. Crush injury patients may present with few signs or symptoms; hence, medical personnel must maintain a high index of suspicion in treating crush victims.

PITFALLS

Several potential pitfalls in response to a structural collapse exist. These include the following:

- Failure to plan evacuation routes prior to an event
- Failure to know who is in command of disaster operations within your local area

- Delayed treatment after the victim extrication
- Delay in starting intravenous fluids
- Low index of suspicion for crush injuries
- Failure to continue the monitoring of patients with a high risk for ARF

Train Derailment

J. Scott Goudie

DESCRIPTION OF EVENT

Railroads provide a vital means of transportation for both passengers and industrial products. The high-volume and varied nature of cargo carried means that railway disasters are an ever-present risk that make possible a wide variety of situations, as demonstrated by past events:

- a high-speed passenger train derailment in the rural Southwest¹
- a train derailment and hazardous material spill in rural North Dakota²
- a collision of two commuter trains in Chicago³
- a freight train derailment with subsequent hazardous material spill and fire in downtown Baltimore⁴

Each situation presents its own unique problems, whether it is a remote accident scene, a high-volume of patients, or a hazardous material spill potentially affecting those on the train, those living nearby, and emergency personnel responding to the scene.

Although most railway disasters are unintentional, arising either from human error or equipment failure, railways remain prominent targets for terrorism, as demonstrated by the Madrid subway bombings in March 2004. The many miles of railroads crossing the United States make it extremely difficult to provide security for every stretch of track, thus providing a potentially soft target for terrorists.

PREINCIDENT ACTIONS

To respond effectively to a train derailment, hospitals, emergency departments, emergency medical services, and fire departments should all develop disaster response plans for mass-casualty and hazardous material disasters. These plans must also be supported by the proper equipment and training with regular tabletop and live disaster drills. A well-established system of communication and coordination between all local emergency services is vital, as well as maintaining points of contact with regional, state, and federal disaster response agencies.

A hazard assessment should be performed to identify the potential for railway disasters in a community based on the number of railways, the population density adja-

cent to the rails, the volume of rail traffic, the characteristics of rail services (e.g., subway, high-speed commuter, industrial freight, hazardous waste), and vulnerable facilities adjacent to the railways (e.g., schools, nursing homes, hospitals, apartment complexes, military bases) that may create unique problems for an emergency response.

POSTINCIDENT ACTIONS

Initial priority should be given to the extraction, triage, transport, and treatment of the victims. Remote railway locations can present difficulties in reaching the scene, necessitating use of aeromedical assets in addition to land-based responders. Once at the scene, it is vital to do the following: (1) perform a rapid assessment to identify any potential hazardous material spills and (2) establish an incident commander and command center in a secure location. If the potential for a hazardous material contamination has not been determined, the information regarding the contents on board the train should be available, along with their material safety data sheets from the managing railroad company.

On-scene triage of victims according to an established system, such as the Simple Triage and Rapid Treatment system, allows for prioritizing medical evacuation of victims back to the medical center according to severity of injury.⁵ The transportation of victims may include all traditional assets such as ground ambulances and aeromedical transports, as well as “lifts of opportunity” that may present themselves such as buses, police or fire vehicles, and military transport. Identification and tracking of the victims after their extrication and evacuation is vital and may be accomplished by triage tag number if no further identification is available on the scene. Definitive identification must be pursued at the time of presentation at the medical centers, for both the living and the deceased, to ensure all victims are recovered and accurately identified.

Early contact and coordination with state, regional, and national organizations such as the National Transportation Safety Board and the Federal Emergency Management Agency are essential in providing an appropriate response to a large-scale railway disaster. Local resources can rapidly be exhausted, thus necessitating

outside aid such as from a National Guard unit or a disaster medical assistance team.

All railway disasters are potentially crime scenes and must be approached as such throughout the response. Extrication of victims is of paramount importance; however, attention must be paid to not destroy any potential evidence. In the case of a terrorist attack, there is also the potential for secondary devices targeted at the emergency responders.

Coordination of early statements and releases to the press should be handled through a single entity, whether it is the public affairs office of the hospital, the local police or fire department, or an outside agency; for instance, Amtrak manages all public affairs information and press releases for any accidents involving their trains.¹

MEDICAL TREATMENT OF CASUALTIES

Passengers will present with a broad spectrum of traumatic injuries, ranging from simple lacerations and fractures to severe head injuries and deceleration injuries (e.g., aortic or mesenteric avulsions). Patterns of injury may vary greatly depending on the passenger's location (e.g., seated versus standing, forward- versus rear-facing seats) at the time of the injury:

- Standing patients have a higher incidence of neck and craniofacial injuries.⁶
- Seated patients have a higher incidence of thoracoabdominal injuries, with those in forward-facing seats having a greater potential for facial injuries and deceleration injuries.⁷

In prolonged extrications, victims may also be suffering from crush syndrome and effects from exposure such as hypothermia or hyperthermia. There may also be a substantial number of burn or blast injuries, depending on the presence of combustible materials onboard the train or due to terrorist explosives.

Traumatic injuries to passengers and railway workers will often be the primary medical challenge; however, in cases of hazardous material exposures, the potential for exposure and illness extends to include rescue workers and residents living near the disaster. After trauma, the most frequent injuries sustained by railroad employees are respiratory irritation, nausea, vomiting, and headache—all suggestive of hazardous material exposure.⁸ Residents near the derailment and first responders are most likely to present with respiratory, dermatologic, or ophthalmic complaints due to exposure.⁴ Proper use of personal protective equipment for rescue workers, decontamination of both victims and rescuers upon leaving the scene, and evacuation of any residents nearby can all minimize the effects of a hazardous material spill.

Be prepared for a significant number of psychological casualties presenting both immediately and delayed.⁹ These victims may present with either psychological complaints, somatic symptoms, or both. Posttraumatic stress disorders have been identified in both train passengers as well as nearby residents after a major train derailment.¹⁰ Establishment of a critical incident support center to pro-

vide stress management, chaplain services, and psychological support for victims and families, as well as first responders, is helpful in minimizing the short- and long-term psychological sequelae after a railway disaster.

CASE PRESENTATION

On a weekday afternoon, the call comes into the emergency department of the county's only community hospital that there has been a reported train derailment in a small outlying town approximately 40 miles away. Initial reports state that a freight train with six workers on board has derailed adjacent to an elementary school and that there is a large fire burning on scene. Local fire and emergency medical systems crews are rolling onto the scene and requesting medical direction.

What are your next moves? How would your response be different if it had been a high-speed commuter train with 100 passengers on board?

UNIQUE CONSIDERATIONS

Train derailments are unique in the diversity of potential problems for responders. A derailment may occur in an urban environment with the subsequent risk of injury to the many people living and working nearby, or it can present in an isolated, rural location thus causing delays in response to the accident. The number of casualties can vary from only a handful of railway workers to hundreds of passengers on board a commuter rail. The possibility of hazardous material exposure exists in every train derailment, which may delay extrication of victims as well as present serious problems for rescue workers and those nearby. For a disaster response plan to be effective in the event of a train disaster, it must take into account all of these diverse possibilities.

PITFALLS

Several potential pitfalls in response to a train derailment exist. These include the following:

- Failure to develop and practice a disaster response plan
- Failure to coordinate response with other agencies
- Failure to recognize hazardous material release
- Failure to maintain integrity of a crime scene for investigators
- Failure to address positive identification of both victims and deceased
- Failure to communicate with the public regarding risk and need for evacuation

Subway Derailment

Jason Dylak and David Marcozzi

DESCRIPTION OF EVENT

Subways are a common means of mass transit found in many urban settings. Subways are essentially electrified trains that can transport hundreds or even thousands of people per train. Since the subway runs on a track, instead of freely on the road, derailment can present a host of problems, ranging from a thump barely noticed by passengers to catastrophic failure resulting in massive injury and death. One of the worst accidents in subway history occurred in New York City on November 1, 1918, when an inexperienced dispatcher (filling in for striking motormen) entered a tunnel too fast and caused the wooden train to derail. The train struck a wall, killing 97 people and injuring 200. This incident led to the Brooklyn Rapid Transit Company going out of business a month later.^{1,2} Subways have become considerably safer in the years that have followed, but accidents including derailments may still occur. Operator error remains the most common cause of derailment.³ Intentional sabotage of tracks or cars can also lead to derailment. On March 11, 2004, 191 people were killed and more than 2000 injured when 10 bomb explosions occurred simultaneously on 4 commuter trains in Madrid, Spain.⁴

The location of these events can present unique challenges for emergency responders. Subways may travel underground, on elevated platforms, or on bridges over bodies of water, gorges, and ravines. An underground subway derailment necessitates evacuation of the train in a dark tunnel with possibly a long walking distance to access points. During an above-ground derailment, train cars may tip over. Train derailment from an elevated railway may result in the train falling off the bridge entirely. Passengers and emergency responders risk falling off the elevated railway as well. Elevated railways passing over water present the additional hazard of drowning and exposure to cold for victims falling into the water. A common hazard to all electrified train accidents is the ever-present risk of electrocution that can result on contact with the third rail, which runs along the track in many subway systems and conducts several

hundred volts of direct current, providing power to the train. Contact with the third rail can be fatal.

PREINCIDENT ACTIONS

Hazard vulnerability analysis by hospital disaster planners should include a survey of subway or train stations located in the vicinity of the hospital. Any past rail accidents that have occurred within the hospital catchment area should be carefully reviewed to determine whether there are “danger zones” where future accidents may be more likely to occur. The kinetic energy of a traveling train is proportional to the number of cars (mass) and the velocity. The higher the kinetic energy, the greater the risk of injury to passengers in the event of a derailment event.⁵ An estimate of the potential number of injuries that could result from a theoretical rail accident can be made by multiplying the number of cars per train traveling through local stations and rail routes by the passenger capacity of each car. If the potential number of patients that could result from such a rail accident exceeds the capacity of local prehospital and hospital resources, multiagency disaster plans should be developed for this scenario.

POSTINCIDENT ACTIONS

Because of the variety of potential disaster scenes after a subway accident, the responder must pay particular attention to scene safety issues. Adequate resources should be mobilized to address the specific scenarios faced and preconceived evacuation plans for the victims should be implemented. After victim rescue operations, assessment of the rail bed must be made to determine structural integrity before reestablishment of service along that route. Train cars must likewise be inspected to determine future usability.

Debriefing with emergency responders should be undertaken by senior members of involved agencies and other trained personnel from specialized organizations after any rescue operation to understand any difficulties that may have been encountered during the rescue and recovery operations.

MEDICAL TREATMENT OF CASUALTIES

Multiple types of casualties may be encountered in victims of rail accidents. In low-speed derailments, musculoskeletal injuries such as ankle and wrist injuries, and injuries due to falls are predominantly seen. In high-speed derailments, deceleration forces may be significant, with a resulting spectrum of traumatic injuries similar to that seen in other patients with high-speed blunt trauma. High-speed derailments occurring in tunnels may result in collision with tunnel support posts or stanchions, which may remain intact but cause passenger cars to collapse.^{6,7} Fire, with smoke and release of toxic gases, may complicate injuries resulting from blunt trauma.⁴

Rail accident scenes are prone to multiple hazards of which emergency responders must be aware and must take precautions to avoid. Live electrical wires or the train's electrified third rail present the risk of electrocution leading to burns and respiratory and cardiac arrest. Fire in a subway tunnel can result in low oxygen levels and the presence of toxic fumes. If fire is present, effective suppression must take place before rescue attempts can be made. There may be a risk of falling debris or collapse of on-scene structures and train cars, as well as the potential that rescuers and victims could fall from elevated railways.

When scene safety is insured, victims should be evacuated from the accident zone as quickly as possible to minimize further risk from on-scene hazards and to allow for appropriate triage, on-scene treatment, and transportation to hospital. High-angle rope rescue techniques may be needed in some cases of elevated railway accidents. The scenario of needing to apply spinal immobilization and extricate hundreds of patients on long boards presents an enormous technical and logistical challenge to emergency responders. In this scenario, deployment of physicians to the field to evaluate and clinically clear patients without evidence of cervical spine injuries can significantly expedite the safe extrication of patients at risk for cervical spine and other injuries.

The triage area should be established upwind and outside of the accident zone, away from potential hazards, in an area that is accessible to transporting ambulances. Patients should be triaged using standard algorithms for a mass-casualty incident. A mass-casualty incident exists when:

1. The number of patients and the nature of their injuries make the normal level of stabilization and care unachievable, and/or
2. The number of Emergency Medical Service personnel that can be brought to the site within the time allowed is not enough, and/or
3. The stabilization capabilities of the hospitals that can be reached within the time allowed are insufficient to handle all the patients.

Basic trauma stabilization of injured patients can be initiated on the scene in preparation for transport to hospital. Patients with smoke inhalation or exposure to other toxic fumes should receive supplemental oxygen.

Patients with electrical burns or respiratory or cardiac arrest resulting from electrical shock should also be anticipated.

CASE PRESENTATION

On a summer Saturday afternoon, an above-ground subway train consisting of 11 cars with approximately 245 passengers and crew is heading toward a popular amusement park and the city aquarium. Unbeknownst to the crew, the track ahead has been vandalized. Spikes joining the track had been pulled, leaving the rails loose although still intact.

The first car passes over the section of the break without incident, but as the second car passes, the track comes apart and the rear truck of the third car derails, twisting the train into an "S" shape and slamming into a wall. The train conductor activates an alarm, and a bystander calls 9-1-1. The train crew, who is uninjured, begins identifying injured passengers. Police, fire, and emergency medical services (EMS) units arrive on the scene, and a mass-casualty incident is declared.

In total, 116 patients are transported. There is one fatality: a massive epidural hematoma with herniation. Three other red-tagged patients are appropriately admitted, treated, and discharged in good health. The train is recovered from the track, taken out of service, rehabilitated, and returned to service. The train bed, wall, and track are repaired. The National Transportation Safety Board determines the cause of the derailment to be sabotage of the track; operator error was not ruled to be involved. The vandals/saboteurs are never identified or apprehended.

UNIQUE CONSIDERATIONS

Subway derailments, when they occur underground or on elevated platforms, may be associated with difficult access issues for rescuers. Underground accidents may be associated with fire, smoke, and toxic gases that present risks to victims and rescuers alike. Rescuers may have to walk long distances through tunnels to reach the accident scene, carrying extrication and other rescue equipment, and then transport patients out on foot. The extrication of passengers from severely damaged or crushed train cars may require the use of heavy equipment outside the scope of standard EMS or fire department capabilities. Planning for such scenarios should occur in advance and involve representation from all relevant response agencies, including the Transit Authority.

PITFALLS

Several potential pitfalls in response to a subway derailment exist. These include the following:

- Inadequate implementation of an emergency plan with sufficient elements, including fire, police, EMS, and government agencies (e.g., the NTSB)
- Slow or incomplete discontinuation of track electricity and service on the line

- Accumulation of toxic gases underground
- Technically difficult rescues and extrications, either due to entrapment in machinery, conditions other than on level ground (e.g., bridge, tunnel underground or underwater), or remote locations
- Patient accountability—some may be entrapped, self-extricated, or transported by private citizens, and there is no way of determining the number of passengers who might be on board at the time of the accident

Bus Accident

Kavita Babu

DESCRIPTION OF EVENT

In 2002, Americans traveled 21.8 billion miles by bus.¹ Despite these extraordinary numbers, serious bus accidents are still an uncommon event. National Security Council data state that the risk of fatal injury for a bus passenger is 170 times lower than that of an automobile occupant.² However, a single bus filled only to its stated capacity may hold more than 50 passengers.³ Therefore, the possibility exists for a bus accident to cause an instant mass-casualty event in virtually any setting.

Data from transit buses for the year 2000 report more than 20,000 injuries and 82 deaths.⁴ Although transit and charter bus data are available, the most complete data on bus accidents are derived from analysis of school bus crashes. More than 22 million American children take the bus to school daily.⁵ In 1999, more than 18,000 people were injured in school bus accidents, resulting in 164 deaths.⁶ Characteristics of those accidents that produced fatalities included front-end and side-impact crashes, overturned buses, and collisions with trains.⁷ According to the National Transportation Safety Bureau, death and significant injury were often attributed to sitting at the point of impact.⁸

Analyses of individual accidents have guided the bus industry safety standards. The primary passenger safety feature of school buses is called *compartmentalization*. Given the size of buses and the lower crash forces imparted to passengers, legislation was passed in 1977 to make compartmentalization standard in the production of new school buses.⁹ Padded seats create a compartment for the passenger between high seat backs and the seat in front. The seats themselves are constructed of steel, and designed to absorb energy by bending. However, this method of protection is particularly limited in rollovers, when passengers may be thrown from their seats.¹⁰

Continued controversy exists over the use of seat belts in school and transit buses. National transportation authorities argue that seat belts in buses increase the risk of serious neck injuries, and that the cost of seat belt implementation may be better allocated for other safety measures. Additionally, the role of seat belts in buses is questioned because their primary purpose in cars is to prevent ejection, an uncommon event in bus accidents.¹¹

Proponents state that seat belts are an essential intervention for preventing injury to passengers during rollover and lateral-impact collisions.¹¹ As this debate continues, research on improving bus safety remains a priority for many government, professional, and parent organizations.

PREINCIDENT ACTIONS

Every public safety system, emergency department, and hospital must have a comprehensive plan in place for approaching a mass-casualty event involving a bus. A serious bus accident can rapidly overwhelm the resources of a single hospital. Activation of local, state, and even federal resources may be required. Prehospital triage is critical to avoiding saturation of the nearest hospital. On-scene personnel should transport patients with unstable conditions to the nearest hospital, whereas patients with minor injuries can be diverted to outlying facilities.

One unique difficulty faced by prehospital personnel at the scene of a bus accident is the difficulty of extricating victims. The standard extrication tools and techniques used in response to car accidents may not be effective in evacuating victims from a bus. Particular difficulties with extrication were noted in an Omaha, Nebraska, accident in 2003. As a result of this accident, the National Transportation Safety Board recently issued a recommendation that all fire and rescue personnel undergo specialized training in bus extrication techniques.¹²

Rapid extrication of bus accident victims is particularly vital in cases in which the bus becomes submerged. Recent accidents in China and India resulted in large death tolls after buses left the road and entered nearby rivers.^{13,14} High numbers of bus accident fatalities in developing countries may also be attributed to older equipment, bus overcrowding, lack of standardized driver training, and hazardous road conditions.

POSTINCIDENT ACTIONS

In recent years, national transportation authorities have identified the collection and assimilation of transit and charter bus accident data as a priority in creating applicable safety interventions. The efforts of clinicians and

local rescue and law enforcement personnel to report all bus accidents are critical for surveillance.

If the bus accident involves a large number of fatalities, part of the disaster response must involve rapid activation of local, state, and national mortuary teams to identify remains in a rapid and accurate manner.¹⁵

MEDICAL TREATMENT OF CASUALTIES

An Australian study reviewing school bus-related fatalities in children identified head injury and blood loss as the most common causes of death.¹⁶ As in other causes of blunt trauma, immediate attention must be directed to airway, breathing, and circulation. Rapid airway management may be required in patients with a depressed Glasgow Coma Scale score or significant burns. Spinal immobilization must be maintained where appropriate. The secondary survey for injuries should be performed rapidly, with a particular focus on triage in the mass-casualty setting. Patients with life- or limb-threatening injuries must be addressed emergently, whereas other patients may be appropriate for immediate transfer or triage to a less urgent level of care. In most bus accidents, there are far more “walking wounded” than patients with incapacitating injuries.¹⁷ However, in the case of multiple serious casualties, the physician or his or her staff must be able to mobilize both hospital and community resources rapidly in avoiding the saturation of any single healthcare site without failing to provide care to all patients.

CASE PRESENTATION

You are working in a 15-bed emergency department of a small community hospital that is 40 minutes by ambulance to the nearest level 1 trauma center. On a Monday morning, you receive pre-notification of a collision between a dump truck and a school bus. The bus overturned, landing on its left side. Flames were initially noted to the rear of the bus but were extinguished upon arrival of fire department personnel. The on-scene paramedic cannot pinpoint the number of passengers on the bus but estimates 20 children. Extrication is proceeding slowly. There is one reported fatality. Local emergency medical services (EMS) dispatch is contacting neighboring towns for assistance, and EMS personnel will transport the first victims to your hospital within 15 minutes.

UNIQUE CONSIDERATIONS

In many ways, the traumatic injuries sustained by any person during a bus accident are not markedly different than those found in a simple motor vehicle collision. However, a bus accident carries the potential to generate far more patients than a car accident, depending on the capacity of the bus and the severity of the accident. Local resources may quickly become overwhelmed.

The nature of patient injuries may be specialized with school bus accidents representing a potential event involving pediatric mass casualties, whereas a charter bus may represent a geriatric mass-casualty event. Additionally, multiple bus accidents have occurred where large numbers of burn victims have been documented, creating need for aggressive airway management and resuscitation.

PITFALLS

Several potential pitfalls in response to a bus accident exist. These include the following:

- Failure to develop adequate mass-casualty protocols at the emergency services, hospital, community, and state level
- Failure to train community EMS personnel in specialized techniques for bus extrication
- Failure to educate schoolchildren and public transportation passengers regarding emergency exit operation and use
- Failure to anticipate a large number of trauma victims
- Failure to anticipate a large number of pediatric victims
- Failure to anticipate a large number of burn victims requiring definitive airway management
- Failure to inform National Transportation Safety Board or National Highway Traffic Safety Administration of bus accidents (of all severity) to provide better data and improve overall safety

Aircraft Crash Preparedness and Response

Dan Hanfling and Christopher R. Lang

DESCRIPTION OF EVENT

There are more than 27,000 commercial flights in the United States each day, making air travel one of the safest means of mass transportation per mile traveled.¹ Nevertheless, the crash of an airplane is often considered a major disaster and often generates significant interest for an extensive period of time. As current technologies improve, and the aviation industry tends to fly larger aircraft on longer flights, the need to prepare for the response to an air crash emergency remains a fundamental element of local disaster planning.² With over 850 airports in the United States handling regional, national, and international air traffic, the potential for response in any given community is more than just theoretical.

PREINCIDENT CONSIDERATIONS

Analysis of National Transportation Safety Board (NTSB) data with regard to aircraft size and the severity of injuries in “hull loss” events demonstrate a declining trend in aviation accident rates over time and an improvement in passenger and crew survival. This can be attributed to the increased use of wide-bodied, larger commercial aircraft. This allows for improved structural integrity, enhanced occupant protection mechanisms, improved fuel cutoff and fire extinguishing capabilities, and the suppression of toxic fumes from burning cabin materials.³ A review of 473 civilian airplane crashes with survivors between 1977 and 1986 demonstrated only eight crashes with more than 50 injured casualties of any degree of severity. Additionally, there were only three crashes in which more than 50 seriously injured casualties occurred.⁴ Another review of eight commercial aviation aircraft crashes in the United States between 1987 and 1991 revealed initial fatality rates ranging from zero to 46%. The number of injured passengers surviving the crash incident averaged over 60 passengers per event.⁵ However, the potential for significantly larger numbers of casualties rises as passenger payload capacity increases. An example of this occurred in Tenerife, Canary Islands, on March 27, 1977, when two fully loaded Boeing 747 jets

collided on the runway and burst into flames, killing over 500 people on the tarmac and critically injuring 60 passengers, many of whom later died.

A significant factor in the survivability of an airplane crash has to do with the aircraft conditions during and immediately after the crash event. An airframe that sustains an impact alone will likely yield many more survivors than an airframe that sustains impact followed by fire and explosion. Highlighting this point is the crash of Avianca Flight 52 in January 1990 on the north shore of Long Island, New York, after running out of fuel. There were 158 passengers on board, of whom 85 survived.^{6,7} The majority of passengers perished because of trauma, not because of fire or smoke inhalation. The risk to passenger safety increases exponentially with the presence of fire or explosion on impact. Even in what may be an otherwise survivable event, fire contributes to significant morbidity and mortality of passengers, primarily from the rapid incapacitation of passengers by heat, smoke, and toxic fumes. Review of the British Airtours Boeing 737 accident at Manchester International Airport on August 22, 1985, demonstrates that passengers died within 4.5 minutes of the emergency being declared, and probably within 2 minutes of smoke and flames entering the fuselage.⁸ This exemplifies the aggressive nature of fire and smoke within the confined space of the cabin and their devastating effects.

The final significant factor related to planning for air crash response is related to the location of crash events. The vast majority of aircraft accidents (85%) occur during takeoff and landings at an airport or occur within a 5-mile radius of the airport. Such statistics predicate the importance of both airport emergency operations planning, as well as off-airport planning, including water-based response plans for those airports adjacent to large bodies of water.

Under U.S. Federal Aviation Regulations (FAR Part 139.325), each airport operator must conduct a full-scale airport emergency plan exercise at least once every 3 years.⁹ This exercise ensures that responding agencies are familiar with their responsibilities under the plan and is intended to improve their proficiency in its execution. Response to aviation emergencies on the airport grounds

begins initially with the airport rescue firefighting (ARFF) resources, but will often quickly escalate to a mutual aid response event. In the event of an off-airport crash, the affected jurisdiction will have the initial responsibility for providing fire and rescue response. In today's environment of increased terrorist events, the deployment of a rocket-propelled grenade (RPG) fired at an aircraft becomes an intense concern. This was exemplified by the near miss of a rocket-propelled grenade on a departing Arka Airlines Boeing 757 departing from Mombassa, Kenya, on November 29, 2002. In the setting of current security risks, any aviation emergency is likely to be considered the result of terrorist action until proven otherwise. Therefore, responses to off-airport incidents are likely to include local, state, and federal emergency responders, including a large contingent of law enforcement assets.¹⁰ If an airport is located near or adjacent to water, the off-airport disaster planning must incorporate an offshore response strategy for a downed aircraft in the water. This response is likely to include airport-based water rescue resources and municipal, Coast Guard, and other Defense Department rotor wing and water-based rescue assets.¹¹

POSTINCIDENT CONSIDERATIONS

Regardless of the location of an air crash event, disaster operations are likely to follow four distinct operational phases (Box 166-1). The initial phase, *emergency response*, is primarily focused on life-saving, firefighting, and safety-related operations. It is during this phase that fire suppression, search and rescue, emergency medical care, traffic direction, and control and perimeter security are established. The first arriving emergency personnel will establish a Unified Command post and establish staging area(s) to provide on-scene management of the incident. Note that if there are multiple crash sites or if there is significant wreckage scattered over a large geographic area, it may be necessary to establish multiple Unified Command posts to provide effective command and control of the disaster scene. This element of aircraft disaster operations will be considered complete when the last surviving passenger(s) are transported from the scene and all life safety hazards at the crash site have been stabilized or eradicated.

The second phase of operations, the *transition and stabilization* phase, will often occur simultaneously with the emergency response phase and is intended to serve as a bridge between the initial response to the air crash event and the investigative and recovery aspects of the incident. It is during this phase that the disaster site

is assessed and long-term strategic and recovery plans are developed. This includes the anticipation of necessary staffing and resource requirements over time. In coordination with the local or state health departments, morgue operations are established, and provisions are made for requests made by the Chief Medical Examiner's office. It is also likely that personnel from the NTSB will begin arriving on the scene during this phase of operations. Finally, operational control of the scene is passed from fire department to police department authorities in anticipation of the next phase of operations.

The *investigation* phase, which begins at the conclusion of the stabilization of the crash site, may last for several days, weeks, or months and includes all aspects of the investigation to determine the cause and origin of the crash. The NTSB retains primary responsibility for coordinating all aspects of the investigation, with significant assistance provided by the Federal Aviation Administration; local, state, and federal law enforcement agencies; and representatives of the involved airline. The NTSB may assume direction and control of the "wreckage site" to conduct an investigation into the cause of the crash. This is accomplished in close coordination with law enforcement organizations to manage the incident scene. The NTSB also works with the airline carrier(s) of the plane(s) involved in the crash, other appropriate airline organizations, and local and state governments to coordinate federal resources that may be required to meet the needs of aviation disaster victims and their families. Family counseling, victim identification and forensic services, communicating with foreign governments, and translation services are among the provisions that can be made available to help local authorities and the airlines deal with a major aviation disaster.¹² The NTSB will lead the aviation crash investigation until it is determined to have been caused by a criminal act, at which point the Federal Bureau of Investigation is given the lead role in coordinating the crisis management response to acts of terrorism.¹³ In addition, the U.S. Department of Homeland Security may elect to send a representative to help coordinate the overall federal response to the incident.¹⁴

The final phase of the incident, the *recovery* phase, begins at the conclusion of the investigative phase and likewise may last for several days, weeks, or months. It begins with the transition towards normal flight operations. This assumes the completion of the clean-up operations at the crash site, the demobilization of staff, equipment, and other resources, and the finalization of all reports, incident records, and other documentation. It is completed by the preparation of an after-action report detailing all four phases of the operational response to the air crash event.

BOX 166-1 POSTINCIDENT OPERATIONAL PHASES

- Phase 1: Emergency Response
- Phase 2: Transition and Stabilization
- Phase 3: Investigation
- Phase 4: Recovery

MEDICAL TREATMENT OF CASUALTIES

The mechanisms of injury in aircraft accidents are primarily related to a combination of blunt, penetrating, and thermal injuries. More than one mechanism of injury is likely to coexist, resulting in multisystem traumatic

injuries. These injuries most often result from one of five major causes, which include explosive decompression, crush and entrapment, passenger restraint systems, burn and thermal exposure, and events associated with evacuation.

Rapid and explosive decompression may be one of the initial events occurring in a loss of aircraft integrity, leading to a crash. This can affect many organ systems including the lungs, sinuses, and gastrointestinal tract. These air-filled structures are predisposed to injury resulting from barotrauma. Lung injuries are the most serious and are due to rapidly increasing positive pressure leading to tearing of lung tissue and subsequent pneumothorax. In addition, traumatic sinus rupture and tympanic membrane rupture can result from increased pressure in the sinuses. Finally, gastrointestinal effects can lead to possible bowel perforation and ventilatory compromise due to elevation of the diaphragm.

Crush and entrapment within the airframe wreckage are also highly likely to result in post-incident casualties. When a plane impacts a surface, there is compression of cabin space that can lead to entrapment and probable crushing. Many injuries seen are fractures, head and neck trauma, and rhabdomyolysis. In addition, the presence of fire, smoke, and water introduce the additional risk of morbidity and mortality related to thermal injuries or drowning.

Passenger restraint systems may cause patterns of injury similar to those seen in motor vehicle crashes; however, the velocity of the impact is greatly increased. This leads to a high incidence of blunt force injuries to the head, thorax, pelvis, and abdomen, in descending order of frequency. Examples include epidural and subdural hematoma, aortic dissection, solid organ lacerations, and pelvic fractures. The lack of shoulder restraints with lap belts allows for greater bodily movement and risk for injury. In addition, untethered objects within the cabin may become projectiles, resulting in blunt or penetrating injuries.

Thermal and burn injuries present a major cause of death from survivable impact. This is due to the confined space of the aircraft and the inability to egress in rapid fashion. Toxic fumes, especially carbon monoxide, pose a major risk (Table 166-1). In a study of military aircraft fatalities occurring between 1986 and 1990, 535 cases were analyzed for carboxyhemoglobin. There were 23 cases (4%) having elevated levels of carboxyhemoglobin (above 10% saturation.) In each case, the victim survived the crash and died in the post-crash fire.¹⁵

Finally, there are many injuries resulting from the evacuation of the aircraft. The crash environment will be chaotic, often with significantly hampered visual perception and significant risk posed by collisions with other passengers or exposed wreckage. Fractures, sprains, and soft tissue injuries predominate. In addition, flash and chemical burns from either jet fuel or hydraulic fluid may pose significant exposure risks.

Specific patterns of injuries in survivors can be divided into three major categories. Fractures are the most common injury, representing close to one quarter of all injuries¹⁶ (Table 166-2). They range from isolated closed fractures requiring minimal medical attention to

TABLE 166-1 MANIFESTATIONS OF CARBOXYHEMOGLOBIN

PERCENT COHB	MANIFESTATIONS
<10	None
10	Shortness of breath (SOB)—vigorous exertion
20	SOB—moderate exertion, slight headache
30	Headache, irritability, easily fatigued, disturbed judgment
40-50	Headache, confusion, collapse, fainting
60-70	Unconsciousness, respiratory failure, death on long exposure
80	Rapidly fatal
>80	Immediately fatal

Data adapted from Klette K, Levine B, Springate C, et al. Toxicological findings in military aircraft fatalities from 1986-1990. *Forensic Sci Int.* 1992;53:143-8.

complex vertebral, pelvic, and open long bone fractures that are often associated with hemodynamic instability and the potential risk from fat embolism. Thermal and burn injuries are another major cause of morbidity in surviving passengers, including the risk of inhalation injury to the airway. Finally, blunt and penetrating trauma to intrathoracic and intra-abdominal organs can result in major bleeding and shock. These are usually related to direct impact or the movement of large objects within the cabin postdisaster.

Some key issues identified by after-action review of Sioux City, Iowa, crash response include the following^{17,18}:

- No identified entry and exit way was available for emergency vehicles. This caused some traffic jams and indecision regarding how to exit the area.
- There was inadequate emergency equipment and resource management. Ambulances had extra equipment including include portable oxygen, intravenous

TABLE 166-2 DISTRIBUTION OF NAVY AND MARINE CORPS AVIATION ACCIDENT INJURIES BY DIAGNOSTIC CATEGORIES

DIAGNOSIS	PERCENT OF TOTAL INJURIES REPORTED
Fracture/dislocation	22.8
Contusion	16.1
Laceration	12.3
Abrasion	8.3
Thermal burn	7.9
Sprain/strain	7.6
Multiple extreme injuries	6.3
Amputation/avulsion	3.6
Hemorrhage	2.4
Perforation/rupture	2.1
Concussion	1.1
Crushing	1.1
Decapitation	1.1
Miscellaneous	7.3

Data taken from Table 25-1 in Aircraft Accident Autopsies from *United States Naval Flight Surgeon's Manual: The Virtual Navy Hospital Project*. 3rd ed. Chapter 25. 1991. Available at: <http://www.vnb.org/FSManual/25/04Autopsy.html>.

CASE PRESENTATION: UNITED FLIGHT 232, JULY 19, 1989

United Airlines Flight 232 departed from Denver Stapleton International Airport for Chicago O'Hare International with 296 passengers onboard. It was a clear day without any weather restrictions. One hour and 17 minutes into the flight, there was a catastrophic failure of the tail-mounted engine (#2) that led to loss of hydraulic systems, virtually paralyzing the aircraft. The plane declared an emergency at 3:20 p.m. near the Sioux City, Iowa airport. Five minutes before crash impact, there were five airport rescue firefighting companies and four local fire engine companies positioned just outside the airport perimeter, awaiting the arrival of the crippled aircraft.

At 4:00 p.m., the plane touched down with the right wing making first impact with the ground. The plane's fuel reserve then ignited, and the aircraft flipped end over end as it ran off the runway into an adjacent cornfield. The tail section was completely severed from the rest of the aircraft. The main cabin and cockpit tumbled forward, finally resting in the inverted position 3700 feet from impact area. Fires and smoke erupted everywhere, and survivors alighted from the crashed plane, screaming for help.

There were over 26 different agencies involved in the response to the crash at the Sioux City airport. Out of 296 passengers and crew, 112 died in the crash. Thirty-five of those deaths were from asphyxia secondary to smoke inhalation (Table 166-3).¹⁷ The number of casualties was greatly minimized by the rapid-fire suppression response. After the fires were controlled, the triage of patients was initiated. The emergency medical service response to the event included the transport of 196 patients to hospitals within 90 minutes of the crash impact using ambulances, helicopters, buses, and vans.

supplies, and pressure dressings that would have been tremendously valuable to the on-scene response. However, these were not left on scene and remained on the individual transport units.

- Uncoordinated release of public information led to inconsistent reporting by media and news organizations.
- Fire engine water pump failure resulted in 10 minutes without adequate supply.
- There was an unknown number of passengers. Children who sat on a guardian's lap were not counted on the passenger manifest.

TABLE 166-3 INJURIES TO UNITED FLIGHT 232 PASSENGERS

INJURIES	CREW	PASSENGERS	TOTAL
Fatal	1	110	111
Serious	6	41	47
Minor	4	121	125
None	0	13	13
Total	11	285	296

Data adapted from National Transportation Safety Board Aircraft Accident Report PBSO-910406NTSB/AAR-SO/06 United Airlines Flight 232, Sioux Gateway Airport, Sioux City, Ia: July 19, 1989. Available at: <http://amelia.db.erau.edu/reports/ntsb/aar/AAR90-06.pdf>.

- Many different languages were spoken without available interpreters, leading to miscommunication during the rescue efforts.

UNIQUE CONSIDERATIONS

Given the significant risk of repeated terrorist attack in the United States, the response to all air crash events will necessarily invoke a significant law enforcement component, particularly in the initial investigative phase of the event. Such a response was exemplified by the response to the TWA Flight 800 crash off the southern coast of Long Island, New York, in the summer of 1996, and more recently, the crash of American Airlines Flight 587 immediately upon takeoff from New York Kennedy International Airport in October 2001. The implication of such a response is that surviving patients brought to the hospitals may eventually need to undergo law enforcement questioning and evaluation. All clothing and other personal items transported with the patient from the disaster scene must necessarily be considered as evidence and therefore must be collected and stored according to agreed-upon procedures, in conjunction with local law enforcement officials. There is an important caveat regarding the presence of firearms or other weapons that may be found on the person of surviving passengers. These would have traditionally been associated with possible hijackers. However, with the reintroduction of armed federal air marshals on board an increasing number of flights, particularly those departing or arriving from key high-threat urban areas, such weapons may in fact be attributable to law enforcement personnel.

PITFALLS

Most disaster scene triage decisions are predicated upon the application of the Simple Triage and Rapid Treatment (START) triage decision-making algorithm. This system is primarily based on the recognition of bodily injuries and the categorization of patients into categories of priority based on specific physiologic criteria, including airway, breathing, and circulation considerations. This is a system that is focused on the treatment and transport of the most emergent patients first, followed by those patients with injuries requiring less urgent attention. It involves a color-coded system that is used to rapidly triage patients into their respective injury status.

And although this triage approach works for the majority of mass-casualty situations, it needs to be adapted for use in air crash disasters, particularly those in which there has been a fire or explosion. Patients who may present with only mild throat irritations, without any other injuries, would likely be placed in the lowest transport priority group. However, such symptoms may be the harbinger of a more serious developing inhalation injury, either due to an explosion and fire through the passenger cabin, exposure to toxic fumes, or aspiration of water or toxic fluids in the event of a water ditching. Such patients must be automatically upgraded in

response category and transported away from the scene in a more rapid manner. These patients may possibly benefit from early aggressive airway management if the index of suspicion of an inhalation injury remains high based on the assessment of the initial out-of-hospital care providers. This exemplifies the need for constant reevaluation and possible changes in triage and treatment status.

Air Show Disaster

Peter D. Panagos

DESCRIPTION OF EVENT

Typically, an air show is a summertime event during which aviators display their flying skills and aircrafts. Although some air shows are held for commercial purposes, many are arranged to raise funds for charities. Usually air shows occur at military or large civilian airfields, located near the coastline or large cities in which a variety of static aircraft and helicopters are on view. When space allows, other entertainment and market stalls are available, adding further to the attraction of the show. Flight performances by military aerobatic teams and civilian aerobatic aircraft as well as large-scale pyrotechnics are presented to attract larger crowds. Due to the public interest in aviation, crowds at a typical air show can range from a few hundred to tens of thousands of attendees.

A disaster at an air show is a multiple-casualty incident in which the primary effects are morbidity and mortality to persons, while the community infrastructure remains intact. Over the last 30 years, there have been air show accidents involving performing aircraft that have caused a significant number of casualties (Table 167-1). Because of the possibility of mass casualties due to ground accidents, aviation mishaps, or terrorism, pre-event planning, incident response, and the post-event reaction must be thoroughly planned to effectively manage any potential situation.

PREINCIDENT ACTIONS

Preparations should include the continuum from basic event planning such as addressing the sanitation needs of a large crowd to planning for area evacuation in case of a large-scale aviation mishap involving significant casualties and a hazardous materials risk.¹⁻⁸ An effective disaster plan will identify potential problems by performing a risk analysis of chemical and environmental hazards,⁷ personnel and physical resources, and transportation elements available to the planners (Box 167-1). Once a plan has been outlined, it must be evaluated for effectiveness and completeness through the implementation of a disaster drill.

A thorough mishap plan includes contingency arrangements with appropriate activities for rescue, fire-fighting, explosive ordnance disposal, logistical support,

medical support, coordination with public affairs/media, coordination with law enforcement officials, wreckage location, security, recovery and preservation, and notification of key personnel.⁹ Disaster preparedness officials have long recognized the value of good training and exercises. Most of the principles of disaster planning are based on the painful lessons learned under actual catastrophic conditions.¹⁰ Exercises provide the opportunity to learn how to perform in realistic and controlled settings that are relatively free of risk.

POSTINCIDENT ACTIONS

In any unannounced event, the alert mechanism must be expeditious because the survival of severely injured individuals is often time sensitive. In an air show disaster involving ground casualties on the airfield, knowledge of the disaster will often be immediate. Notification of a crash may come over primary or secondary communication networks, and a crash message is disseminated to include aircraft type, nature of emergency, location of crash or landing runway, number of persons on board, hazardous cargo, potential ground casualties, and other pertinent information. If there are survivors at the scene, the urge to charge in to render care should be avoided. Trained rescue teams will bring casualties to a safe area or allow the medical team into the area when it is safe.

When multiple casualties are involved, a system of triage may be needed.³ Specific areas for casualty management should be predesignated with standard nomenclature. It is the medical leader's responsibility to keep the Incident Commander abreast of numbers and types of casualties, the need for additional support, and any other facts the command post needs to make decisions.^{11,12}

If an aircraft crashes in a remote setting, all responding personnel from the airfield will proceed to a prearranged assembly point for convoy to the area. In any disaster, medical personnel should enter the area only when it is declared safe.

Once the survivors have been taken care of and the remains of the deceased secured or removed, an assessment of the adequacy of response should be made as soon as possible to include supplies and equipment eval-

TABLE 167-1 FATAL CRASHES AT AIR SHOWS OVER THE LAST 30 YEARS

DATE	LOCATION	DESCRIPTION	NO. OF PERSONS INJURED/KILLED
July 2002	Western Ukraine	Russian Sukhoi Su-27 performing maneuvers crashed into crowd	84/115
June 1999	Bratislava, Slovakia	British Royal Air Force Hawk 200 crashed during air show	1/1
July 1997	Ostend, Belgium	Light aircraft mounting an aerobatics display crashed into crowd around a Red Cross tent	9/57
September 1997	Chesapeake Air Show, Glenn L Martin State Airport, Baltimore, MD	F-117A crashed during flyby	5/0
August 1988	Ramstein Air Force Base, West Germany	Three Italian Air Force jets collided midair and crashed into crowd	70/100s
June 1988	Mulhouse-Habsheim, French-Swiss border	New Airbus A320 crashed during low-level demonstration flight	3/133
September 1982	Mannheim, West Germany	U.S. Army Chinook helicopter carrying multi-nation sky divers crashed	46 killed
June 1973	Paris, France	Prototype Russian Tupolev Tu-144, a supersonic airliner, dubbed "Concordski" exploded midair during Paris air show	15 (6 crew, 9 ground)

uations (e.g., too little? inappropriate? not available?) and personnel (e.g., adequately training? management performance?). These evaluations should be used to make changes in the disaster response plan and improve future response.

The psychological impact of the mishap on the response team members and the community should not be overlooked. A critical incident debriefing or other intervention by mental health workers should be considered for the responding or on-site workers.^{13,14} Other interventions must be considered for family and friends.

MEDICAL TREATMENT OF CASUALTIES

In any large-scale disaster, once the site has been deemed safe, the next priority is the triage, treatment, movement, and evacuation of casualties. During an air show without a mass-casualty event, the types of injuries and illnesses treated vary based on meteorologic conditions and geographic location. The conditions encountered are typical complaints seen in emergency departments such as dehydration, intoxication, sunburn, animal/insect bites, trips/falls, exacerbation of chronic illness, and altercations.¹

In the event of an aircraft crash involving ground personnel, the potential for multisystem life-threatening injuries increases. In many aircraft accident fatalities, the injuries appear extensive from multiple trauma, burns, or both. Explosive and blast injuries involving penetrating and blunt trauma will result from the sudden deceleration of the airframe into the ground with ignition and disbursement of aircraft flammable materials and ordnance. Explosive-related injuries will affect most organ systems and produce unique patterns of injury seldom seen outside the combat arena. The management of these injuries in the field will often be limited to triage, stabilization, and transportation to an appropriate level of care.¹⁵⁻²¹

If the aircrew successfully exits the aircraft, rescue personnel should be aware of human impact injury patterns.

Although aircraft structures are designed to improve crash survivability, the human tolerance to deceleration and postcrash explosions is a complex function of many factors.²²⁻²⁴ Based on Armed Forces Institute of Pathology injury analysis, there are four major injury types to be considered: thermal, intrusive, impact, and deceleration.^{22,23,25} Though protected by flame retardant clothing, aircrew often sustain thermal injuries secondary to ignition of aircraft fuel and materials, inhalation of soot and combustion products including carbon monoxide, skin and soft tissue burns, soft tissue contraction and charring, thermal fractures and amputations, and severe burns. Intrusive injuries from the loss of occupiable space due to the intrusion of main rotor blades, propellers, trees, or wires are also common causes of severe injury. Finally, impact and deceleration forces cause injuries based on the position during deceleration and the distribution of force over the body parts (Table 167-2). For example, the pilot who ejects before impact may survive but may sustain extremity fractures resulting from the violent extremity movements involved in a high-speed ejection.

Aircraft wreckage sites can have multiple hazards. Personnel involved in the recovery, examination, and documentation of wreckage may be exposed to physical hazards posed by such things as hazardous cargo, flammable and toxic fluids, sharp or heavy objects, and disease. Hazardous materials, such as cartridge-actuated devices, tires, and oxygen bottles are major concerns. Explosive ordnance disposal personnel should target items such as pressurized bottles, hydraulic reservoirs, and canopy detonation cord to secure the scene and prevent further injury.^{9,24,26-33}

Finally, once all injured or trapped victims have been cleared from the crash site, the area should be considered a crime scene. Wreckage and cargo should not be disturbed or moved except to the extent necessary for personnel safety. Arrangements should be made for security at the accident scene to protect the wreckage from additional damage and to protect rescue personnel and the public from injury.

BOX 167-1 PRE-AIR SHOW RISK ANALYSIS

Security Requirements

- Isolation of air show and base operations
- Terrorism/vandalism/theft concerns

Parking Plan and Traffic Control

- General public
- Handicapped
- VIP
- Crowd arrival and departure plan

FAA Coordination

- Schedule practice for dynamic shows
- Airspace coordination

Emergency Planning and Drills

- Published and practiced
- Community resources informed

Communications and PA System

- Many methods and backup communication systems available
- Phonebook of key personnel and services

Crowd Control Barriers

- No-smoking signs in hazardous areas
- Parking away from sensitive areas

Pedestrian Concerns

- Trip hazards
- Sound and sun mitigation options
- Comfort stations
- Lost-parent stations
- Published safety guidelines
- Medical response plan

Medical Response Plan

- First-aid stations clearly identified
- Medical personnel placed in crowd
- Airfield and local EMS transportation
- LZ identified for rotary ring evacuation

Restroom Facilities

- Sufficient numbers for crowd
- Contract for routine cleaning
- Handwash stations

Vendor Setup

- Area and infrastructure available to support

FAA, Federal Aviation Administration; PA, public address; EMS, emergency medical services; LZ, landing zone.

UNIQUE CONSIDERATIONS

Most advanced military aircraft contain composite structures consisting of light, strong, stiff fibers embedded in a matrix material. Although these materials offer a significant structural advantage, they present a danger to rescue and medical personnel. Studies have shown that composite fibers can cause mild short-term skin, eye, and respiratory problems, but the long-term carcinogenic potential is unknown. Therefore, prudence is required in using personal protective equipment.

The reinforcing fibers most commonly used in aircrafts are graphite, bismaleimide, and boron fibers (such as Kevlar). For example, in the F-18A/B, there are 1000 lbs (or 9.8% total aircraft structural weight) of composite material.²² These fibers, when released from an epoxy matrix, become fine splinters that can easily be driven into the skin and will cause irritation. Graphite fibers

TABLE 167-2 DECELERATIVE INJURIES AND APPROXIMATE G FORCES INVOLVED

BODY PART/INJURY	DECELERATIVE FORCE (G)
Pulmonary contusion	25
Nose fracture	30
Vertebral body compression	20-30 (less in thoracic region or if poor body position)
Fracture dislocation of C-1 or C-2	20-40
Mandible fracture	40
Maxilla fracture	50
Aorta intimal tear	50
Aorta transection	80-100 (at ligamentum arteriosum)
Pelvic fracture	100-200
Vertebral body transection	200-300 (through body, not intervertebral disc)
Total body fragmentation	350
Concussion	60 G over 0.02 sec 100 G over 0.005 sec 180 G over 0.002 sec

Adapted from *The U.S. Naval Flight Surgeon's Pocket Reference to Aircraft Mishap Investigation*, 4th ed. Pensacola: The Naval Safety Center, Aeromedical Division in conjunction with The Society of United States Naval Flight Surgeons; 1995.

CASE PRESENTATION

It was supposed to be the grand finale to a beautiful, family day event; then everything went wrong for the low-flying Russian-built Sukhoi Su-27, a 5.5-ton supersonic fighter aircraft (a long-range air fighter comparable to the U.S. F-15). More than 1500 people watched the free air show, part of celebrations to mark the 60th anniversary of a local Air Force unit. Witnesses said the jet was performing complex aerobatic maneuvers before it reportedly lost power, clipped some trees and another plane, cartwheeled across the ground, and crashed into a huge fireball. The two-pilot crew safely ejected from the aircraft before the plane hit the crowded spectator stands. As one witness stated, it was "a huge ball of fire, as big a house, and black smoke... I barely had enough time to clutch my young daughter before the explosive wave threw us to the ground, and severed arms and legs were flying all over." In all, 84 persons were killed (26 were 18 years of age or younger), and more than 116 were hospitalized with various injuries.

The crash of the fighter jet was caused by pilot error, an official report into the incident has concluded. The head of the commission set up to investigate the crash said the pilots had failed to follow the flight plan and performed difficult maneuvers they had not done before. Additionally, operational issues, organizational problems, and a lack of safety measures had contributed to make it the world's worst air show disaster. These events occurred at Sknyliv Airport, near Lviv, Ukraine, on July 27, 2002.

are very small and light and pose a respiratory threat similar to asbestos. While the aircraft is still burning or smoking, only firefighters should be in the immediate vicinity. Once the fire is completely extinguished and cooled, the composite material is normally sprayed with a fixant, such as polyacrylic acid or aircraft firefighting

foam to contain release of composite fiber material. Finally, it is recommended that all personnel around the released fibers wear a National Institute for Occupational Safety and Health–approved disposable air-filtering mask, Tyvek disposable overalls, puncture-resistant gloves and goggles while on scene and take a shower before leaving the scene.^{22,25,29,30}

Additionally, the risk of being exposed to blood and body fluids is possible in any mishap involving human injury. Human immunodeficiency virus, hepatitis B, Lyme disease, and tetanus pose a threat to rescue personnel. Hepatitis B virus can survive in a dried state for several weeks. Therefore, it is recommended that all crash scene rescue and medical personnel become familiar with potential on-scene hazards, adhere to Occupational Safety and Health Administration work practice controls,³¹ and make use of personal protective equipment.³²

PITFALLS

Several potential pitfalls in response to an air show disaster attack exist. These include the following:

- Failure to identify, prepare for, and properly train for a mass-casualty event by not developing contingency plans and periodically reviewing and correcting errors in the plans
- Failure to plan for the medical needs of a mass gathering composed of both geriatric and pediatric persons, many with significant preexisting diseases, exposed to a wide range of environmental elements and stresses unique to an airfield
- Failure to recognize the unique injuries sustained by ground personnel from explosive-related forces in close proximity to an aircraft crash
- Failure to appreciate that emergency responders may become casualties themselves if they do not recognize the hazardous dangers of a modern aircraft crash scene containing composite materials, biologic hazards, and unexploded ordnance. (Use of personal protective gear is paramount to avoid responder injury.)
- Failure to recognize the unique injury patterns of aircraft crash survivors who have experienced sudden deceleration forces (high G) and exposure to hazardous materials

Asteroid, Meteoroid, and Spacecraft Reentry Accidents

Jay Lemery and Faith Vilas

DESCRIPTION OF EVENT

From its origins 4.6 billion years ago, the natural history of our planet is replete with evidence of extraterrestrial impacts. Comets, asteroids, and meteoroids are the cosmic “impactors” that are theoretically both the originators (first organic molecules) and destructors (demise of the dinosaurs) of terrestrial life.^{1,2} Evidence of these impacts on our world remains, for example, in the mile-wide meteor crater in Arizona and in the impact site off the coast of the Yucatan Peninsula, believed to have caused the extinction of the dinosaurs 65 million years ago. Impacts of such magnitude are exceedingly rare, yet even less than 100 years ago, a small meteoroid 60 m in diameter is thought to have exploded 8 km over a sparsely populated region of Siberia, leveling all vegetation for hundreds of square kilometers. Most meteoroids incinerate while entering Earth’s atmosphere, as can be witnessed by any falling star on a clear night. In fact, about 100 tons of cosmic material fall to Earth daily, mostly in the form of tiny dust particles.³ As our understanding and interaction with the cosmos has broadened over the last few decades, we have realized that there are quantifiable risks from impactors to humanity, ranging from locally traumatic to globally cataclysmic. We will address these events as three distinct entities:

1. Local-effect near-Earth object (NEO) impacts
2. Global-effect NEO impacts
3. Artificial orbital debris reentry

The risk posed by an impactor is directly proportional to its size² (Table 168-1). Those less than 50 m in diameter will most likely incinerate. Impactors 1 to 2 km in diameter will devastate the area surrounding the impact site. Impactors larger than 2 km in diameter have the potential to cause obliterative local damage, as well as displace large amounts of dust into the stratosphere. The consequent effects would resemble a “nuclear winter,” affecting the entire globe, changing entire ecosystems with a resultant drop in global temperature, loss of agricultural productivity, and possible societal breakdown.² Since over 70% of the Earth is covered with water, an

ocean impact could cause tsunamis with inland flooding extending tens of kilometers into the coastal plains.

Orbital debris, the artificial residual of the last 40 years of human endeavors into space, is another source of a potential terrestrial impactor. According to the U.S. Air Force Space Command, there are currently over 8900 objects orbiting Earth.⁴ Although the vast majority of orbital debris pieces incinerate upon reentry, some components could survive, whether due to heat-resistant material (e.g., shuttle tiles) or a design that sheds heat fast enough to keep object temperatures below the component’s melting point. As the *Columbia* space shuttle tragedy demonstrated, controlled reentry can fail, in which case suborbital debris would be expected to survive reentry in greater quantity with a commensurate impact potential on life and property.

PREINCIDENT ACTIONS

Asteroids and comets are classified as NEOs when they orbit close to the sun (and therefore Earth). NEOs of interest to astronomers addressing the impact hazard are those greater than 150 m in diameter that pass Earth within 1.3 times the average distance from the sun to Earth (93 million miles). The National Aeronautics and Space Administration (NASA)’s goal is to discover 90% of all NEOs with a diameter more than 1 km by 2008.

As of spring 2004, 2883 NEOs have been discovered: 719 of these are asteroids with diameters larger than 1 km, and 607 have been classified as potentially hazardous asteroids. The risk of impact by any specific potentially hazardous asteroid is extremely small, on the order of 10 to 100 times less than the annual risk of a single person being struck by lightning.⁵

NEOs 50 to 1000 m in Diameter

An impactor with a diameter larger than 50 m will reach Earth’s surface on average once every 100 years. The composition of the impactor could determine the extent and type of local damage. If the object has less physical coherence, such as a loosely bound, low-density comet

Environmental perturbations caused by the impacts of asteroids and comets. *Rev Geophysics*. 1997;35:41-78.

body containing ice, it might not remain whole prior to impact and could explode in the atmosphere over Earth's surface. Scientists believe this happened in the *Tunguska* explosion over Siberia on June 30, 1908.

Generally, the diametrical sizes at which incoming objects will break apart when they enter Earth's atmosphere are 540 m for icy objects, 330 m for rocks, and 200 m for solid iron. These objects will change shape, flattening out to 5 to 10 times their original diameters because of the immense heat and pressure generated as they pass through the atmosphere. A surface impact will excavate material dependent on incoming velocity and angle of impact, resulting in a crater 10 to 25 times the size of the impactor. One model estimates that the 40-km-diameter Puchezh-Katunsky crater in Russia was created by a 2-km diameter rocky asteroid moving at a velocity of 20 km/sec with a 45-degree angle of impact.^{6,7,8} This impact destroyed near-surface layers of land to a depth of 100 m up to 40 km from the center of the impact.

Impactors less than 1 km in size are expected to have locally devastating effects, including total destruction within the resulting crater, thermal radiation surface fires, air blast compression, tidal wave flooding of low-lying areas, and compression wave injuries well beyond the crater zone. An event such as the *Tunguska* explosion might have occurred with minimal impact on humanity; however, if delayed by only a few hours, the more populous regions of Europe (and millions of lives) would have been in jeopardy.

NEOs 1 to 2 km in Diameter

Impacts from NEOs larger than 1 km in diameter are thought to occur, on average, every few hundred thou-

sand years. NEOs of this size can have globally devastating effects; the resulting crater could reach 50 km in diameter. Debris would be launched into the stratosphere, blocking sunlight and threatening agricultural production globally. Super-heated impact debris would rain back down on Earth's surface. An ocean impact would produce flooding tens of kilometers inland. Although rare, we have witnessed such an impact in the last decade within our solar system. The comet Shoemaker-Levy 9 impacts on Jupiter in 1994 were a series of 20 discernible impact fragments ranging up to 2 km in diameter. Had this comet hit Earth, it would have killed billions of people and risked most species on our planet.⁹

NEOs 10 to 15 km in Diameter

NEOs 10 to 15 km in diameter will strike Earth even less frequently, on the order of once every 500,000 years. Global "earthquakes" from the impact, tsunamis, and total destruction over hundreds of kilometers would culminate in nuclear winter that would ensue for decades. The effect of such an impact would result in major global climate change, such as that which triggered the demise of the dinosaurs.

Orbital Debris

Orbital debris is the artificial byproduct of the last 50 years of human endeavors into space. According to U.S. Strategic Command, orbital debris can be categorized as 7% operational satellites, 15% rocket bodies, and about 78% fragmentation and inactive satellites.⁴ The further degradation of these objects is facilitated by solar heating

and solar radiation, component explosions, and debris collisions. Motor casings, aluminum oxide exhaust particles, motor-liner residuals, release bolts, solid-fuel fragments, paint chips, and insulation are only some of the 70,000 objects approximately 2 cm in size that have been observed at altitudes 850 to 1000 km above Earth (Space Shuttles and the International Space Station orbit at 340–400 km).¹⁰

Although the intense pressure and heat of reentry will incinerate much of the mass of orbital debris, some satellite components can withstand this process. Components that have a sufficiently high melting temperature or a shape that allows rapid heat dispersal will have a higher probability of persisting. When debris pieces enter the lower regions of the atmosphere, they will lose velocity, begin to cool, and fall virtually straight down from the sky at relatively low speeds (terminal velocity); these are clearly a potential hazard to life and property.

Although NASA attempts to track orbital debris and predict where debris from a randomly reentering satellite will hit Earth, it is an uncertain science: the atmospheric density varies greatly at high altitudes, thus confounding the calculation of reentrant drag. Other confounding factors include variations in the gravitational field, solar radiation pressure, and atmospheric drag. The predicted time to reentry is generally accurate to within 10% of the actual time, although this translates to a margin of error of several miles on the ground. Over the last 40 years, more than 1400 metric tons of materials are believed to have survived reentry without report of injury.⁴

In the event that Earth becomes at risk of being hit by a moderate to large impactor, we would likely know well in advance, perhaps by several years to decades. There would be an immediate, intense psychological reaction in the public, with likely intense media coverage and speculation. An incredible challenge would be posed to scientists, public health officials, and political leaders to relay the known risks and possible solutions to the public accurately. A discordance between calculated risks and publicly perceived risks can be expected, contributing to widespread fear and even mass hysteria.¹¹ Familiar doomsday scenario patterns of behavior are likely to emerge on the fringes of society. Mental health providers could expect an increase in anxiety, depression, or both among a large portion of the population.

POSTINCIDENT ACTIONS

As previously discussed, the risk of damage of an impactor is related to its size, and casualties and property damage should be treated as patients would be in other mass-casualty incidents.

Meteorites are classified as “irons” (nickel-iron metal) or “stones.” *Stones* can be divided into two subgroups: chondrites and achondrites. *Chondrites* (about 86% of stones) are aggregates of early solar system materials that have not been significantly altered since formation of the solar system. *Achondrites* (about 8% of stones) are the products of melting and recrystallization of mostly magnesian silicates. One percent of meteorites are a conglomerate of those two types (called *stony irons*).

When a meteorite strikes, it does so at terminal velocity and has therefore cooled from the intense temperatures of atmospheric entry. The outer layer, or fusion crust, is usually 1 to 2 mm thick, the rest having burned off during entry and generally posing no risk of burn from contact (silicate materials are traditionally poor conductors of heat). There are reports of eyewitnesses picking up an object that has fallen, cracking it in two, and discovering ice particles. Meteorites are composed of materials that are abundantly found on Earth and pose no toxic or radiation risk.

Historically, the controlled reentry of large components of artificial orbital material (Skylab, Mir) has been directed to remote, uninhabited parts of the planet (oceans). As seen with *Columbia*, however, spacecraft components can return to Earth relatively intact. Beyond the risk of impact, they can pose a toxicologic risk. Rocket propellants such as hydrazine and nitrogen tetroxide pose a chemical burn and inhalation risk. Structural materials such as beryllium have been known to cause pulmonary damage. Other potential hazards include ammonia, radiation sources (e.g., radioactive altimeters, live ordnance (e.g., pyrotechnics for emergency hatch opening), and other exotic compounds (e.g., scientific payloads, solar arrays, environmental control items such as lithium perchlorate and permanganate). Currently, there are no known nuclear-powered devices (e.g., powered by uranium) in orbit.

Once an orbital debris piece is committed to a reentrant trajectory, it will fracture and scatter over a predictable pattern based on mass. The “footprint” of debris will consist of heavier objects at the “heel” of the footprint and lighter objects at the “toe.”

In the certain cases of reentry events, forensic and possibly national security concerns will necessitate the mobilization of law enforcement personnel across several jurisdictions. As seen with *Columbia* in 2002, a concerted effort between law enforcement agencies in several states and NASA, coupled with direct appeals to the public, were initiated to preserve the integrity of the debris sites and to preclude souvenir hunters from disturbing debris fields. In such cases, mobilization of the military (national security concerns or naval salvage) may be deemed necessary, as well as international coordination if debris fields cross national borders.

MEDICAL TREATMENT OF CASUALTIES

There is nothing unique to the medical treatment of casualties from the events discussed in this chapter. Blunt trauma is the likely mechanism of smaller impactors, expanding to burn and blast injuries for larger impactors. For large-scale impactors approaching the 1-km-diameter mark, humanitarian/refugee crises will be a major concern.

Psychological treatment will be another important consideration in any impactor scenario. Often even the smallest meteorite impacts are covered widely in the news media and may trigger anxiety and concern in otherwise unaffected portions of society. Mental health will

be a major concern in the event of an orbital debris impact involving the loss of life. The scope of such a tragedy on the national psyche can affect all segments of the population, and there is a risk of the infliction of depression and posttraumatic stress disorder.

Special concern should be made for those suffering personal loss. Despite efforts to shield them from further anguish, astronauts and other NASA staff (not unlike the New York City firefighters after the World Trade Center bombings on September 11, 2001) played a major role in the search for the remains of *Columbia*, prompting concerns of exacerbating already severe mental trauma.

UNIQUE CONSIDERATIONS

Perhaps unique to this chapter is the potential scope of the disaster. If an NEO larger than 1 to 2 km in diameter was identified as a probable Earth impactor, the need for international coordination would be unprecedented. The logistical scope of such an endeavor would be daunting. Whereas protocols are in place among astronomic groups to verify impactors and their risks before a public announcement, the ramifications of living in the age of the Internet could easily unglue efforts to sequester such proceedings. Initial efforts would likely focus on understanding the shape, configuration, mineral composition, and spin state of an impactor. These characteristics would further clarify risk and, potentially, a strategy for deflection using existing technology of conventional rockets and explosives.¹² Future strategies could include attaching solar sails or engines to the NEO to deflect its path.

A final consideration should be mentioned. As space-related technology proliferates and becomes more accessible over the next decades, satellites and space vehicles may become susceptible targets for terrorists, particularly as an impactor over urban areas, power/chemical complexes, or military targets.

PITFALLS

One pitfall that should be anticipated with any impactor event is relying on uninterrupted global communication. The effects of an impactor entering the ionosphere may disrupt satellite communication and possible security net-

works. It is reported that those who have observed meteor “fireballs” before impact experience a metallic taste sensation, possibly due to an electromagnetic disturbance.

Building Collapse

Catherine Y. Lee and Timothy Davis

DESCRIPTION OF EVENT

The attacks on Sept. 11, 2001, shocked the American public with the destruction of the World Trade Center towers. It also brought to the forefront of disaster medicine the danger of building collapse, or *progressive collapse*, a principal if not the leading cause of injury and death in building failures.¹ In the engineering world, progressive collapse has been studied for 40 years since the 1968 Ronan Point disaster.² Progressive collapse is a “chain reaction of structural failures that follow from damage to a relatively small portion of a structure” or “the spread of an initial local failure from element to element that eventually results in the collapse of an entire structure or a disproportionately large part of it.”^{3,4} Simply stated, progressive collapse is a “domino effect,” causing the sequential collapse of one floor on top of lower floors.³ In this chapter, the terms *building collapse*, *structural collapse*, and *progressive collapse* are used interchangeably.

There are six causes of building collapse: bad design, faulty construction, foundation failure, extraordinary loads, unexpected failure, and a combination of these causes. Some causes of bad design are errors in engineering computation, failure to consider all stresses and weights, reliance on inaccurate data, and poor choice of materials.⁵ Faulty construction may be the most common reason for building collapse around the world. It results from the use of inferior steel, bad riveting, infirm fastening and securing, and bad welds.⁵ In the case of foundation failure, the earth beneath a building may be unsuitable to support the weight of the building. Such is the case during an earthquake, when buildings are shaken off their mountings if built on top of unstable soil or not properly tied to their foundations.⁶ Extraordinary loads, which exceed the normal calculated stress that a building can withstand, include earthquakes, tornadoes, tsunamis, or man-generated events such as a motor vehicle striking a key support pillar, a gas explosion, or a bombing.⁴ For example, explosions damage buildings due to extremely high, instantaneous pressures from the blast wave.³ Depending on the size of the explosion, distance from the building, and sturdiness of building construction, an explosion can induce progressive collapse in a matter of milliseconds.³ The blast will first target the weakest point of the building closest to the detonation

and push onto the exterior walls of the lower floors, leading to wall failure and window breakage.³ While the shock wave expands, it enters the structure and pushes upwards and downwards, onto all floors of the building, inducing collapse.³ The reflection of the oncoming, or *incident*, blast wave against hindering structures like hard surfaces of a building’s exterior, can lead to additional pressures up to 13 times greater than the peak incident pressure.^{3,7} Laboratory tests have shown that surfaces exposed perpendicularly to the incident blast wave may experience pressures up to 5000 psi,³ yet typical window glass breaks at an incident overpressure of 0.15 to 0.22 psi.³

PREINCIDENT ACTIONS

Although engineers note that progressive collapse cannot be totally prevented from occurring, they agree that tools can be designed to improve building performance to resist or improve building performance against collapse.^{1,8} National institutes encourage designing multihazard resistance and mitigation suitable to withstand progressive collapse from all threats including natural and technologic disasters.¹ Specific mitigation against terrorist bombings focuses more on window and glass hazards, stand-off distancing, and “hardening” of the exterior. Site design and modification for perimeter defense using soil, bollards, planters, and retaining walls in addition to increasing stand-off distance between the facility and possible threats (such as a truck bomb) can deter and delay terrorist attack capable of insinuating building collapse.³ Strategies to limit parking, vehicular entry, and access inside or near the structure are additional methods for mitigation.³ But once these measures have failed, structural “hardening” to fortify the building’s exterior is used to mitigate the effects of an explosion once it has occurred. The objective of designing the exterior wall is to ensure that structures like walls, doors, and windows fail in a flexible mode, as opposed to a brittle mode that would induce shear and result in multiple fragments of cement, glass, and other materials capable of serious injury.³ In the 1998 bombings of the U.S. Embassies in Kenya and Tanzania, the U.S. Department of State found: “Although there was little structural damage to the five-story reinforced concrete building, the explosion

reduced much of the interior to rubble—destroying windows, window frames, internal office partitions and other fixtures on the rear side of the building. The secondary fragmentation from flying glass, internal concrete block walls, furniture, and fixtures caused most of the embassy casualties.”^{1,8,9} Nonstructural components such as ceiling fixtures, lights, windows, office equipment, computers, files, air conditioners, electrical equipment, and objects stored on shelves and hung on walls can also become an injury hazard.^{3,6} In an earthquake, these nonstructural elements are likely to be unhooked, dislodged, and flung, causing injury and damage.³ Additionally, the U.S. Federal Emergency Management Agency recommends that building design be optimized to facilitate emergency rescue and response, allowing feasible evacuation, rescue, and recovery efforts through effective placement, structural design, and redundancy of emergency exits and electrical/mechanical systems.³

POSTINCIDENT ACTIONS

After a building collapse, trapped survivors requiring quick rescue “where minutes count” are rare. An expeditious headlong, poorly planned ingress into the “hot zone” can risk valuable human assets with limited potential benefit. The rules for traumatic arrest still apply—attempts to resuscitate persons with blunt traumatic arrest are typically futile.

The bulk of surviving casualties will arrive over a 60-minute period at the closest hospital(s), either self-transported or transported by emergency medical services (EMS). Disaster managers should expect high resource utilization from hospitalized survivors, far exceeding the benchmark comparisons for similar injury severity score (ISS) casualties. Critically injured progressive collapse survivors can be compared with casualties of explosive injury, and they require an extraordinary amount of hospital resources. Hospitalized explosion survivors have longer than usual hospital and intensive care unit length of stay, more surgeries, and more ventilator time, and they are more often discharged to a rehabilitation facility compared with ISS-equivalent casualties of motor vehicle or gunshot wounds.^{10,11}

Some general emergency management options apply:

1. Follow your hospital and regional disaster system plan.
2. Expect increased severity and delayed arrival of casualties.
3. Expect an “upside-down” triage—the most severely injured arrive after the less injured, who bypass EMS triage and go directly to the closest hospitals.¹²
4. Double the first hour’s casualties for a rough prediction of total first wave of casualties.¹²
5. Obtain and record details about the nature of the event, potential toxic exposures and environmental hazards, and casualty location using all reliable informants including local police and fire departments, EMS, Incident Command System, regional emergency management agency, local health department, and eyewitness casualties. The need for epidemiologic injury data is an imperative national agenda.¹³

MEDICAL TREATMENT

Progressive structural collapse produces casualty and injury patterns similar to earthquakes and can be more severe than blast injuries alone.¹⁴ The final casualty toll and injury pattern depend most on preexisting circumstances: time of day, occupancy, warning, evacuation proficiency, individual health status, and building design and materials. The majority of casualty survivors will have minor injuries and require only outpatient or self-care. Standard penetrating and blunt trauma to any body surface is the most common injury seen among survivors, with the most severely injured consisting of burns, traumatic amputations, and head, chest, and abdominal injuries.¹⁴⁻¹⁶ Characteristic injuries seen in building collapse are shown in Table 169-1. Frykberg notes a substantial amount of immediate death and constant critical mortality rate among victims of a terrorist bombing building collapse, despite differences in TNT-equivalents of blast force.¹⁶

Most persons caught in the direct path of the collapse will not survive and will either be dead on-scene or dead on arrival, regardless of postcollapse rescue efforts. Trapped survivors are most often found in air spaces adjacent to partially intact support structures. Few survivors are rescued after the first 24 hours, although young children can be an exception. More than half of all children may have head or face trauma. Because children’s airways can be easily occluded, the primary cause of cardiopulmonary arrest in children may be respiratory. Therefore, children in cardiopulmonary arrest should first have their airways cleared. If there is no spontaneous pulse or respirations, they too are unsalvageable and CPR should not be initiated.

Most casualties will meet either anatomic, physiologic, or mechanism of injury criteria to be transported immediately to a level I or II trauma center, and limited scene time remains the standard. Assume crush syndrome and rhabdomyolysis for any casualty trapped for longer than 1 hour. Compartment syndrome, rhabdomyolysis, and acute renal failure are associated with structural collapse, prolonged extrication, severe burns, and some poisonings. All casualties with substantial blunt injuries should be screened for acidosis, electrolyte imbalance, and renal failure. Resuscitation efforts should focus on correcting the underlying cause—for example, fasciotomy or benzodiazepine for agitation or seizures; crystalloid for treating volume depletion, correcting acidosis with sodium bicarbonate; and hemodialysis for renal failure or intractable hyperkalemia.

UNIQUE CONSIDERATIONS

Traumatic amputation of any limb may be a marker for multisystem injuries, since such injuries usually result from close proximity to a blast.^{17,18} Wounds can be grossly contaminated. Consider delaying primary closure until after an assessment of tetanus status has been performed. Ensure close follow-up of wounds, head

TABLE 169-1 MECHANISMS OF INJURY ASSOCIATED WITH PROGRESSIVE COLLAPSE

CATEGORY	CHARACTERISTICS	BODY PART AFFECTED	TYPES OF INJURIES
Penetrating Injury	Results from flying debris and fragments.	Any body part may be affected	Penetrating ballistic (fragmentation) Eye penetration (can be occult)
Blunt Injury	Results from falling objects, blown debris, or persons being thrown by the blast wind.	Any body part may be affected.	Fracture and traumatic amputation Closed and open brain injury
Primary Blast Injury	Unique to high explosives, results from the impact of the overpressurization wave with body surfaces.	Gas-filled structures are most susceptible (i.e., lungs, GI tract, and middle ear).	Blast lung (pulmonary barotrauma) TM rupture and middle ear damage Abdominal hemorrhage and perforation Globe (eye) rupture Concussion (TBI without physical signs of head injury)
Other	All injuries, illnesses, or diseases not due to penetrating, blunt, or primary blast injury. Includes exacerbation or complications of existing conditions	Any body part may be affected.	Burns (flash, partial, and full thickness) Crush injuries Closed and open brain injury Asthma, COPD, or other breathing problems from dust, smoke, or toxic fumes Angina Hyperglycemia, hypertension

GI, Gastrointestinal; TM, tympanic membrane; TBI, traumatic brain injury; COPD, chronic obstructive pulmonary disease.

CASE PRESENTATION

Newham, London, was a newly developed borough in 1968, spotted with brand new apartment towers and promising an upgraded lifestyle from the previous dirty and rundown homes that had characterized West and East Ham towns. Using an engineering method that was perceived as safe and quick in construction, the Ronan Point Apartment Tower was built in 2 years, opening in 1968 as a 210-foot-high building consisting of over 100 flats. Tenants moved in immediately. The apartment building had been occupied for only 2 months when a natural gas explosion on an 18th floor apartment triggered the structural failure of an entire corner of flats. Subsequent floors below were blown out, allowing a domino-effect collapse of wall and floor sections from the top to the ground. The majority of the 260 residents fled down stairwells in advance of the collapse that toppled floors like a deck of cards. However, four people died immediately as a result of the blast although more could have died if the flats were completely occupied. An elderly patient died later in hospital, leading to a total of 17 injured survivors.

Residents saw the design failures such as use of cost-cutting when choosing building materials, poor workmanship, and lack of adequate building inspection as the reasons for the building collapse. Ronan Point was demolished in 1986, and fewer towers have been built since the disaster.

injuries, and complaints related to the patient's eyes, ears, and stress level. Air embolism can occur and can present as stroke, myocardial infarction, acute abdomen, blindness, deafness, spinal cord injury, or claudication. Hyperbaric oxygen therapy may be effective in some cases.^{19,20}

If collapse was preceded by an explosion, clinical signs of blast-related abdominal injuries can be initially

silent until signs of acute abdomen or sepsis are advanced.²¹ Primary blast lung and blast abdomen after explosions are associated with high mortality rates.^{22,23} The symptoms of mild traumatic brain injury (e.g., concussion) and posttraumatic stress disorder might be identical.²⁴

Auditory system injuries and concussions are easily overlooked. Communications and instructions may need to be written because of tinnitus and sudden temporary or permanent deafness.²⁵ Consider the possibility of exposure to inhaled toxins and poisonings (e.g., carbon monoxide, cyanide, methemoglobin) in both industrial and criminal explosions.²⁶

In August 2003, a military hospital in Mozdok, Russia, was bombed, resulting in the partial building collapse of the 3-story structure killing 41 people and entrapping nurses, doctors, and personnel.²⁷ A hospital building collapse can result in the loss of a critical community resource that cannot be easily replaced.

Lastly, crowd surge or stampede can be more deadly than the original event. On January 27, 2002, a large military ammunition dump in Lagos, Nigeria, exploded, immediately killing 300. But another 800 persons, including small children, were trampled to death during the mass exodus that left several blocks of buildings completely and partially collapsed.²⁸

PITFALLS

Several potential pitfalls in response to a building collapse exist.

- Do not discourage buddy rescue and self-transport of casualties. The majority of rescue is conducted by survivors and bystanders. Self-evacuation clears the scene and moves the bulk of the exposed population out of harm's way.

- Do not hold critical casualties in temporary triage sites instead of immediately transporting. Trauma never improves in the field, and trauma's golden hour does not stop for a disaster.
- The U.S. Federal Emergency Medical Treatment and Active Labor Act prevents the expeditious movement of excess outpatient casualties to hospitals with excess outpatient capacity.²⁹
- Another pitfall is activating an entire hospital's disaster plan for a distant regional event and not releasing recalled staff in a timely manner. Only the closest one to three hospitals receive the majority of the casualties, and half of all casualties arrive over a 60-minute period.
- Lack of ventilators and cardiac monitors is a common limit or delay in inter-hospital transfer of critical casualties.
- It should not be assumed that all ambulatory casualties are "worried well." All have been exposed to a variable amount of physical trauma and environmental hazards. Israeli pediatric traumatologists have proposed eliminating "Green" or "Minimal" from the triage protocol.³⁰
- Adult casualties in cardiopulmonary arrest are either dead or unsalvageable. No attempt should be made to resuscitate beyond confirming the absence of vital signs.

Bridge Collapse

Laura Diane Melville and Najma Rahman-Khan

DESCRIPTION OF EVENTS

On the morning of May 9, 1980, the *Summit Venture* had just entered a difficult portion of the shipping channel leading into Tampa Bay that passed under the Sunshine Skyway Bridge. The boat was a tanker the size of two football fields. A sudden squall blew up and created almost zero visibility, and the ship's radar ceased to function. Based on a number of factors, the captain made the decision to go forward and try to pass under the bridge. The ship rammed the south pier 700 feet from the center of the channel, causing the center span of the Skyway to collapse into the channel below. Several cars and a Greyhound bus disappeared into the Bay. Thirty-five people died in the disaster.¹

There is such a dearth of medical or disaster planning literature specifically addressing the collapse of bridges that information must be gathered from newspaper and other stories to understand what has happened and what could happen. Most of the time a bridge collapses due to structural failures; however, there can be other causes such as weather (including floods, tornados, earthquakes), explosions (both accidental or nonaccidental), acts of war or terrorism, objects crashing into the bridge (such as a barge), and potential nuclear or dirty bombs. Since the events of Sept. 11, 2001 in New York City, we can easily imagine scenarios in which a bridge with major traffic burdens (including pedestrian, motor, and rail) and significant symbolism (such as the Golden Gate Bridge or the Brooklyn Bridge) becomes a target of a terrorist attack. During war, bridges become targets for those same reasons. The T-shaped Aioi Bridge was the target for "Little Boy"—the atomic bomb dropped on Hiroshima.

It is important to remember that not all bridges cross water. Highway overpasses are essentially bridges, and the collapse of such structures also occurs. This kind of collapse would require interventions more like those required for structural collapses, such as urban search and rescue teams and confined-space medical interventions.

A brief description of the different types of bridges may be useful in understanding the types of risks they are subject to. There are several different types of bridges, such as arch, cable-stayed, suspension, draw span, truss, and beam bridges, with the first three being the most common. Arch bridges are relatively small, usually 130 to 500

feet in length. This type of bridge allows no movement in horizontal bearing, so these bridges are usually located on stable ground and cross over valleys and rivers.

Cable-stayed bridges are usually 300 to 1600 feet long with a continuous bridge that has one or two towers erected in the middle with support cables attaching the bridge to the towers. The towers bear the brunt of the load. This design provides strong support against earthquakes and strong winds but remains vulnerable to shifting or uneven sinking in the ground. The new Sunshine Skyway Bridge is an example of a single-tower cable-stayed bridge.

Suspension bridges, such as the Golden Gate Bridge, usually span about 2000 to 7000 feet. These bridges have cables that are attached to either end to transmit the load to either anchorage. These anchorages at either side provide strong support, but the construction makes the bridge vulnerable to strong winds. The collapse of the Tacoma Narrows Bridge, also known as "Galloping Gertie," is a famous example of the failure of a suspension bridge.²⁻⁴

The Tacoma Narrows Bridge is a case of a suspension bridge gone wrong. It collapsed in 1940 because of strong winds, but the bridge's undulations were an attraction to locals and tourists for years before the actual collapse. Due to its suspension wire construction, there were both vertical and horizontal undulations in the bridge that contributed to its failure. During some winds, there was as much as a 28-foot disparity between the left and right sides of the bridge. Before that event, there was pressure to construct bridges to maximize "lightness, grace, and flexibility"; however, this collapse forced a reevaluation of this in favor of safety and stability.² The impressive amateur video taken just before the collapse can be viewed on the Internet.³

Another famous bridge disaster was the May 26, 2002 collapse of the Oklahoma I-40 bridge across the Arkansas River after it was rammed by a empty oil barge. More than a dozen cars and tractor-trailers went into the river, and 14 people died. This disaster was reminiscent of the Sunshine Skyway disaster. Like the former event, there had been a number of prior incidents that could have served as a warning that this was a real possibility. The rescue effort had to be delayed several days because of the murky water conditions. Thirteen people died by drowning, and one died by blunt trauma to the head. According to the National Transportation Safety Board,

the bridge may have collapsed because of its old design; had it been retrofitted to modern standards, it may have withstood the impact.^{5,6}

Not all bridges transport cars. During the 1997 Israeli Maccabiah Games, a pedestrian bridge (footbridge) passing over the polluted Yarkon River collapsed, killing four athletes and injuring many more. Three of the deaths were attributed to infectious complications caused by ingesting the polluted water. Medical data on the types of injuries sustained in any bridge collapse are exceedingly difficult to access, but the one available abstract reported on the minor injuries sustained by these athletes. Of the 65 people who sustained nonfatal injuries as a direct result of the bridge collapse, the most common anatomic regions of musculoskeletal injuries were the thigh (20.9%), lumbar spine (15.3%), and the foot and ankle (13.3%). The types of injury most commonly reported were sprains (49.0%) and strains (27.6%).⁷ However, the abstract had no information about any victims being seriously injured. It seems that all of the athletes who actually fell into the river suffered severe consequences. Information gleaned from newspaper coverage suggests that when motor vehicles or trains are involved, the degree of injury can be much more wide ranging. Material from the Sunshine Skyway collapse and the Oklahoma bridge disaster demonstrate that most of those who died had suffered major trauma, drowning, or in some cases both. Under most circumstances, it is rare for drowning victims to suffer any trauma other than cervical spine injuries.^{8,9} This is important for those planning to treat potential victims of injuries resulting from a collapsed bridge.

PREINCIDENT ACTIONS

Each government agency (state, county, city, township) that manages a public bridge is required by the Federal Highway Administration to have a crisis management plan.² These involve such agencies as the police, sheriff, fire, rescue, emergency medical services, coast guard, Army Corp of Engineers, Federal Aviation Administration, and railroads.

Hospitals should be aware of the plans for bridges in their area and should have an understanding of how loss of the transportation route and the influx of patients will affect their facilities. This should be one of the many scenarios envisioned in the hospital disaster plan. A critical factor in this planning should be the expectation that many staff members may not be able to get to or from work—this could mean anyone from cleaning staff to a hospital's only two trauma surgeons. Hospital representatives should be involved in the creation of the federal state and local plans because emergency departments (EDs) can expect to be the center point of any medical consequences. Important issues will be traffic re-routing, designation of receiving hospitals, etc.

There are software programs available such as the Geographical Resource Intranet Portal, created by the Oklahoma Department of Transportation (ODOT), that can overlay all the area roads with information about ability to handle trucks and high traffic volume, locations

of hospitals, and other information that can allow a quick return of traffic flow. This program allowed the ODOT to detour traffic within 2 hours after the 2002 collapse of an I-40 bridge.¹⁰ Those hospitals with hyperbaric chambers should be identified in case they are required for victims or rescuers.

Communication issues, both within the hospital and with outside agencies, are paramount and must be addressed prior to the event itself. This is often one of the most challenging parts of developing and implementing a disaster plan, and it should be emphasized in planning and drilling. Search and rescue teams, with divers, will likely be needed for recovery of victims trapped under structures and underwater. There must be planned routes for emergency vehicles and rescue personnel to get to and from the event site. Knowledge of the body of water (e.g., currents and pollutants) could also be critical to effective rescue efforts. If the collapse occurs due to weather, earthquake, or terrorism, there will be damage to other structures and resources including the hospital itself; chemical or nuclear weapons may be involved.¹¹

Those who will be performing triage must be clear about the rules of mass-casualty triage, based on the principle of “the greatest good for the greatest number.” This is based on the likelihood of successful resuscitation and the resources available. Most mass-casualty triage systems tag patients with black, red, yellow, and green tags corresponding to dead, emergent, urgent, and the walking wounded, respectively. Two examples of this kind of system are the Simple Triage and Rapid Treatment (START) system and the Jump START for pediatric triage.¹² A person removed from cold waters with no vital signs would be extensively resuscitated in non-mass-casualty settings and would be black-tagged in the event of a mass-casualty incident.

If the bridge collapse is part of a large event, the Federal Emergency Management Agency and disaster medical assistance teams may become part of the response after the first few days. Disaster medical assistance teams are designed to be a rapid-response element to supplement local medical care until other federal or contract resources can be mobilized, or until the situation is resolved.¹³

POSTINCIDENT ACTIONS

It is often impossible to attempt rescue without risk to the rescuer, but it is vital to secure the area as much as possible and ensure the maximum possible safety for everyone on-scene. A collapsed bridge can be particularly dangerous because the elevated structure may continue to break down. Large amounts of debris underwater can endanger divers, as can weather and current conditions. Under certain circumstances, this may include evaluation for any coincidental biologic, chemical, or radiation terrorism.

Plans that are in place must be implemented in an orderly fashion. It is paramount that communication between agencies occurs as smoothly as possible. As in all of the situations addressed in this book, coordination of federal, state, and local resources will lead to the most

effective and efficient handling of the situation. The conventional wisdom is that a response team must be able to stand alone for 12 to 24 hours.^{11,13} This isolation may be prolonged if the bridge has collapsed due to severe weather conditions or a geologic event such as an earthquake. If the hospital itself has been compromised by the surrounding events (e.g., the power is out because of an earthquake), internal as well as external disaster plans may need to be implemented. Urban search and rescue teams will likely require activation, and preliminary medical care may have to be delivered at the scene for victims who are trapped alive. If there are large numbers of victims, it will be important to bring stable patients to hospitals farthest from the scene. The walking wounded and the worried well often take themselves to the closest hospital, and the severely injured are transported there.¹¹

Other disaster management issues that warrant inclusion in hospital disaster plans for bridge collapse include what to do with medical and nonmedical volunteers; hospital capabilities regarding trauma and pediatrics; how and where to transfer patients who require care that cannot be provided; and how to get staff to the facility if the usual traffic routes are not available.

MEDICAL TREATMENT OF CASUALTIES

It is beyond the scope of this chapter to cover the detailed medical treatment of the many types of injuries that could be seen in the event of a bridge collapse. These topics are covered in other sections of the book. For any bridge over water, near-drowning will be an important mechanism of injury to expect. Although near-drowning injuries are not typically associated with other trauma, this scenario has been shown to produce both blunt injury and drowning. It is likely that the trauma victims in this situation were incapacitated by their injuries and drowned secondarily.

Blast injuries will occur if there are any explosions. Primary blast injury occurs as a direct effect of changes in atmospheric pressure caused by a blast wave. Secondary blast injuries occur when objects accelerated by the energy of the explosion strike a victim, causing either blunt or penetrating ballistic trauma. Tertiary blast injuries result from a victim's body being displaced by expanding gases and high winds; trauma then occurs from tumbling and colliding with objects. Primary blast injury mostly occurs in gas-containing organ systems, notably the middle ear, lungs, and bowel. Few victims of primary blast injury survive to require treatment.¹⁴

Hypothermia may be a factor complicating the care of both submersed and entrapped patients; however, it may in fact improve survival and neurologic outcome in some patients, particularly the drowning victims. The principle that the patient is "not dead till warm and dead" is the norm for emergency medicine,¹¹ but if disaster triage protocols have been implemented, patients who do not have respirations or a pulse will not be resuscitated regardless of their temperature. These are the patients who will likely present the most difficult ethical and

emotional challenge for personnel on-scene and at receiving hospitals.

Any victims trapped under rubble or in crushed vehicles can sustain crush injuries and may require treatment based on principles of confined-space medicine at the scene and on arrival in the ED. Head injuries are also common. As described above, pollution may complicate the treatment requirements of submersion victims. As in any disaster, stress-related exacerbations of medical illness and psychological issues will require intervention for victims, responders, and family members.^{11,15}

CASE PRESENTATION

It is mid-February, and you and one other ED attending physician are working the night shift at a level II trauma center. About 2 miles away is an interstate highway that crosses the large river in your area. The university level I trauma center is across the river. In fact, quite a few of your staff work at both hospitals and live on the other side of the river. The bridge is old and scheduled for repairs in the next fiscal year. Your hospital has participated in the local Office of Emergency Management and Federal Highway Management Office's disaster planning.

It is 6:00 AM, and you are getting ready for change of shift. A couple of residents come in from a smoke break and tell you they think they heard thunder, but it is a bright, beautiful day. You tell them they should quit smoking and get ready to hand over the ED. About 15 minutes later, your EMS phone rings and you are notified that there has been a terrible accident—a large fuel truck has exploded and caused the bridge to collapse. You are on standby to receive up to 50 patients. There are several vehicles on fire, and several have plunged into the icy waters below. No one is quite sure what happened, and rumors of terrorism are already spreading among your staff. Because the traffic was two-way, there are injured persons on both sides of the bridge—those on your side will be coming to your hospital regardless of their degree of injury.

You notify your hospital administrator and initiate your disaster plan, including additional triage areas, notifying the operating room and all your surgeons. The clinic down the hall from your ED is opened to handle non-urgent patients. Your department chairman calls to say she is on her way in by police department helicopter, which will land nearby because your facility does not have a helipad.

Patients are beginning to come in now, and your beds are filling up. Several are critically injured, with burns and blunt trauma. No victims have been recovered from the waters yet, but the coast guard is almost on scene and the search and rescue team is also en route. There are questions about chemical exposure. Several cardiologists who live next to the hospital have just arrived in the ED to help, along with a number of neighbors who want to give blood. You are the Incident Commander for your hospital and are constantly on the phone with EMS, police and fire personnel, and your counterpart at University General. More staff is on the way in. You hear the rescue divers are having trouble getting to victims because of river conditions, but your first hypothermic near-drowning victim is on his way in, by Basic Life Support (BLS) with a faint pulse and an unobtainable blood pressure reading....

UNIQUE CONSIDERATIONS

Bridges are most likely to collapse due to a combination of severe environmental circumstance, structural flaws, and wear and tear. However, sudden collapse caused by structural failure, impact, or attack can occur. Staff may not be able to come to work or get home if the bridge is critical for access to that area or if traffic becomes intensely snarled.

Although drowning victims rarely have concurrent traumatic injuries other than cervical spine injuries, people in vehicles that slam into water and then submerge will suffer both insults. Most are unlikely to survive severe traumatic injury followed by submersion, but a patient with these types of injuries should be anticipated in this scenario. Collapse of bridges that do not cross water may lead to trapped and crushed victims requiring intervention more like those for other structural collapses, as described in studies of confined-space medicine. In addition, exposure to polluted water could lead to chemical toxicity and overwhelming sepsis.

PITFALLS

Several potential pitfalls in response to a bridge collapse exist. These include the following:

- Failure to plan for collapse of any local or important bridge
- Failure to be aware of and incorporate plans already in place by state and local authorities
- Failure to have hospital disaster plans in place prior to an incident
- Failure to include the possibility of bridge collapse in plans for larger events such as earthquakes, flooding, or a terrorist attack
- Failure to consider larger events (e.g., earthquake or flood) when planning for a possible bridge collapse
- Failure to consider that such larger events (e.g., earthquake or flood) may compromise the functioning of the hospital itself

- Lack of knowledge regarding water conditions, including level of pollution and chemical content of polluted water
- Failure to plan alternate ways for staff to get to the hospital

Human Stampede

Angela M. Mills and C. Crawford Mechem

DESCRIPTION OF EVENT

Human stampede is one of the most disastrous examples of human crowd behavior. Triggers include building fires and evacuations and a rush for ingress or egress at large sporting events or concerts. In large crowd stampedes, there are often serious injuries and fatalities resulting from crushing and trampling. On Nov. 28, 1942, a fire began at the Coconut Grove, a popular Boston nightclub, causing widespread panic and a stampeding crowd. Inward-opening doors and doors sealed shut prevented escape. As a result, 491 persons died and over 400 were injured.¹ On Apr. 15, 1989, during a semi-final cup soccer game in Sheffield, England, there was a large crushing incident of late-arriving fans who entered a confined area at the Hillsborough stadium. Persons were unable to escape this area due to a surrounding fence; 95 died and more than 400 required hospital treatment.^{2,3} These are only two examples of countless episodes of human stampede.

A model for crowd disasters aids in understanding the causes, prevention, and alleviation of an ongoing incident. The four elements of this model form the acronym *FIST* and include the force (F) of the crowd or crowd pressure; information (I), whether real or perceived, on which the crowd acts; physical space (S) involved in the disaster; and time (T) or duration of the event.⁴ Forces are generated by persons pushing and leaning against each other. There is often a lack of communication from front to back in a crowd, with persons in the rear pushing forward, injuring those in front. As individuals are injured or fall, they become obstacles to the movement of others. Access to the fallen becomes impossible.^{4,5} Large numbers of humans involved in a disaster event tend to exhibit mass behavior and do what others do. As people crowd and jamming occurs, alternative exits are frequently overlooked or not used adequately, resulting in additional injuries.⁶

Escape panics have been studied extensively and have the following characteristics. Panicking persons attempt to move faster than usual and begin pushing and having physical contact with others. This movement, especially around bottlenecks, becomes uncoordinated. Exits become clogged. The pressures generated by a crowd may exceed 4500 N (1000 lb), allowing steel railings to bend and brick walls to fall.^{4,6,7}

The widening of a corridor has been demonstrated to slow down movement of panicking persons rather than allowing for faster movement. In a study performed with mice, the most efficient escape was a door large enough for only one mouse to fit through at a time. As door widths were increased, the mice ceased lining up and began competing with one another, prolonging the escape rate.⁸ This behavior also pertains to rushing pedestrians who will block an exit that they could safely pass through at walking speed. Jamming and clogging may be minimized in the construction of venues by avoiding bottlenecks and placing columns asymmetrically in front of exits to improve outflow.⁶

A human stampede leads to various injuries and fatalities, with traumatic asphyxia being the most common cause of death and serious injury. The majority of deaths are due to compressive asphyxia as persons are stacked vertically on top of one another or horizontally with associated pushing and leaning forces. Traumatic asphyxia is caused by a severe crush injury to the chest or upper abdomen. The mechanism is believed to be acute, severe venous hypertension.^{9,10} The various presentations include asystolic cardiac arrest, status epilepticus, prolonged confusion, and cortical blindness.² The majority of signs are confined to the upper torso, with the lower torso being spared. Clinical manifestations include facial edema and petechiae, cranial cyanosis, subconjunctival hemorrhage, exophthalmos, and ecchymotic hemorrhages of the face and upper chest.

Life-threatening pulmonary, cardiac, and gastrointestinal injuries may occur with traumatic asphyxia. These include pulmonary contusion, pneumothorax, myocardial contusion, flail chest, liver and splenic lacerations, and gastrointestinal hemorrhage. Superior vena cava syndrome may mimic the features of traumatic asphyxia and should be ruled out. Basilar skull fractures may also present similarly. Skull fractures are rare in traumatic asphyxia because the compressive force is usually to the chest or upper abdomen. Morbidity and mortality are associated with the severity and duration of compression and the high incidence of associated injuries. These injuries should be ruled out by computed tomography scan, duplex ultrasound, or echocardiogram as dictated by the physical examination. Long-term neurologic sequelae are rare, and full recovery may be achieved with

early reestablishment of ventilation and correction of hypoxia.^{9,10}

In addition to traumatic asphyxia and its associated injuries, many other injuries may occur secondary to stampede including musculoskeletal trauma, soft tissue crush injuries, acute right heart strain,³ and brachial plexus injuries.² Crush injuries, including crush syndrome, compartment syndrome, and acute traumatic ischemia, lead to hemorrhage, edema, and hypoperfusion with resulting tissue hypoxia and ischemia. Although any tissue may be affected, nerve and muscle located in myofascial compartments are at increased risk. Cellular death leads to release of potassium, phosphate, and myoglobin as part of crush syndrome with rhabdomyolysis. Most crush syndromes occur as a result of compression for 4 or more hours. Complications include hypovolemia, hypotension, and disseminated intravascular coagulation, with renal failure being the most serious complication. Peak creatine kinase level has been shown to correlate with the occurrence of renal failure and mortality.¹¹⁻¹³

PREINCIDENT ACTIONS

Human stampedes can occur at venues with or without organized mass-gathering medical care. Mass-gathering events require extensive coordination of various agencies including emergency medical services, fire and police departments, local emergency departments and hospitals, local government agencies, and others. Factors in planning for large events may include the type and duration of event, physical plant and location characteristics, routes of ingress and egress, and age of attendees. As a result of previous stampedes, much has been learned for the prevention of future incidents. Factors used in prevention may include providing reserved seating rather than general admission to large events, avoiding use of fixed barricades, ensuring availability of multiple exits, minimizing bottlenecks, limiting access to alcohol, and having the crowd form into queues.^{4,14,15}

POSTINCIDENT ACTIONS

The Incident Command System, a standard emergency management system used throughout the United States, should be activated to coordinate the response to a human stampede. Establishment of effective communication is vital. Prehospital providers must commence triage and rapid treatment and determine the most sensible distribution of patients to area hospitals. Hospitals, and in particular emergency departments, should have disaster protocols available to effectively handle mass-casualty events.¹⁶

MEDICAL TREATMENT OF CASUALTIES

Standard trauma protocols should be followed when caring for victims of human stampede. Treatment of traumatic asphyxia is largely supportive and aimed at the

associated injuries, which include pulmonary and myocardial contusion, pneumothoraces, intra-abdominal injuries, and neurologic injuries. Prompt delivery of oxygen and effective ventilation compose the mainstay of treatment, as well as elevation of the head of bed. Prognosis is excellent for those persons who survive the initial crush injury, with a recovery rate of approximately 90% for patients surviving the initial hour.¹⁰

As massive compression occurs, one needs to evaluate a patient who has incurred injury in a stampede for crush injuries including the sequelae of crush and compartment syndromes. The goal of therapy is to prevent renal failure by avoiding hypotension and maintaining urine output. The administration of appropriate intravenous fluid therapy with crystalloid solution should be initiated as early as possible, even before extrication, to maximize intravascular volume and renal perfusion. Urine output should be maintained at approximately 200 mL/hour. Alkalinization of the urine has been shown to increase the solubility and excretion of myoglobin and prevent renal failure. The urine pH level should be maintained between 6 and 7. The use of mannitol is controversial but may aid in diuresis. If compartment syndrome is suspected, compartment pressures should be measured directly, and, if elevated, fasciotomy may be required.¹¹⁻¹³ Hyperbaric oxygen therapy has also been shown to be effective in severe extremity crush injuries.¹⁷

CASE PRESENTATION

It is Saturday night, and more than 1200 persons have gathered at a large downtown nightclub to hear a famous rock band perform. A fire starts as a result of patrons smoking in the lavatory and spreads quickly through the building. Persons panic and rush to the closest exits, only to find many of them locked. Those in the rear of the crowd push forward, causing many of those in front to fall and become obstacles for those rushing forward. A call is placed to 9-1-1 and emergency responders arrive but have difficulty reaching patients. There are well over 100 persons injured. Patients begin arriving at your emergency department. A 22-year-old woman is transported receiving oxygen and having facial edema and petechiae. A 23-year-old man is brought in unconscious with multiple ecchymoses about the face and torso. Other patients continue to arrive.

UNIQUE CONSIDERATIONS

In the event of a human stampede, access to patients early on, as well as extrication of patients, may be difficult if not impossible. The safety of emergency responders must be considered. Traumatic asphyxia and the crush syndrome are rare clinical entities that may be associated with high morbidity and mortality. Early and aggressive therapy, often initiated in the prehospital setting and even before extrication, may be required to ensure the best possible outcome. Adequate planning, public education, and interagency cooperation play key

roles in minimizing the risk of human stampede and its associated injuries and deaths.

PITFALLS

Several potential pitfalls in response to a human stampede exist. These include the following:

- Failure to adequately plan and coordinate the necessary agencies needed to respond to mass-gathering events
- Failure to alert appropriate persons, hospitals, and emergency departments to a human stampede event
- Failure to rapidly restore oxygenation and ventilation to victims of a human stampede
- Failure to identify and aggressively treat associated injuries of traumatic asphyxia and massive compression

Mining Accident

Dale M. Molé

DESCRIPTION OF EVENT

The Industrial Revolution significantly increased the demand for fossil fuels. In America, outcrop deposits of coal along the James River in Virginia supplied fuel for blacksmith forges as early as 1702, and when surface supplies diminished, miners followed the coal seams underground. Deeper mines combined with poor ventilation increased the formation of explosive mixtures of methane. The inevitable occurred in 1810 with the first coal mine explosion.¹

Mine disasters in the first half of the twentieth century involved hundreds of deaths in each accident. Advances in mine technology and safety have greatly reduced the hazard of underground occupations since the early days, but they have not completely eliminated danger. In the United States alone, 169 miners have lost their lives in coal mine mishaps since 1980.²

In the immediate aftermath of a mine accident, surviving until rescue is the first priority of trapped miners. Obstacles to survival include poor communication, extreme darkness, confined space, hypothermia, toxic atmosphere, and injuries.

One of the most challenging aspects of any rescue operation is establishing the existence, location, and condition of any survivors. Mine communication systems are often damaged or unreachable in a disaster. Low-frequency radio waves can penetrate rock and offer promise for minewide alarm and communication devices. Seismic locators can detect the vibrations produced by trapped miners in some circumstances. If a survival borehole is drilled, tapping on the drill using prearranged tap codes provides useful information.

Shutting off electricity to reduce ignition sources for fires or explosions is often the first action after a mine accident. Plunged into absolute darkness, the miners must rely on limited-duration battery-powered helmet lights, making survival efforts more arduous.

Cool ambient mine temperatures combined with water from mine operations, aquifers, rain, or flooding creates a major problem for miners who get wet. Immersion in water increases conductive heat loss by as much as fivefold, hastening the onset of hypothermia. Adaptive survival mechanisms (e.g., shivering thermogenesis) increase metabolic heat production by two to five times,

but they also significantly increase oxygen consumption and carbon dioxide production—a major problem in small, airtight spaces.³ Hypothermia depresses the central nervous system, impairs judgment, and prevents the accomplishment of appropriate survival actions.

The atmosphere within a mine is composed of many gases. Early miners used canaries as biologic atmosphere monitors because the birds are overcome by relatively small amounts of noxious gases or damp. The word *damp*, originally derived from the German word *dampf* meaning “fog” or “vapor,” is the mining vernacular to describe any mixture of gases in a underground mine, usually noxious or oxygen deficient.

Firedamp primarily refers to methane resulting from the decomposition of coal or other carbonaceous material decaying in an anoxic environment and is explosive when present in air in concentrations of 5% to 15%. The Davy safety lamp, one of the earliest detection devices, detects concentrations as low as 1%. Flame color and height indicates the amount of methane present. Low oxygen levels extinguish the flame entirely. Special colorimetric detectors are now used.

Blackdamp, referring to an anoxic mixture of nitrogen and carbon dioxide, extinguishes flame and causes death by suffocation. Carbon dioxide is produced by the complete combustion of carbonaceous material, metabolism of miners and animals, decay of organic matter, oxidation of coal, or the chemical action of acid water on carbonates.

Chokedamp is any anoxic mixture of mine gases. *Whitedamp* contains large amounts of carbon monoxide; is found in the exhaust of diesel engines, detonated explosives, wood or coal fires; and is the result of the incomplete combustion of carbonaceous materials. This colorless, tasteless, odorless gas competes with oxygen for hemoglobin binding sites and binds with an affinity 218 times greater. The oxyhemoglobin dissociation curve is transformed from the normal sigmoid to an asymptotic shape, impairing or preventing oxygen transport to the tissues. Tissues with high oxygen demands (e.g., brain and heart) are among the first affected. Symptoms include fatigue, dizziness, headache, seizures, unconsciousness, and hypotension.

Afterdamp is the gas produced by an explosion. It almost always contains dangerous amounts of carbon

monoxide and oxides of nitrogen, reported in terms of nitrogen dioxide that can form nitric acid in the lungs. *Stink damp*, or hydrogen sulfide gas, has a characteristic pungent smell of rotten eggs. The byproduct of organic decomposition, the action of mine acid on sulfur minerals, or the burning of explosives containing sulfur such as black powder or dynamite, it is soluble in water and may be liberated whenever a mine pool is agitated. It is extremely poisonous and has a mechanism of action similar to cyanide. High concentrations produce loss of consciousness, seizures, and death with just a few breaths.

Other gases include highly explosive hydrogen gas from battery-charging stations; sulfur dioxide, which creates sulfuric acid in the lungs; and acetylene resulting from methane heated in a low-oxygen atmosphere or the interaction of calcium carbide with water.

Oxygen is essential for survival. It is the partial pressure of oxygen, not the absolute percentage, that determines whether the ambient atmosphere can sustain life. Fire or metabolic activity can rapidly consume the available oxygen in a confined, airtight space. Flooding can compress air pockets, raising the total pressure and therefore the partial pressure of oxygen to dangerous levels. Since air is 21% oxygen and normal atmospheric pressure (1 atmosphere absolute [ata]) is equivalent to 760 torr, the partial pressure of oxygen is 760 times 0.21, or 160 torr. Expressed in atmospheres absolute, this would be 1 ata times 0.21, or 0.21 ata. If the atmospheric pressure were doubled to a total pressure of 1520 torr, or 2 ata, the partial pressure of oxygen could be expressed as $(1520 \text{ torr} \times 0.21) = 320 \text{ torr}$, or $(2 \text{ ata} \times 0.21) = 0.42 \text{ ata}$. Pulmonary oxygen toxicity results from prolonged exposure to high-oxygen partial pressures in excess of 0.5 ata. Breathing 0.6 ata oxygen produces respiratory symptoms in the majority of humans in less than 24 hours.⁴ Conversely, as survivors in a closed space consume the available oxygen, the partial pressure of oxygen falls, producing signs and symptoms of hypoxia such as dyspnea (i.e., air hunger), cyanosis, impaired cognition, poor muscle coordination, and unconsciousness.

Nitrogen composes 79% of our atmosphere and is generally considered an inert (metabolically inactive) gas. When breathed at increased pressure, however, it produces a narcotic effect in a dose-dependent fashion; that is, the higher the partial pressure of nitrogen, the greater the narcosis. Nitrogen narcosis causes both cognitive and psychomotor disturbances. Breathing room air at 4 to 7 ata results in exposure to elevated partial pressures of nitrogen high enough to cause delayed response to auditory and visual stimuli, impaired neuromuscular coordination, a loss of clear thinking, and a tendency toward idea fixation. The effect is similar to ethanol intoxication, and it can significantly impair the ability of miners to take the necessary steps to ensure survival.

Carbon dioxide comprises only 0.001 ata, or one-tenth of 1% of the atmosphere. It is a by-product of cellular metabolism, and for each standard cubic foot of oxygen consumed an almost equal amount of carbon dioxide is produced. If the carbon dioxide level climbs past 0.10 ata, unconsciousness is soon followed by death. In an airtight space, it is the carbon dioxide level that limits survival, not the amount of oxygen.⁵

In prolonged survival situations, food and water also become important considerations. Inadequate caloric intake can produce starvation diarrhea, making survival less likely.⁶

PREINCIDENT ACTIONS

One of the most significant advances in mine rescue operations occurred in 1856 with the introduction of self-contained breathing apparatus, allowing rescuers to conduct operations with increased safety. Part 49 of Title 30 of the Code of Federal Regulations requires every mine in the country to have mine rescue teams. It stipulates how many members each team should have and outlines physical and training standards and required equipment, maintenance, and storage. Modern mine rescue, with enhanced team training and improved equipment, has transformed chaotic, uncoordinated rescue attempts into efficient, well-coordinated group efforts. The full integration of medical elements into the team is essential for a successful outcome to rescue operations.

Today's teams use modern gas detection and communication equipment, seismic locators, geophones, and other devices to locate miners. Rescue vans are outfitted with breathing apparatus, recharging facilities, hand tools, medical supplies, and gas analysis equipment. A qualitative and quantitative knowledge of constituent gases within the mine provides important clues to past events, as well as current atmosphere conditions such as elevated carbon monoxide levels suggestive of a fire.

Mine emergency operations teams can drill boreholes down from the surface to reach miners. Once a small-diameter "survival hole" is drilled, rescuers can lower microphones, lights, and cameras into the mine to help locate the miners, to determine their situation, and to lend support and assistance while a rescue hole is drilled. Trapped miners can be safely hauled to the surface in specially designed "rescue capsules."

POSTINCIDENT ACTIONS

The first few hours after the emergency are the most critical. Coordination of mine rescue teams, mine personnel, and local, state, and federal officials is essential. A command center forms the hub of mine rescue operations and contains communications equipment, underground diagrams, and local area maps. As mine rescue teams arrive, a rotation schedule is prepared, designating which teams are to be the exploration team, backup team, and standby team. A bench area with running water allows breathing apparatus to be cleaned, tested, and prepared.

Establishing perimeter security is essential to keep roads open for emergency personnel and to ensure that curious bystanders do not hinder rescue efforts or become injured while on mine property. Company personnel or police officers should guard all routes to the mine.

A press center should be established away from the disaster site and should be the only area where news media

receive information. A public affairs officer will authorize, issue, and ensure the accuracy of the information being released to the public. The family waiting area should be away from any rescue activity and the media center.

Provision should be made to feed and house rescue personnel during an emergency. Food can be catered or brought in from a nearby restaurant. The American Red Cross is skilled at providing disaster relief services. Nearby motels can often provide sleeping quarters, or if none are available, tents and cots can be set up at the rescue site. Ensuring adequate field hygiene is critical to preventing infectious disease outbreaks among rescue personnel.

Mine exploration is the process of assessing conditions underground and locating miners during a rescue or recovery operation. The safest route into the mine is determined before anyone goes underground. In a shaft mine, the cage (i.e., elevator) is thoroughly tested for proper operation, and the shaft is tested for the presence of gases, smoke, or water.

In some disaster situations, conditions may make it possible to begin the initial exploration without self-contained breathing apparatus. This “barefaced” exploration is conducted only when the ventilation system is operating properly and gas tests demonstrate a safe atmosphere. Backup crews with apparatus are stationed nearby, ready to perform a rescue if necessary. Barefaced exploration stops where disruptions in ventilation are discovered, when gas analysis indicates the presence of noxious or explosive gases or an oxygen deficiency, or when smoke or damage is encountered. A “fresh air base” is usually established at the point where conditions no longer permit barefaced exploration. Teams equipped with breathing apparatus continue exploration from the fresh air base. Typical mine rescue equipment includes gas detectors, oxygen indicators, communication equipment, thermal imaging cameras or heat-sensing devices, link-line, map board and marker, scaling bar, walking stick, stretcher, first aid kit, fire extinguisher, tools, blankets, and extra breathing apparatus. Before going underground, each team is briefed about what has happened in the mine and what conditions currently exist.

Since every underground coal mine contains harmful gases, dust fumes, and smoke, a ventilation system draws air from the surface via the main intake shaft. Ventilation controls force air to move in certain directions and at certain velocities to safely ventilate all sections of the mine. The main fan creates a pressure differential and must be monitored or guarded to ensure the rescue team’s safety while underground after the fresh air base is established and exploration is under way. Changes in ventilation are only made by the command center. As the team advances through the mine, all ventilation controls are examined. Team members must be able to recognize damaged ventilation controls, determine the direction and velocity of ventilation air by using an anemometer or smoke tube, measure the cross-sectional

area of a mine entry, and calculate the volume of air by using the area and velocity. The quantity of air (measured in cubic feet) is equal to the area (in square feet) multiplied by the velocity (in feet per minute.)

Fires in underground mines are especially hazardous because they pose explosion hazards, consume oxygen, and produce smoke, toxic gases, and heat. Ventilation is always maintained during a fire to carry off explosive gases and distillates away from the fire area and to direct the smoke, heat, and flames away from the team. The most frequent cause of explosions in coal mines is the ignition of methane gas, coal dust, or a combination of the two. Explosions can blow out roof supports, damage ventilation controls, twist or scatter machinery, and ignite numerous fires. Roof and ribs can be weakened, and fires can be spread. Further explosions may occur because of damage to the ventilation system during the initial explosion.

MEDICAL TREATMENT OF CASUALTIES

In a disaster in which several miners are trapped underground, or in which injuries are sustained after an explosion, roof fall, or fire, a temporary medical treatment facility should be established. After initial stabilization, a carefully considered means of patient transport may include ambulances or evacuation aircraft, with medical crew on standby. If large numbers of corpses are being recovered from the mine, a temporary morgue is necessary.

UNIQUE CONSIDERATIONS

Delayed care for contaminated wounds and crush injuries, as well as the synergistic effects of toxic gases, hypothermia, and inadequate nutrition make medical management of the victims of a mining accident especially challenging. Provision for decontamination is essential after prolonged underground dwelling. Carbon monoxide poisoning may require treatment with hyperbaric oxygen.

PITFALLS

Several potential pitfalls in response to a mining accident exist. Failure to consider the effects of elevated pressure in mine flooding situations may result in death or permanent disability upon rescue due to decompression sickness. In addition, inadequate medical integration into mine rescue team training may result in suboptimal performance in real emergencies, leading to preventable morbidity and mortality.

On the evening of July 24, 2002, miners working 240 feet underground in the Quecreek coal mine breached a wall separating them from the water-filled Saxon mine. One hundred fifty million gallons of water flooding into the mine compressed the air to more than twice the normal atmospheric pressure.

At the request of local officials, U.S. Navy recompression chambers, normally used for submarine rescue operations, were set up in a barn on the William Arnold family farm within 18 hours of the first call for assistance. Nine multi-place recompression chambers, five small monoplace chambers, and 60 Navy personnel were on site and ready to receive patients.

After the correct position was determined via global positioning system coordinates, a 6-inch survival hole was drilled. When the drill was shut down, tapping was heard on the other end. Nine taps were sent from topside and nine taps were returned from below, indicating that nine miners were alive. High-pressure air pumped down through the drill rig provided a source of fresh air and helped to prevent water from rising within the mine. Turbine pumps at the mine entrance pumped water out of the mine, but at a rate that would take weeks to pump the mine dry.

A 32-inch rescue hole was drilled. A cylindrical yellow steel cage, the rescue capsule, would lift miners one at a time up 245 feet through the hole. A remote video camera attached to the capsule would assist in determining conditions within the mine and look for signs of life. Since most of the rescue hole was unsheathed and could collapse at any time, food, water, and blankets were loaded into the basket for the first trip below.

To prevent rapid depressurization when the drill pierced the mine, a special cap for the rescue hole was designed and rapidly constructed on site, allowing the removal of miners while maintaining pressure in the mine. Once at normal pressure, the miners had about 15 minutes before the onset of decompression sickness symptoms. During this latent period, they had to be moved from the rescue hole, had to undergo a quick medical examination and decontamination, and had to be returned to depth in the recompression chambers and then decompressed using tables developed at the Navy Experimental Diving Unit in Panama City, Florida, for submarine rescue.

Working at full capacity, pumps were able to lower the water level and reduce the pressure in the mine at a rate of about 10 cm of water per hour in what turned out to be an almost perfect air saturation decompression schedule. Shortly after midnight, the first miner reached the surface. Covered in coal dust from head to toe, he was carried up the hillside to the decontamination tent, where his clothes are cut away and a cursory medical history and examination were conducted. After soap and warm water decontamination, he was quickly moved to the medical treatment area. While the civilian emergency medical technicians started an intravenous line for the patient, Navy personnel obtained vital signs and performed a physical examination. The process was repeated eight more times, with the last miner being brought to the surface at 2:45 AM. One patient required treatment in the recompression chamber after suffering symptoms of decompression sickness.⁷

Submarine or Surface Vessel Accident

Steven T. Cobery and Dale M. Molé

DESCRIPTION OF EVENT

Vessels that travel on the surface of the water fulfill many vital needs in support of the nations of the world today. Oversea shipping remains the preeminent means for transporting large amounts of material internationally. Naval vessels actively deploy, conducting missions throughout the world with conventional and special weapons aboard. Within coastal and near-land waters, millions of fishing vessels of varying sizes scour the seas, providing both a vital food source and a substantial addition to many local economies. Huge cruise liners offer every conceivable type of enjoyment and relaxation for the millions of vacationers they entertain each year. Submarines, almost exclusively military in usage, silently and stealthily patrol every ocean on earth, often under adverse conditions and far removed from readily available medical attention.

Each of these segments of the shipping world poses very unique problems when it comes to the medical care of the personnel and passengers aboard. The medical facilities aboard most ships are sparse because space is a scarce commodity on most vessels. The capability of first responders is impaired both by their level of knowledge and training and the amount and quality of available medical equipment. Dedicated, medically trained personnel exist only on larger ships; the role of the “ship’s doc” is often a collateral duty of nonmedical personnel on smaller commercial vessels. Diagnostic imaging and laboratory testing are nonexistent in almost all cases. Communication equipment capabilities vary from very advanced satellite voice communications to visual line-of-sight signaling. The challenges posed by a seaborne mass-casualty incident or disaster to shore-based facilities are enormous.

All sea traffic faces the common foe of an unpredictable and often hazardous work environment. The inner workings of any vessel afloat are choreographed in an effort to conserve energy, personnel, money, and space. Imagine the occupational hazards present in a land-based facility that combines a power plant powerful enough to light several neighborhoods, a processing facility capable of independently handling tons of material daily, and a mechanical plant with a vast array of rotating machinery and high-pressure systems. The occupational hazards of these facilities alone produce

huge risks for their workers. Now take this facility, place it on a moving platform that has approximately one-quarter the footprint, and operate it with efficiency in an external environment that can range from dead calm to “the perfect storm”—that is, 30-foot waves with wind gusting to 100 miles/hour. The risks for mass casualties and accidents exponentially increase due to the constraints placed by operating at sea in a dangerous environment, both internal and external to the ship.

Three types of casualties commonly plague all shipping vessels: fire, high-pressure/high-temperature occupational exposures, and flooding/drowning. Fires are often called a ship’s worst enemy. Because of the myriad of flammable and combustible materials onboard the ship, all classes of fires represent an omnipresent and often fatal danger at sea. In addition to the fire itself, smoke inhalation, electric shock, exposure to toxic gases, and chemical burns secondarily compound the casualties generated by an onboard fire. Consequently, firefighting skills and equipment occupy important places in the priorities of the crew. Fires can occur virtually anywhere on the ship and from any source. The power plant and hydraulic plants represent the majority of fire locations.¹ The priority of the crew in the event of a fire is first to extinguish the fire, and second to attend to the casualties. This prioritization can sometimes delay bringing injured persons to the attention of medical facilities, particularly when the fire occurs at sea rather than pier side.

In addition to fires in the propulsion plant, occupational exposures to high-pressure and high-temperature gases and fluids uniquely challenge the onboard medical capabilities. Most ships are powered by one of four means: steam, diesel-electric, gas turbine, and nuclear.² Each employ high-temperature, high-pressure gases to turn the prime mover, a turbine, often rotating at speeds in excess of 2000 revolutions per minute. Catastrophic rupture of the piping system in the propulsion plant can rapidly lead to death within minutes in the closed compartments of the engine room. Focal exposure to these fluids causes burns, high-pressure stream-penetrating injuries, toxic inhalation or ingestion, or blunt trauma. With nuclear propulsion, radiologic exposure complicates both the injury and its treatment. A unique feature of maritime engineering applications is that the mechanical and auxiliary systems of the ship are not restricted to

a defined industrial space; high-pressure air, hydraulics, and inert gas systems run the length of the ship, including living, recreation, food service, and open deck spaces.

In any maritime setting, water supports, passes through, and sometimes surrounds the hull of the vessel. The sheer power of the ocean adds a dimension of hazard not seen on land. Flooding on board is often not the result of a breach in the hull itself; most often, it is the result of a cooling water system failure or hull penetration interlock failure. The force of a sudden inrush of water can easily cause primary blunt trauma or secondary trauma associated with falls or impact. Drowning casualties, whether due to persons being swept overboard or occurring as a result of catastrophic flooding, frequently present themselves in a more delayed fashion by nature. Anoxic brain injury, hypothermia, and cardiorespiratory failure are common complications.³ The constant presence of the power of the sea makes these types of casualties a continuous threat.

Submarine disasters provide their own unique challenges. Submarines sink because of uncontrolled flooding. Only marginally buoyant by design, relatively small amounts of flooding can prevent a submarine from surfacing, especially if propulsion is lost. If this happens in the deep ocean, there are no medical issues since the submarine implodes once crush depth is exceeded. However, since collisions are most likely to occur over the continental shelf, having survivors trapped in a sunken submarine is a real possibility.

The decision to await rescue or to begin escape depends on the external as well as the internal environment of the submarine. In water deeper than 180 m, escape is not currently an option, despite a hostile internal submarine environment (i.e., high pressure, low oxygen, toxic gases). Weather over the disaster site may prevent the timely rescue of survivors. The ability for a submarine crew to survive for between 5 and 7 days is the ideal goal, but the nature of the disaster may result in significantly shorter times.

Barriers to survival are many. The ingress of water reduces the internal submarine volume, compressing the air and subjecting the crew to an elevated atmospheric pressure. As the total pressure increases, the partial pressure of constituent gases increases as well. Oxygen and nitrogen, the primary constituents of air, are lethal at high partial pressures. Central nervous system oxygen toxicity can cause death in a matter of minutes. High partial pressures of nitrogen produce narcosis in a dose-dependent fashion, as well as loading tissue with excess nitrogen. Survivors with nitrogen-saturated tissues must be decompressed or slowly returned to normal atmospheric pressure to avoid potentially fatal decompression sickness. Carbon dioxide produced by human metabolism is the limiting factor for submariners trapped in an airtight compartment, since carbon dioxide climbs to deadly levels before oxygen becomes insufficient to sustain life. Since the average ocean temperature is 4°C, clothing wet from flooding can quickly lead to hypothermia. Shivering helps to maintain core temperature but markedly increases the consumption of oxygen and the production of carbon dioxide. Toxic gases from fire or chlorine produced by flooded batteries may force the

crew to use emergency breathing apparatus or escape under unfavorable conditions.⁴

Submarine escape is potentially hazardous under the best conditions. Pulmonary barotrauma resulting in arterial gas embolism, as well as fulminate decompression sickness, are conditions that may occur and require immediate hyperbaric oxygen treatment.

PREINCIDENT ACTIONS

Hospital staff, emergency department personnel, outpatient facilities, and port control authorities should have an established, well-rehearsed plan to initiate reliable communications in a timely manner to ensure the prepared receipt of casualties. Assigning geographic areas of responsibility to primary receiving facilities will simplify routing of the injured and improve response times. Mass-casualty plans, which integrate local, state, and federal agencies, including both the coast guard and naval bases in the region, will establish the most efficient means of conveyance, triage, and treatment. Knowledge of receiving facility flight pad capabilities, including global positioning system coordinates of the helipad, the capacities in terms of type and number of helicopters capable of being accommodated, and special local area flight considerations, should be evident in these plans. Special decontamination procedures to be used in the event of radiologic contamination or exposure to hazardous materials should be in place to handle these unique potentialities. Secondary facilities should be identified to receive overflow casualties for which the primary facility cannot provide care.

POSTINCIDENT ACTIONS

Once notified of incoming casualties from a seaborne platform, feedback to the port control authorities and U.S. Coast Guard/U.S. Navy will assist in refining mass-casualty planning for future events.

MEDICAL TREATMENT OF CASUALTIES

Because of the relatively wide variety of casualties that can be encountered from a shipborne accident, the treatment of the injuries should follow the standard of care for that specific injury. Two common complicating factors, however, should be addressed. Prolonged exposure to the elements at sea can rapidly lead to hypothermia. In most oceans, hypothermia ($T_c < 35^\circ\text{C}$) occurs in less than 30 minutes. The onset varies with multiple factors, including water temperature, sea state, amount and type of clothing worn by the patient, body habitus, and other factors.⁵ Although exposure suits are required aboard many sea-going vessels, due to the exigency of the casualty or their physical location, many casualties may not be able to access these suits. Hypothermia becomes a primary injury that can sometimes be overlooked in the face of other, more obvious injuries.

Contamination with toxic or hazardous material, including radioactive fluids or waste, is a silent, invisible complicating factor in the treatment of these casualties. Before any intake, treatment, or care, proper containment or decontamination, in accordance with the mass-casualty plans, must occur to ensure the safety of the treating personnel and the other patients at the receiving facility. However, disaster management planning must include the provision for providing life- or limb-saving medical treatment for contaminated injured personnel while maintaining a safe environment for the medical staff. Every emergency department must have a well-rehearsed treatment/decontamination plan for contaminated patients. Most radioactive surface contamination can be removed using soapy, lukewarm water to gently wash the affected area. Scrubbing runs the risk of embedding these contaminants and should be avoided.⁴ Chemical exposures should be assessed for their acidity/basicity to ensure proper usage of neutralizing agents. Once patients have been verified clean/decontaminated, physical entrance into the treating facility can safely occur. Life-saving interventions for the contaminated patient must be weighed against the risk of exposure to the treating personnel.

Radiologic controls, in the event of a radioactive release or spill, can greatly slow response, recovery, and treatment times. Very specific regulations govern the management of radiologic sites. These regulations are written in an effort to minimize the exposure of radioactive materials to the public. In the event of a casualty involving contaminated, injured personnel, public exposure will be limited by the reliance on the receiving facility to safely decontaminate the injured in an effort to minimize any delay in medical attention. However, the benefit of life- and limb-saving measures must outweigh the risk of low-level radioactive exposure of the medical responders.

Explosive hazards are real potentials on many vessels, particularly warships. Most disasters occurring on U.S. naval vessels will be managed by the regional commander and the organic medical facilities and personnel in that command. However, disasters remote from dedicated U.S. naval medical centers capable of handling mass casualties may require civilian assistance, particularly when deployed out of territorial waters. Knowledge of and planning for the treatment of injuries associated with explosive trauma (e.g., blunt/penetrating trauma, amputations, blast injury) complete any plan dealing with seaborne disasters.

CASE PRESENTATION

On the evening of August 26, 1988, the Peruvian submarine *Pacocha* with 49 persons aboard was struck by a Japanese fishing vessel while returning to the port of Callao, Peru. The submarine sank in 140 feet of water about 6 nautical miles from land. Twenty-three crewmembers managed to scramble overboard, but three of those later drowned or succumbed to exposure in the 14° C water prior to rescue. The captain and three of his crew drowned immediately while attempting to save the submarine.

Twenty-two submariners were trapped in the forward compartment, where flooding had increased the internal pressure to about three times normal atmospheric pressure. After about 20 hours, rising carbon dioxide levels forced the survivors to begin escaping from the submarine. Upon reaching the surface, all required recompression treatment in a hyperbaric chamber for decompression sickness. Of these 22 submariners, 1 died and another suffered severe brain damage/quadruplegia.⁶

PITFALLS

Several potential pitfalls in response to a naval vessel accident exist. These include the following:

- Failure to fully exercise the sea disaster mass-casualty plan
- Failure to consider radiologic or toxic contamination in the process of providing treatment for affected persons
- Allowing low-level radioactive contamination to delay life- or limb-saving medical treatment
- Poor communications hampering efforts to properly coordinate patient transport
- Failure to anticipate and properly treat hypothermia in casualties exposed to the environment
- Failure to adequately communicate instructions for basic medical care to on-scene personnel lacking medical expertise
- Lack of knowledge regarding the location of hyperbaric facilities

UNIQUE CONSIDERATIONS

Shipboard spaces are often difficult to navigate, particularly with bulky medical gear and stretchers. Consequently, initial assessment, extraction, and transport to the weather decks can present challenges that hamper the provision of care. Accurate relaying of patient location on the ship can speed recovery times, particularly on smaller ships that will rely on outside medical assistance on board the ship.

chapter 174

Aircraft Hijacking

Kurt R. Horst

DESCRIPTION OF EVENT

Aircraft hijacking is defined as the armed takeover of an aircraft.¹ Prior to the events involving the World Trade Center in New York City on Sept. 11, 2001, most hijackings involved the use of the aircraft as transportation and the passengers as hostages. The hijackers would then typically present specific demands, which would be negotiated.¹

The first recorded aircraft hijacking occurred in 1931 in Peru when a group of armed revolutionaries approached a Ford Tri-motor aircraft and attempted to force the pilot to fly them to their destination.^{1,2} The pilot refused, and after a 10-day standoff during which the revolution had been successful, the pilot was released.^{1,2} Unfortunately, many aircraft hijackings do not end so peacefully. A few noteworthy incidents are presented in Table 174-1.

Before the events of Sept. 11, 2001, anti-hijacking training followed what was termed the *Common Strategy*. This philosophy was based on prior experiences with hijackers. It instructed aircrews to avoid attempts to overpower these persons, and encouraged actions to resolve hijackings peacefully, even by accommodating the hijackers when necessary. But the goal of the Sept. 11 hijackings was to use the aircraft to perform a suicide attack, rendering the Common Strategy obsolete.⁵

Since this attack, training has been altered and is now referred to as the *Crew Training Common Strategy*. It now instructs pilots to not open the cockpit door and new Federal Aviation Administration regulations require the reinforcement of those doors. However, if the door is breached, the flight crew will attempt to protect the aircraft from being taken over.⁶ New legislation, including the Arming Pilots Against Terrorism Act of 2002, has opened the way for the training and deputization of pilots.^{6,7} This will allow pilots to carry a firearm and provide an added safeguard to the security of the flight deck.^{6,7}

In November 2001, the Aviation and Transportation Security Act was passed and the Transportation Security Administration (TSA) was created to oversee travel security.^{8,9} Initially placed under the U.S. Department of Transportation, the TSA now falls under the Department of Homeland Security.⁹ The TSA is now responsible for overseeing the screening of passengers, baggage, and cargo to detect possible threats, including explosives.^{8,9}

As seen with historical examples of aircraft hijackings, many hostage situations are resolved with force. The emergence of the field of tactical emergency medical support over the last decade may provide a key role in such operations. Emergency medical providers, optimally trained at the paramedic level, serve as members of special weapons and tactics (SWAT) teams. SWAT teams often have a role in resolving hostage situations involving aircraft. The ability to provide immediate, high-level medical attention to hostage victims after entry is made may increase survival of those injured in the incident.^{10,11}

PREINCIDENT ACTIONS

Much of the focus on aircraft hijackings has centered on modalities to detect and prevent them from occurring. As outlined in detail previously, the TSA was developed to spearhead many of the changes that have occurred since the Sept. 11, 2001, hijackings in the United States.^{8,9}

Medical personnel should be aware of the various injury patterns that may be present in victims involved in an aircraft hijacking and hostage situation. Knowledge and participation in tactical emergency medical support operations will improve survivability.^{10,11} Acute exacerbations of pre-event medical conditions among victims may occur during the hostage situation. This may be precipitated by the stress of the event itself or due to the lack of availability of the patient's own routine medications. For example, a diabetic might develop a hyperglycemic reaction due to lack of access to his insulin that he placed in his checked luggage for an anticipated short flight. As such, emergency responders should be prepared to treat a myriad of primary medical conditions.

Continued training of airline personnel using the Crew Training Common Strategy will be imperative in preventing future suicide hijackings.^{6,7} The arming of pilots is clearly a controversial issue. However, if carried out, proper training in firearms safety and use is required.⁷ The presence of air marshals, law enforcement officers who fly aboard commercial flights, may also provide added protection because they have specialized training in the prevention of hijackings.¹² Finally, aircraft passengers may find themselves in a position where they must

TABLE 174-1 SELECTED AIRCRAFT HIJACKINGS

1968	Three members of the Front for the Liberation of Palestine (PFLP) hijack an El Al plane. After 40 days, the hostages and hijackers are released. ^{1,2}
1969	Eight U.S. airliners are hijacked to Cuba in 1 month. This leads to development of a Federal Aviation Administration task force that creates a hijacker “profile” used in conjunction with weapons-screening devices. ²
1970	Four airliners, including one operated by a U.S. carrier, are hijacked by the PFLP. Three are successful and force landings in the Jordanian desert, where they are exploded after the passengers deplane. All hostages are subsequently freed after seven PFLP members are released from prison. ^{1,3}
1970	A copilot is fatally wounded by a hijacker on an Eastern Airlines flight. The copilot shoots and severely wounds the hijacker. The pilot, who was also injured, safely lands the aircraft. ²
1976	Palestinians hijack an Air France aircraft. After landing in Uganda, Israeli commandos free 105 passengers after they storm a building where the hijackers had relocated the hostages. Three passengers, all the hijackers, and one commando are killed. ¹
1982	Fifty-nine people die when Egyptian commandos infiltrate an EgyptAir plane after it is hijacked by Palestinians and flown to Malta. ²
1984	Four Arab hijackers aboard a Kuwait Airways jetliner force the aircraft to land in Iran. Once there, they kill two American citizens and commit other brutalities against the passengers. Iranian forces storm the aircraft, freeing the remaining hostages. ³
1985	Lebanese Shiite Moslems hijack a TWA airliner in Athens and kill a U.S. serviceman onboard the flight. The rest of the passengers are released in stages over the course of 2 weeks. The International Security and Development Cooperation Act of 1985 is signed 2 months later and provides monies for development of new airport security devices and hiring of additional security inspectors to serve as air marshals. ^{3,4}
1986	After a 16-hour standoff, 22 people are killed when Pakistani forces storm a hijacked Pan Am flight in Karachi. ^{1,2}
1988	The explosion of a Pan American jetliner over Lockerbie, Scotland, by an explosive device in a cassette player prompts the institution of a number of security measures, including installation of devices to detect explosives and stricter penalties for trying to take a gun through airport screening sites. ^{3,4}
1996	One hundred twenty-five passengers are killed when an Ethiopian Airlines flight crashes into the Indian Ocean when hijackers refuse to allow the pilot to land and refuel. Fifty passengers survive. ²
2001	On September 11, three American aircraft are hijacked and deliberately used to cause destruction at the World Trade Center towers in New York City and the Pentagon in Washington, DC. A fourth hijacked aircraft crashes in Pennsylvania after passengers attempt to retake the plane. ^{1,2,4}

act. This will certainly be a hard decision, and giving advice in this particular manner is difficult. However, as seen on Sept. 11, 2001, the action of private citizens prevented the fourth airliner from reaching its target.⁵

POSTINCIDENT ACTIONS

The information just described can be used to develop a specific action plan in the event that a hijacking attempt has begun. Once on the ground, negotiations

may occur between the hijackers and law enforcement personnel. Alternatively, the aircraft may be entered by specialty teams that will use an array of techniques to gain entry and incapacitate the hijackers. Medical personnel must be readily available to treat injuries to hijackers and hostages alike.

MEDICAL TREATMENT OF CASUALTIES

A variety of injury patterns are likely to be expected among victims of aircraft hijackings. With more stringent screening of passengers and luggage, there may be a lesser chance of seeing gunshot wounds, especially compared with prior hijackings. However, with some pilots now carrying weapons and the possibility of armed rescue attempts by military special forces and SWAT teams once the aircraft is on the ground, the possibility of seeing such patterns of injury remains. As such, emergency personnel attached to these teams and in the emergency department must be prepared to provide appropriate immediate care. Additionally, penetrating trauma from an array of instruments such as knives, screwdrivers, and other sharp objects should be treated in a manner similar to gunshot wounds.

Evaluation, as always, should begin with an assessment of airway, breathing, and circulation and then progress to a secondary survey. Intubation should be performed as needed, and intravenous resuscitation should begin with crystalloid solutions.

Penetrating trauma to the chest may result in cardiac injury leading to pericardial tamponade, which must be immediately recognized and treated with fluid boluses, needle aspiration, and subsequent surgical intervention.^{13,14} Beck’s triad, while not always present, is indicative of pericardial tamponade and consists of hypotension, distended neck veins, and muffled heart sounds. Ultrasonography is used to confirm the diagnosis. Thoracotomy may also play a role in the treatment of this condition.¹⁴ If a tension pneumothorax is suspected (evidenced by hypotension, distended neck veins, unilateral decreased breath sounds, and tracheal deviation), immediate needle decompression must be performed before obtaining a chest radiograph.^{13,15} A tube thoracostomy may then be performed.¹⁵ Simple pneumothorax, hemothorax, and a variety of injuries to the great vessels and lung parenchyma may also occur and must be identified early as surgical therapy may be indicated.^{13,14}

Penetrating abdominal trauma can be recognized by the identification of a penetrating wound, evisceration, and the presence of tenderness and peritoneal signs on physical examination. Any aberration in vital signs may also point to the presence of internal hemorrhage.¹⁶ Diagnostic peritoneal lavage, focused abdominal sonography for trauma (FAST), and computed tomography (CT) scan all may play a role in the management of a stable patient. However, emergent exploratory laparotomy may be required, especially if the patient becomes unstable.^{16,17}

Penetrating trauma to the neck may result in damage to a number of structures including vasculature, the esophagus,

and trachea. Specialty surgical services are necessary to further evaluate these injuries as many may require surgical intervention.¹⁸ Penetrating head wounds produce brain injury and hemorrhage and require CT scan and neurosurgical evaluation. Complications include infection, seizure disorders, and variable neurologic dysfunction.¹⁹

The potential for blunt trauma also exists. Blows to the head may result in an array of injuries, including epidural and subdural hematomas and intraparenchymal hemorrhage, which may be diagnosed by CT and should prompt neurosurgical consultation.¹⁹ Blows to the chest may result in rib fractures, pneumothorax, and hemothorax, which can be treated with needle decompression and tube thoracostomy when necessary.¹⁵ Blunt trauma to the abdomen can cause solid organ injury and internal hemorrhaging. Physical examination findings include abdominal tenderness, peritoneal signs, and abdominal abrasions or areas of ecchymosis. Evaluation with ultrasound (FAST examination), CT scan, or diagnostic peritoneal lavage is indicated, and positive findings may warrant monitoring or surgical intervention.²⁰ The management of extremity trauma includes control of hemorrhage and stabilization of possible fractures until the patient reaches definitive care.

Exposure to chemical incapacitants such as 1-chloroacetophenone (Mace) and oleoresin capsicum (i.e., pepper spray) may also occur. These agents are irritants that affect the eyes, respiratory tract, and skin. Rescuers and healthcare providers should wear appropriate protective equipment to avoid exposure to the irritant, which may be more persistent in enclosed spaces, and the victim should be removed immediately from the area of release. Skin should be washed with soap and water. Respiratory symptoms may require the use of inhaled beta₂ agonists such as albuterol.²¹ Eye symptoms

should be treated with contact lens removal (if they are present) and eye irrigation. After improvement of symptoms, the eyes should be examined with the use of a slit lamp to detect corneal abrasions, and topical antibiotic should be prescribed if abrasions are present.²²

Additionally, a number of victims will likely have underlying medical conditions that may require treatment. A major area of concern among all victims is that of psychological trauma. This may take the form of acute stress reactions, and some may develop posttraumatic stress disorder. One possible method of intervening to prevent this disorder or decrease its symptoms is a debriefing of the event soon after its occurrence. After the December 1994 hijacking of an Air France plane, passengers underwent a debriefing of the incident by a team of psychiatrists. During the hijacking, two passengers were killed by hijackers in front of passengers in the first 5 hours, and a third was executed the next day. Thirty-five passengers were released before the aircraft departed for Marseilles. The other 188 were released after a total of 54 hours after a military assault of the aircraft. It was found that the group of passengers who were initially released suffered from more psychological reactions, perhaps as a result of concern over being executed by hostages immediately after being freed.²³ Unfortunately, this study did not follow up with patients to determine whether this single debriefing prevented worsening or occurrence of psychological symptoms. Although many support the use of an immediate debriefing technique (e.g., critical incident stress debriefing), some reviews have not found this form of single-session therapy to be beneficial.²⁴ A better technique may be to use the debriefing as a bridge to further outpatient therapy if it is determined that the patient would benefit from ongoing care.

CASE PRESENTATION

Three men board a plane at Baltimore Washington International (BWI) Airport bound for Los Angeles. Moments after the plane lifts off, the three men brandish pepper spray containers and announce that they are taking over the plane. They are also holding some type of sharpened wooden instruments. Members of the flight crew attempt to disable one of the men, but they become incapacitated when they are exposed to the pepper spray.

One of the men begins hammering at the cockpit door, ordering that it be opened immediately or he will begin killing hostages. The pilot and copilot verify that the door is secure and immediately radio the air traffic controller who quickly diverts them back to BWI. The air traffic controller also notifies local authorities, who immediately respond to the airport.

An air marshal sitting near one of the hijackers is able to incapacitate him. One of the remaining hijackers grabs a person from a seat near him and holds the sharpened object to his throat, threatening to kill him. The air marshal, realizing they are now on final approach back at BWI airport, stands back and attempts to negotiate with the hijacker.

The aircraft lands and is quickly met by members of the local SWAT team who also possess a dedicated medical

component. They know the number of hijackers at this point and determine the best location for entry of the airplane. The team storms the plane and ultimately shoots the hijacker who was holding the man hostage. The other two hijackers are arrested without incident.

The paramedics attached to the SWAT team attempt to treat the hijacker, but he has sustained a fatal injury to the head. They recognize that many people in the front of the aircraft, including three members of the flight crew, are experiencing some difficulty breathing and tearing of the eyes. They recognize a possible exposure to a chemical irritant and don masks and gloves. These victims are rapidly extricated from the airplane and their eyes are irrigated. Those experiencing respiratory symptoms are treated with oxygen and albuterol. These patients are evaluated at a local hospital and released a few hours later.

A passenger with a history of myocardial infarction reports that he has had chest pain for the last hour but had forgotten to pack his nitroglycerin in his carry-on luggage. He is diaphoretic, tachypneic, and notes that the pain radiates into his left arm. Paramedics administer oxygen, aspirin, and nitroglycerin with some improvement. He is admitted at a local hospital and diagnosed with acute myocardial infarction.

UNIQUE CONSIDERATIONS

Elements of an aircraft hijacking that are unique include the following:

- Although historical examples of hijackings involved hostage taking and negotiating of demands, the possibility of suicide hijackings is now present.
- Airplanes represent a relatively small, closed space, and if they are in flight, hostages are prevented from attempting to escape.
- The flight deck must remain locked down at all times, irrespective of events occurring in the passenger compartment.
- Pilots on the flight deck may be carrying guns to prevent hijackers from taking over the aircraft.
- Air marshals may be present to assist in overcoming a would-be hijacker.
- Due to the confined space, an increased number of injuries may be expected if special teams gain entry to eliminate the threat posed by the hijackers.
- Exposure to chemical incapacitants in this closed space may result in a large number of occupants becoming symptomatic after exposure.
- Many passengers will experience some form of psychological reaction after the event.
- Passengers may experience acute exacerbations of underlying medical conditions.

PITFALLS

Several potential pitfalls exist in response to an aircraft hijacking. These include the following:

- Not having appropriate and rigid screening practices in place to detect potential weapons that may be placed on the aircraft
- Assuming that hijackers only wish to divert the flight and land at another locale
- Allowing hijackers to overtake the flight deck by opening the flight deck door
- Improper training of the flight crew regarding the Crew Training Common Strategy on how to deal with an attempted hijacking
- Not incorporating medical assets into special response teams that may gain entry into the aircraft in an attempt to rescue hostages
- Medical personnel not wearing appropriate protective equipment, especially when exposure to chemical incapacitants is likely

Aircraft Crash into a High-Rise Building

Kurt R. Horst

DESCRIPTION OF EVENT

The attacks on the World Trade Center in New York City on Sept. 11, 2001, are a grim example of the immense damage and destruction that can result when an airplane impacts a high-rise structure. A thorough examination of this disaster may yield a greater understanding of the effects of such an event. Within 20 minutes of each other, two Boeing 767 jets collided with the north and south towers of the World Trade Center, instantly killing the 157 passengers and crew and countless others in each building. In less than 2 hours, both towers had collapsed.¹

The World Trade Center towers were completed in 1973 and stood over 1300 feet high.² They were constructed using a lightweight perimeter tube design, essentially creating a structure akin to an egg crate.^{2,3} As such, the design was redundant and, if a few columns failed, the load would be transmitted to adjacent columns.³ The design allowed for toleration of enormous wind loads and withstanding the impact of an airplane—specifically, a Boeing 707.^{3,4}

Why, then, did the towers ultimately collapse? Investigations and research are ongoing, but one possible theory points to the resulting fires that occurred as likely being the chief cause. Immediately after each impact, the initial explosion ignited tens of thousands of gallons of jet fuel, which spread rapidly through the involved floors. It is believed that the immense heat, coupled with the near-instantaneous spread of the fire throughout the structure, led to structural damage and distortion of the steel beams. Eventually, multiple beams at that level failed, and the floor below the impact site could not withstand the massive weight of the 10 to 20 floors above that came crashing down. The buildings ultimately fell because of the inertia of their massive weight, the fact that the buildings themselves were 95% air, and that there was an insignificant lateral load applied to the structure.³

As a result of these attacks, more than 2800 people were killed, including over 400 emergency responders.⁵ In each tower the catastrophic event consisted of a large-scale mass-casualty incident (MCI) with many varying components. It began with an explosion (likely to have resulted in blast-type injuries) followed by a high-rise fire, which presented its own unique challenges. The subsequent building collapse created a potential need

for confined-space rescue.⁶ Injuries surrounding the buildings included blast injury, inhalation injury, and thermal injury.⁷ Additionally, the involvement of not one, but two high-rise structures added to the complexity of the event, whereby two asynchronous crashes essentially led to two MCI events.⁶

After these attacks, the U.S. Federal Aviation Administration halted all aircraft activity in the United States. The military diverted resources to the East Coast of the United States and military air patrols were begun.^{8,9} General aviation slowly resumed as new security measures were implemented.¹⁰

Initial confusion and incorrect communication may have led to a delay in evacuation of one or both buildings.¹¹ Communication difficulties also occurred during the response to the incident. As would be expected, radio transmissions increased, many of which were incomplete or unintelligible after the first aircraft struck the first tower. Of note, a New York Police Department helicopter communicated information regarding the impending collapse of the towers, but this information does not appear to have been relayed to emergency responders on-scene.¹²

Finally, a large number of private citizens, physicians, nurses, and other healthcare providers arrived on-scene to provide assistance after the attacks. This process, termed *convergent volunteerism*, although well intentioned, presents a problem on many levels. These persons, in general, are not trained to work in the prehospital setting. They generally lack appropriate safety and personal protective equipment for field operations and may put their lives and the lives of others in jeopardy. These persons also typically engage in freelancing, creating their own triage and treatment areas that have no ability to communicate with the Incident Commander. Verification of credentials and the process of ensuring personnel accountability may be compromised.¹³

PREINCIDENT ACTIONS

A number of lessons can be learned from this tragic event, many of which are intuitive from the discussion above. One primary goal would be to investigate ways to improve the structural integrity of high-rise buildings to

ensure that they will withstand this threat. Although the World Trade Center towers did withstand the initial impact, they ultimately collapsed as a result of loss of structural integrity due to the heat of the subsequent fires.^{3,4} Many organizations are continuing to investigate the cause of the collapse, and perhaps this will lead to improved integrity of buildings in the future. In addition, the availability of structural engineers to assess buildings immediately after impact will be of great benefit to determine the likelihood of impending collapse. They will also be useful in evaluating the damage to surrounding structures, as was seen after the Sept. 11, 2001, attacks.⁵

In light of the relatively short time available for evacuation, coupled with the tremendous size of high-rise buildings, it is imperative that emergency egress routes are well planned, easily understood, and practiced. The addition of clear, concise, and correct information broadcast over multiple loudspeakers may aid in decreasing the time that occupants spend debating whether the threat is serious enough to warrant evacuation.^{5,14}

From the perspective of emergency personnel, it is imperative that strict adherence to all protocols and the Incident Command System is maintained. Personnel accountability must be enforced, and the safety of rescue personnel must be maintained.¹⁵ Additional and redundant systems of communications must be instituted to decrease system failures.¹⁶ At the same time, contingency plans (e.g., using runners) for total systems failure must be devised. Training specific to this environment must be provided to all emergency personnel and may include high-rise and structural fire suppression and rescue operations, recognition of precursors to building collapse, and confined-space rescue.

Medical triage systems must be used and practiced before an MCI occurs.¹⁷ Specific information about hospitals in the immediate and distant areas, bed status, and specialty capabilities must be available to aid in patient distribution from patient-collection sites. Mutual aid agreements with surrounding ambulance and fire services must be in place before the event to ensure that adequate resources are available for the incident.¹⁸⁻²⁰ The Federal Emergency Management Agency can also provide a variety of mutual aid resources at the federal level when requested.²¹ In addition, it is important to recognize that all resources should not be deployed to the single incident because the average daily number of emergency calls received will continue to arrive.¹³

Finally, hospital disaster plans should augment normal staffing with additional resources.¹³ This should minimize the problem of convergent volunteerism, which creates a hazard at the hospital and at the scene of the incident. Hospitals must also be prepared for the presentation of patients in waves, with large numbers of walking wounded presenting with minor injuries first, followed by more severely injured patients. The next groups of patients will likely include those rescued from the structure as well as injured emergency personnel.⁷

Certainly, the prevention of this type of incident from occurring again is a paramount concern. In November 2001, the Aviation and Transportation Security Act was approved in the United States, creating the Transportation Security Administration. It also provided for a number of

new security measures, including enhanced screening at airports and the strengthening of flight deck doors aboard commercial aircraft. Provisions for the deployment of specially trained law enforcement agents (i.e., air marshals) onto commercial flights were also outlined.²² Lastly, a final line of defense should be in place in the event that an aircraft is overtaken and poses a threat to a high-rise structure in a large city. As seen after Sept. 11, 2001, this last-resort option included military flight patrols capable of rapidly responding to a potential threat and exerting deadly force when necessary.⁸

POSTINCIDENT ACTIONS

An action plan can be developed based on the experience of the New York World Trade Center attacks that can be used to guide an effective emergency response, minimizing injury and loss of life. After an aircraft has crashed into a high-rise structure, the following measures should be undertaken:

- Airspace restrictions should be instituted around the site and likely around the city and local airports. In many cases, as in the Sept. 11, 2001, attacks, the restrictions will be broader.
- A military air presence should be put into place around the area of the incident to provide for possible protection if the incident was the result of a terrorist act.
- Fire or police helicopter assets should be placed around the structure and should continually monitor for any signs of impending collapse.
- Police should set up a perimeter around the incident site to prevent access from bystanders and nonemergency personnel (this includes volunteers who arrive on scene to assist).
- The Incident Command System should be initiated.
- Redundant communication systems should be in place and must be able to handle the ensuing increased amount of radio traffic.
- Mutual aid agreements with surrounding services and private companies should be called into effect. Designated staging areas should be assigned to prevent congestion at the scene.
- Rescue and fire suppression operations should be initiated.
- Designated triage sites around the area of the incident should be set up and staffed by emergency medical services and fire personnel. These areas should be far enough from the actual site of the incident to prevent them from becoming involved if the structure were to collapse.
- Immediate evacuation of the involved building should begin. There should be no debate among occupants about whether to do so, and emergency egress routes should be used.
- During the rescue operation, as safety issues arise or if there is concern for building collapse, a clear warning signal notifying all crews to immediately evacuate should be broadcast.
- All resources at local and outlying hospitals should be available, and patients must be properly dispersed

throughout these facilities rather than over-triaging to the nearest facilities.

- Hospitals should institute their disaster plans, retaining on-duty employees and calling in additional resources as needed.
- Emergency medical and fire resources should also be in place to continue to handle the usual daily emergency call volume.
- Crews should rest frequently and remain hydrated. Rescue and emergency medical “go teams” should be set up to respond to emergency personnel entrapment or injury.
- In the event of a building collapse or simply a prolonged incident scene that will overwhelm local resources, plans should be in place to request additional local, state, and federal assets. This may include specialty teams, including search and rescue, disaster medical assistance teams, disaster mortuary assistance teams, and veterinary medical assistance teams.

MEDICAL TREATMENT OF CASUALTIES

Blast-injury patterns will be seen in victims of this type of incident. Victims may be located either inside the structure at varying distances from the impact site or below the impact as a result of falling debris. The typical array

of blunt and penetrating trauma will be caused by the initial impact, flying debris, and blast winds.²³ As a result, victims may suffer open and closed head injury that must be rapidly diagnosed. The possibility of spinal injury is also present if the victim is struck by an object or impacts a wall or other structure after being displaced by the blast wind. Lacerations and fractures, as well as all forms of thoracic and abdominal trauma, can result.²⁴ Primary blast injury, which affects gas-containing organs, such as the lung, bowel, and middle ear, can present special challenges to healthcare providers and must be diagnosed early.^{23,24}

Thermal and inhalation injury can result from the ensuing fires as jet fuel and room contents ignite after the initial impact.⁵ These may be severe in many cases, especially in those close to the initial impact site. Burns should be characterized by type and severity and referred to burn centers when necessary. Treatment may be as simple as the application of antibiotic ointment; however, full-thickness and circumferential burns of the chest may require escharotomy.²⁵ Occupants must be examined for signs of inhalation injury, including soot in the nasopharynx or oropharynx, difficulty breathing, and stridor, and they must be continually monitored for a change in condition. Early aggressive airway management should occur if there is suspicion of such injury.^{25,26} Toxic inhalation of carbon monoxide or cyanide must be identified early and may require hyperbaric oxygen therapy or

CASE PRESENTATION

At 10:30 AM, an air traffic controller at Chicago's O'Hare International Airport loses radio contact with a Boeing 757 and recognizes that its flight path has changed. After multiple attempts at radio contact, he recognizes a possible emergency and notifies his superior. Two F-15 military jets are diverted from a nearby training mission to investigate.

As the military pilots approach the aircraft, they report that it is losing altitude and is heading for the Sears Tower in Chicago. Before they are able to gather more information, the 757 impacts the 87th floor. A resulting fireball is seen as debris falls from the structure.

Recognizing that this may be a possible terrorist attack, Federal Aviation Administration representatives immediately set air restrictions for the city of Chicago, and all airlines leaving Chicago's airports are grounded. Aircraft en route to O'Hare and Midway airports are diverted. The military launches multiple groups of F-16 and F-15 fighters, which are now patrolling major cities across the United States.

Chicago police set up a perimeter around the incident and launch helicopters to survey the damage and provide immediate updates of changes or spread of the incident. Local fire and emergency medical services respond. The Incident Command System is put into place immediately, and triage areas are set up outside the immediate danger areas in case of collapse to serve as collection points for walking wounded and rescued occupants from the structure. Teams for initial treatment and evacuation of those who are injured are placed nearer the incident to provide immediate care and transport.

Immediately after the impact, the evacuation of the Sears Tower commences. Hundreds of persons exit the building and are directed through streets away from the incident. Firefighters entering the building begin assisting occupants and extinguishing the fire, which has spread to the 85th floor.

At 11:25 AM, Chicago police helicopters notice an area of the structure near the 86th floor that appears to be bowing outward. This is communicated to the Incident Commander, who orders an immediate evacuation of rescue personnel. A structural engineer is taken via helicopter to inspect the impact site. He feels that, at least at this point, the building remains structurally sound. He does note that with the continued spread of the fire, this will not remain the case.

After another 2 hours, the fires are extinguished. A few stairwells above the impact site remained intact, and a number of occupants above the 87th floor were able to be rescued.

It was estimated there were 8000 occupants at the time of the impact. Three hundred casualties were treated by emergency medical services at the designated triage areas and were distributed to local hospitals. It is estimated that 7300 occupants were evacuated. Two hundred ten passengers aboard the 757 and 700 occupants of the building were killed. While an investigation is ongoing, it does appear to have been a terrorist act.

All local hospitals immediately instituted hospital disaster plans on viewing television news reports and on receiving notification from the Chicago Fire Department. Hospital employees remained on duty, and those at home either came to the hospital or tried to rest in case they were needed as per their specific disaster plans.

the administration of a cyanide antidote kit, respectively.²⁶ In the context of a collapse, the large amount of dust and debris may also contribute to inhalation injury, as was seen on the attacks on the World Trade Center.⁷ Such injury may trigger asthma attacks and exacerbate underlying pulmonary conditions.²⁴

Emergency personnel should be trained in the proper use of personal protective equipment, including goggles, gloves, and respirators, when there is dust present after a collapse.²⁷ Standard treatment of blunt and penetrating trauma should be performed, including an initial assessment of airway, breathing, and circulation followed by a thorough secondary survey to identify other injuries. Supplemental oxygen should be applied, and intubation should be performed when needed. Wounds should be covered and likely fractures splinted. Early neurosurgical, surgical, and orthopedic evaluation should occur in the emergency department and appropriate interventions performed.

UNIQUE CONSIDERATIONS

An aircraft crash into a high-rise structure represents a unique environment. There tend to be a number of potential injury patterns, encompassing blunt trauma, penetrating trauma, thermal injury, and inhalation injury. Due to the large size of the structure, it may be difficult to obtain access to patients because the impact site generally will be among the upper levels of the building. The resulting fires may impede occupants from escaping and prevent rescue personnel from reaching victims and fighting the fires. The ongoing concerns around the resulting structural integrity of the building may be difficult to ascertain, and the possibility of secondary collapse is ever present.

The locations of these incidents, typically within cities, will likely result in damage not only to the structure impacted, but also to surrounding buildings. Falling debris may damage nearby structures, making them structurally unsound.⁵ These secondary impacts may therefore force the evacuation of nearby businesses and homes. The potential for secondary fire spread to these buildings is also not outside the realm of possibility. There will likely be injury and mortality below the impact side from falling debris.

Evacuation may not only include the impacted high-rise, but also a substantial portion of the area around that locale. The egress of thousands of people, not just from one building but perhaps from an entire area of a city, presents its own unique challenges. Evacuation routes in the city should be well marked, and plans for moving this populace should be developed before the occurrence of such an incident.

The concern over a possible terrorist attack must make rescuers wary of a possible secondary explosive device which, as seen on Sept. 11, 2001, may take the form of a second aircraft.²³ As such, a strong police and possibly military presence will be required to protect the scene and surrounding air space. The impact on air travel and the airlines will likely be dramatic.

PITFALLS

Several potential pitfalls in response to an aircraft crash into a high-rise building exist. These include the following:

- Failure to institute and follow the Incident Command System
- Failure to develop a series of redundant communications systems as well as contingency plans for total systems failure
- Failure to immediately evacuate the involved high-rise as well as buildings near-by
- Failure to recognize signs of potential or impending building collapse
- Failure to control access to the scene (Note: This is sometimes difficult to accomplish based on available resources and the size of the area involved.)
- Failure to prevent unsolicited volunteers from entering the scene
- Failure to adhere to triage protocols
- Failure to have a hospital disaster plan in place in each facility to provide for an influx of large numbers of patients
- Failure to recognize the need to continue to staff the daily emergency medical and fire service needs of the community that occur outside of the incident on a daily basis

Airliner Crash into a Nuclear Power Plant

Rick G. Kulkarni

DESCRIPTION OF EVENT

Nuclear power plants have been recognized as being potential targets of future terrorist attacks. Following the tragic events of Sept. 11, 2001, at the World Trade Center and the Pentagon in the United States, awareness has increased considerably among the public, federal regulatory agencies, and legislators regarding inadequacies in the ability of nuclear power plants to withstand direct attacks by large, high-speed passenger jets with full or nearly full fuel tanks.¹ The U.S. Nuclear Regulatory Commission (NRC), the federal agency responsible for security at the 100-plus nuclear power plants in the United States, has issued several regulatory orders to all licensed nuclear power plants to meet the increased security threat.^{2,3}

After the 1979 accident at Three Mile Island near Harrisburg, Pennsylvania, U.S. Congress enacted legislation mandating that all nuclear power plants be covered by emergency contingency plans. A direct consequence of this act was the imposition of a requirement by the NRC that operators of nuclear power plants maintain a 10-mile emergency planning zone equipped with warning sirens all around the plant.¹ Off-site preparedness (i.e., state and local government emergency preparedness activities that take place beyond the nuclear power plant boundaries) is the responsibility of the Federal Emergency Management Agency.⁴

Nuclear power plants are designed to withstand extreme events such as earthquakes and hurricanes. However, direct impacts by large, fuel-laden airliners into the containment building of the plant are not specifically addressed in the design specifications. The risk of a meltdown and subsequent contamination leading to the exposure of a large number of persons to escaping radioactivity by a direct impact of an airliner into the containment building can occur only if structural integrity of the building is compromised.⁵ Without a breach caused in the containment building, the radioactive fission products would mostly remain where they are. Such large-scale damage to the containment building could occur either as a direct consequence of the impact itself—a possibility especially for older plants where degradation of the building's construction materials over time may be a factor—or through a delayed loss of strength of the structural members resulting from a sustained and intense conflagration, similar to the one that melted the

structural steel in the World Trade Center buildings in New York. Additionally, for a meltdown to occur, there would also have to be subsequent or concomitant direct damage to the reactor vessel and its control equipment or disruption of normal functioning of the cooling mechanism designed to control the heat generated from the nuclear reaction within the fuel rods.^{1,5}

The NRC is currently conducting a detailed engineering analysis of the possible effects of such a crash scenario. Spokespersons for the NRC have repeatedly testified to Congress and other regulatory federal agencies that “most plane crashes into containment buildings would not result in significant releases of radiation.”²

If a large-scale contamination event were to occur, the immediate effects of radiation exposure on humans would most affect the rapidly dividing radiosensitive cells in the gastrointestinal tract and the integument. The central nervous system is also affected due to edema. Hematopoietic effects are ultimately the cause of delayed death if patients survive the immediate effects of radiation poisoning.⁶

Gastrointestinal Manifestations

Gastrointestinal manifestations can occur within 30 minutes of a severe exposure (for example, >10 Gy) or after 6 hours with a lesser exposure (e.g., <0.5 Gy). A higher dose generally results in an earlier onset of symptoms and a more protracted course. The first symptoms include nausea, vomiting, anorexia, and diarrhea. The denuded intestinal tract is a major source of septicemia, especially when combined with the hematopoietic effects of the radiation exposure. Patients will often also become dehydrated due to transudation of plasma into the gastrointestinal tract.⁶

Integument

Increasing exposure to radiation leads to epilation, erythema, and desquamation of the skin. Erythema and blistering with necrosis can develop within hours of a severe exposure or within 1 to 2 days after a lesser exposure.⁶

Central Nervous System

Massive exposure leads to edema of the brain. Patients may complain of headache or vertigo. Ominous signs

are altered mental status with or without the development of seizures.⁶

PREINCIDENT ACTIONS

The NRC is spearheading the effort to ensure the safety of our nuclear power plants from an airliner attack scenario. Since Sept. 11, 2001, the NRC has addressed several aspects of a comprehensive security plan including increased patrols, augmented security forces, installation of additional physical barriers, enhanced coordination with law enforcement agencies, and more restrictive site access for all personnel. Several legislative measures that call for actions ranging from the installation of anti-aircraft weapons at all nuclear sites to the deployment of National Guard troops were introduced into Congress since Sept. 11, 2001.³ In addition, proposals to increase the stockpiling of iodine pills are currently under consideration.³

Public awareness of a potential nuclear power plant accident is also important. Persons living in close proximity to plants should be able to recognize the sound of a warning siren, know its relevance, and be ready to begin evacuation in a timely and orderly fashion. They should have emergency supplies available for use in the event of a power disruption and should consider stocking iodine pills themselves. As a part of federally mandated measures after the Three Mile Island accident, Congress required all nuclear power plants to work with the NRC to conduct evacuation and emergency shutdown exercises regularly in the event of a plant malfunction, accident, or terrorist attack. Both the NRC and the Federal Emergency Management Agency monitor the exercises.^{2,4} All nuclear power plants in the United States have remained at the highest alert level since the Sept. 11, 2001, attacks. The NRC and other agencies, including commercial nuclear plant operators, have also significantly limited the amount of technical information made available to the public.

POSTINCIDENT ACTIONS

Once an incident has occurred, it is crucial that a predetermined disaster plan is commenced immediately. Using appropriate personal protection equipment for radiation exposure, rescue personnel should evacuate victims who are not able to leave the scene of the incident themselves in an orderly fashion. Emergency trauma care should be rendered to those victims presenting with blast and burn injuries. Also understand that there may be patients presenting with crush injury. The care of mass casualties from blast, burn, and crush injuries is discussed elsewhere in this book. All victims should be evacuated to a location upwind from the site and evaluated for degree of exposure (Table 176-1). Contaminated clothing should be removed from victims. Receiving hospitals should be notified early during postincident actions. Victims of radiation poisoning should be kept separated from other patients in the treatment area. Isolated water and ventilation systems should be used in designated containment and decontamination areas. Security personnel should control access to minimize the spread of contamination.⁶

TABLE 176-1 ILLNESS CATEGORIZATION FOR WHOLE-BODY RADIATION EXPOSURE*

CATEGORY	EXPOSURE (GY)	SYMPTOMS
Asymptomatic	<1	None
Mild	1-2	Nausea, vomiting ALC at 48 hours > 2000/mm ³
Moderate	2-4	Moderate GI symptoms ALC at 48 hours > 1200/mm ³
Severe	4-10	Severe GI symptoms ALC at 48 hours < 1200/mm ³
Fatal	>10-12	Severe GI symptoms within 30 minutes ALC at 48 hours < 300/mm ³

ALC, Absolute lymphocyte count; GI, Gastrointestinal.

*LD₅₀ = 4.5 Gy with medical treatment (100% without medical treatment).

All rescue and medical personnel should use universal precautions with gowns, gloves, masks, and shoe covers. Radiation survey monitors should be used to prevent contamination beyond known areas. All equipment and clothing suspected to be contaminated should be placed into secured plastic bags for proper storage and disposal.

The release of a radioactive form of iodine would be a significant component of a release event from a nuclear power plant. Radioactive iodine is absorbed and remains concentrated into the thyroid glands of humans, thus posing a long-term increased risk of cancer of the gland.^{7,8} All exposed persons, especially within the emergency planning zone, should be administered potassium iodide pills within 1 hour of exposure to prevent the absorption of the radioactive iodine.^{6,7}

mination areas. Security personnel should control access to minimize the spread of contamination.⁶

MEDICAL TREATMENT OF CASUALTIES

Clearly, the first layer of casualties will present with blast and burn injuries. These patients should be cared for per standard trauma protocol. The concern for decontamination should be only for those patients not requiring immediate, life-saving medical intervention. Such intervention should be done first, and decontamination should then follow. Treatment should be tailored to the degree of exposure to radiation and the manifestation of symptoms. However, there are core measures common to all victims of radiation exposure. All wounds should be irrigated with saline followed by 3% hydrogen peroxide or a soapy solution. Gastrointestinal decontamination with whole-bowel irrigation with activated charcoal is indicated within 2 hours of exposure for those with moderate or greater levels of exposure. Supportive treatment with intravenous antiemetic agents, intravenous fluid to replace gastrointestinal losses, and the dressing of open wounds and burns is indicated. Also indicated is early transport to a medical facility where advanced treatment such as the institution of viral prophylaxis, administration of hematopoietic growth factors, and bone marrow transplantation can be performed.⁴

Local police officials report that a group of men have been stopped on a California highway between Los Angeles and San Diego in a car laden with weapons and documents pointing to an attack on the San Onofre nuclear power plant. The incident is reported immediately to the U.S. NRC and to the Department of Defense (DoD). At the same time, the North American Aerospace Defense Command alerts the NRC and the DoD that a 767 Boeing passenger jet seems to be heading for San Onofre and it not responding to direct communication efforts.

Military personnel in jet aircrafts are scrambled from Edwards Air Force Base in Lancaster, California. Their mission is to intercept the passenger jet and order it to change course and land immediately at San Diego International Airport. Additionally, emergency measures to shut down the nuclear power plant are implemented at San Onofre. Minutes later, before the Air Force jets can make visual contact with the passenger jet's cockpit crew, the Boeing 767 crashes into the main containment-building tower of the power plant. Although the crash does not immediately compromise the structural integrity of the reactor's core

concrete containment building, it wipes out off-site power to the reactor necessary for the shutdown process. Backup generators fail, and a leak of reactor coolant raises the specter of a meltdown.

An emergency is declared in the area surrounding the nuclear power plant. Persons living in northern San Diego County, Orange County, and adjoining Los Angeles County are ordered to evacuate. Those who have potassium iodide are advised to "swallow one dose now."

Protesters quickly organize behind barricades outside the San Diego International Airport conference room—the headquarters for operations—where reporters receive intermittent briefings on the situation. It seems that a core reactor meltdown has been averted through the use of secondary backup generators, quick response, and the efficient action of local firefighter crews to extinguish the fire from the airliner's impact, and the competent implementation of emergency shutdown protocols by the power plant's staff. Two hundred forty-five persons in the passenger airliner and five persons on the ground were killed in the incident.

UNIQUE CONSIDERATIONS

Gross structural failure of the containment building is essential for a large-scale contamination event occurring from a reactor material release. Although the containment building may not be compromised by the direct impact of an airliner, the effect of a subsequent jet fuel fire or explosion could cause further mechanical and thermal damage to the containment facility, resulting in a structural collapse of the building.

Nuclear power plants house many more times the amount of radioactive substances than do stored nuclear weapons. If there is an accidental disaster or a deliberate act of sabotage, the release of only a small portion of this material will have severe consequences.

Radiation cannot be detected by sight, smell, or any other sense. This should be a consideration of responders and other personnel. Another element to be kept in mind is that the ingestion of a nonradioactive iodine pill will prevent the absorption and concentration of radioactive iodine released during a nuclear power plant meltdown.

Although there have been no incidents of an airliner crash into a nuclear power plant, the possibility of this type of terrorist attack cannot be excluded. Increased vigilance and preparedness of local, regional, state, and federal agencies as well as of the medical staff in areas with operational nuclear power plants is indicated.

- Failure to quickly isolate affected persons
- Failure to notify receiving hospitals in a timely manner
- Failure to properly categorize victims based on their degree of exposure
- Failure to identify and treat emergent traumatic injuries
- Failure to create a plan for mass treatment in the event of an attack

PITFALLS

Several potential pitfalls in response to an aircraft crash into a nuclear power plant exist. These include the following:

- Failure of rescue personnel to use appropriate personal protective equipment

Dirty Bomb (Radiologic Dispersal Device)*

George A. Alexander

DESCRIPTION OF EVENT

A *dirty bomb* is a device that combines radioactive materials with conventional explosives. Global terrorist organizations are believed to be interested in and capable of constructing dirty bombs and launching attacks with them.¹ There are only two documented cases of terrorist use of dirty bombs in the world today.² Both incidents occurred in Russia. In 1995, Chechen insurgents buried a cesium-137 dirty bomb in a park in Moscow and alerted the media before its detonation. In 1998, a container of radioactive materials was found attached to an explosive mine near a railroad line in Chechnya. Dirty bombs are attractive to terrorists because they are relatively easy to acquire and have the potential of causing casualties, contamination of widespread areas, adverse psychological effects, and economic disruption. A dirty bomb threat potentially poses a medical and public health disaster.

A dirty bomb can be made from traditional dynamite, trinitrotoluene (TNT), ammonium nitrate, or a variety of other explosive materials.³ When detonated, it kills or injures by the initial blast, which causes damage from the expansion of hot gases, and by dispersing radioactive materials that are highly toxic over a wide geographic area without a nuclear explosion. The dispersal effects of a dirty bomb depend on the amount of explosives used, the physical form of the radioactive source, and the atmospheric conditions.⁴ A dirty bomb is also known technically as a *radiologic dispersal device*.

Many different radioactive sources can be used to fabricate a dirty bomb. Radioactive sources can be obtained illicitly from hospitals and medical clinics, industrial radiography and gauging devices, food sterilizers, power sources, communication devices, navigator beacons, oil well logging, and scientific research laboratories. Some common radioactive sources that have a high probability of being used as a dirty bomb based on their availability include cobalt-60, strontium-90, cesium-137, iridium-192, radium-226, plutonium-238, americium-241, and californium-252.

*The views expressed in this chapter are those of the author and do not necessarily represent the official policy or position of the National Cancer Institute, the National Institutes of Health, or the Department of Health and Human Services.

Alpha-emitting radiation sources pose serious health hazards if they are inhaled, ingested, or deposited in an open wound. Beta-emitting sources can cause deep beta burns on the skin. Gamma rays may penetrate body tissues and cause deep tissue injury.

The most likely dirty bomb scenarios would involve the use of either a few small low-level radioactive sources or a large amount of highly radioactive sources combined with high explosives. The first scenario considers use of a dirty bomb containing a few curies of a gamma-ray source such as cobalt-60 or cesium-137 combined with a few kilograms of high explosive. In this case, the dirty bomb might be used with the primary intent of causing fear or panic among people and disrupting their community. Since the amount of radioactivity is small, the radiation exposure to individuals would be low, and no immediate effects on health would be expected. The probability of long-term health effects would be small.

The second scenario considers use of a dirty bomb containing large sources of penetrating radiation coupled with sophisticated high explosives. The detonation would disperse considerable amounts of radioactive material over a large area. Persons injured by the blast are likely to be contaminated with radioactivity and may receive life-threatening doses of radiation. Such a device is intended to kill tens or hundreds of persons, to injure and sicken hundreds or thousands, and to cause widespread panic.⁵

Recognizing that a conventional explosive device has been detonated may be simple because of the associated blast. However, it may take considerable time before the radioactive component of the dirty bomb attack is recognized. Therefore, it is important that first responders use radiation-detection equipment to identify a radioactive component after any explosion.⁶

Recognition of acute radiation injury is based on the patient's medical history and clinical findings.⁷ The extent of radiation injury depends on three factors: depth of penetration of the radiation, dose of radiation absorbed, and volume of tissue irradiated. For localized radiation exposure, the initial signs of injury might be a radiation burn including erythema, blistering, or desquamation. With a low whole-body dose of 0 to 100 cGy from a dirty bomb, a patient would generally have no symptoms. With a moderate whole-body dose of 100 to 200 cGy, the

patient may exhibit the prodromal phase (nausea and vomiting) of acute radiation syndrome. At doses exceeding 300 cGy, patients would experience nausea, vomiting, diarrhea, erythema, and fever. A useful method of predicting the clinical severity of radiation injury is the time to onset of vomiting. If the time to vomiting is less than 4 hours, the patient has received a high dose of radiation.

Laboratory data show that early changes in lymphocyte counts are associated with the severity of radiation injury. Absolute lymphocyte counts less than 1000 mm³ and greater than 500 mm³ indicate moderate and severe levels of radiation exposure, respectively. Complete blood counts can be repeated every 4 to 6 hours to evaluate lymphocyte depletion kinetics. The appearance of chromosome dicentrics in peripheral blood lymphocytes is also useful in calculating exposure dose. In patients who have developed acute radiation syndrome, within 2 to 3 weeks bone marrow suppression may occur with associated neutropenia, lymphopenia, and thrombocytopenia.

PREINCIDENT ACTIONS

One of the most important preemptive actions that emergency medical service agencies, hospital-based emergency departments, and outpatient facilities should do is to determine whether their community is a possible target for a terrorist dirty bomb attack. Coordinating with local and state law enforcement and response agencies should provide a framework in which to assess the dirty bomb threat and develop a medical radiation incident or injury protocol. The protocol should be incorporated into the overall disaster plan. The radiation disaster plan should address decontamination, security, radiation monitoring, and decorporation of radioactive materials. The hospital radiation safety officer should be included in the medical radiation response team. Hospital staff should understand the hazards of radioactive contamination and be trained in radiation-monitoring techniques. Staff would need access to dosimeters, Geiger-Mueller counters, and personal protective equipment. Radiation-detection capabilities are critical to an effective medical response. Hospitals should have a realistic decontamination plan for patients, a lockdown plan to control access, and evacuation plans. A radiation risk communication program is required for the public.

POSTINCIDENT ACTIONS

Emergency medical first responders arriving on the scene of a dirty bomb incident should initiate actions to treat or evacuate casualties. All response personnel should be advised of the explosive and radiologic hazards that may be present. Healthcare providers should advise others regarding safety measures to be taken to protect the public and to mitigate the radiation health effects. Patients evacuated from the scene and arriving at hospitals or medical clinics should be routinely monitored for radiation and decontaminated as needed.

Healthcare providers should control any exposure of hospital personnel to contamination. Clinicians should seek the assistance and cooperation of state and local authorities and inform them of casualties and possible hazards. Hospital radiation safety staff should periodically monitor the emergency department for radioactive contamination.

MEDICAL TREATMENT OF CASUALTIES

Injuries associated with dirty bombs pose new and significant challenges for clinicians. Since radiation affects many organ systems, it can complicate blast and thermal injuries associated with a dirty bomb. Conventional injuries should be treated first, since radiation contamination is not a life-threatening medical emergency. Patients with traumatic blast and radiation injury should be resuscitated and stabilized. The assessment of patient airway, breathing, and circulation always takes priority. Victims of radiation exposure require more specialized treatment, and specialists in hematology, oncology, radiation, and infectious disease should be consulted. Effective treatment of internally contaminated patients requires knowledge of both the relevant radioactive isotope and its physical form. Treatment should be instituted quickly to ensure its effectiveness. However, with a terrorist incident, initially the radioactive source or sources are not known.⁸ Several general approaches may be used to treat internal radiation contamination, including reduction of absorption (administer Prussian blue), dilution (force fluids), removal of blockage (use potassium iodide), rectification of displacement by non-radioactive materials (administer oral phosphate), mobilization as a means of elimination from tissue (use ammonium chloride), and chelation (achieve with Ca-DTPA and Zn-DTPA).⁹

Patients who have received a low whole-body radiation dose may develop gastrointestinal tract distress within the first 2 days. Antiemetic agents may be effective in reducing the gastrointestinal symptoms, which will usually subside within the first day. If not, the administration of parenteral fluids should be considered.

The prognosis for patients who have suffered traumatic blast, burn, and radiation injury is worse than for patients with radiation injury alone.¹⁰ A wound that is contaminated with radioactive materials should be rinsed with saline and treated using conventional aseptic techniques.⁴ Wounds contaminated with alpha-emitting radioactive isotopes are usually excised. In patients who receive whole-body doses of radiation greater than 100 cGy, the wound should be closed as soon as possible to prevent it from becoming an entry for lethal infection.

In spite of the wide availability of antibiotics, infections from opportunistic pathogens pose a major problem among patients exposed to intermediate and high doses of radiation. In these cases, the primary determinants of survival are treatment of microbial infections and aggressive resuscitation of the bone marrow.¹⁰

On a busy Thursday morning, you hear a radio news report of a massive explosion in a crowded downtown district of your large city. Casualties are being evacuated from the scene to local area hospitals. Officials believe the explosion may be due to a natural gas leak.

Later, you see a 47-year-old man who was brought to the emergency department of your hospital after being trapped for nearly 3 hours by fallen debris in a collapsed building at the scene of the explosion. He complains of left thigh pain, dizziness, nausea, weakness, and a burning sensation in his chest. Your high index of suspicion prompts radiation monitoring to be performed, and this

reveals a significant level of radioactivity from a beta-gamma emitter. A cursory examination reveals multiple superficial facial and upper extremity lacerations and a deep penetrating wound of the left thigh. The results of an initial complete blood count are unremarkable.

Meanwhile, the mayor has announced that the explosion may have been caused by a terrorist radioactive dirty bomb. Two more patients with multiple injuries are brought to the hospital by ambulance. The emergency waiting room is now filled with a dozen walk-in patients complaining of nausea and vomiting.

UNIQUE CONSIDERATIONS

In contrast to popular belief, a dirty bomb is not considered a weapon of mass destruction.⁵ Instead, it is used as a weapon of mass *disruption*.³ Because radiation is colorless, odorless, tasteless, silent, and invisible, the uncertainty of not knowing whether one is being or has been exposed to radiation instills fear and panic in most people. The psychological effects of a dirty bomb incident require special consideration.

Recognition of the importance of social and psychological issues will be essential in responding to a terrorist dirty bomb attack.⁶ Such an incident can cause profound psychosocial effects at every level of society including individual, family, community, and the nation. A dirty bomb attack has the capability of causing widespread fear, an increased sense of vulnerability, and loss of trust and confidence in societal institutions.⁶ The effects can be emotional, physical, cognitive, or interpersonal in nature. Significant numbers of people may suffer chronic distress years after an attack. Although a dirty bomb attack will create unique challenges, basic tenets of disaster mental health should still be followed in treating those affected.

PITFALLS

Obstacles to the provision of optimal medical care include the following:

- Failure to adequately prepare of medical response planning for possible terrorist dirty bomb attacks before they occur
- Failure to coordinate with local and state emergency response agencies

- Lack of understanding by medical providers of the basic science of radioactive isotopes
- Failure to consult with specialists who have clinical experience in the medical management of the effects of radiation exposure
- Lack of recognition that anxiety-induced nausea and vomiting may occur after a dirty bomb attack (This phenomenon has been observed after radiation accidents in which people thought they had been exposed to radiation even in the absence of actual exposure.¹¹)

Explosion at a Nuclear Waste Storage Facility

Constance G. Nichols

DESCRIPTION OF EVENT

Nuclear waste is the radioactive by-product of radionuclides used in medicine, industry, research, weapons development and manufacture, and power generation. Any facility that uses radionuclides is, in theory, a nuclear waste storage facility. Each site must have safe, secure storage for spent radionuclides until they are taken to a more definitive storage facility. Currently 131 facilities exist in the United States, with the Yucca Mountain, Nevada, site is the planned final repository for nuclear waste.

A fire, natural disaster, or intentional detonation of explosives in such a facility will potentially result in the release of radioactive materials of varying levels of injury and lethality. In 1982, the U.S. Congress directed the Department of Energy to construct a permanent underground storage facility for spent nuclear reactor fuel and other forms of high-level nuclear waste. In 1987, Congress directed the Department of Energy to develop only Yucca Mountain, Nevada, as a potential site, and President Bush recommended Yucca Mountain as a site in 2002. Due to problems with development, it is unlikely that Yucca Mountain will open as scheduled in 2010.

Sites holding waste pending long-term disposal are now trying to expand their wet pool storage (a less expensive option) because the existing wet pool storage is reaching capacity. Some are looking at the more expensive dry storage (i.e., steel containers in concrete bunkers) as a temporizing measure.¹

The U.S. Nuclear Regulatory Commission has felt that exposure of citizens to spent fuel would be unlikely because it is contained in a ceramic material. Exposure would require that the spent fuel be pulverized, such as in a high-speed impact or explosion, or the spent fuel would need to burn at high temperatures in a sustained fire.¹ Unfortunately, very similar conditions occurred with the use of airliners as bombs on Sept. 11, 2001.

The development of the Nevada site has been slow and controversial, and the area will not be available for many years. Therefore, it is necessary to regard any place that uses radionuclides as a potential nuclear waste storage facility.

A conventional non-nuclear explosion at a site of nuclear waste storage would be similar in some ways to that of a radiation dispersal device or “dirty” bomb. It would differ in the concentration, amount, and variety of radionuclides dispersed. Another important factor would be whether the explosion was accidental or planned in such a way as to maximize dispersal of radionuclides.

PREINCIDENT ACTIONS

Cities and hospitals all have general disaster plans. Sites storing nuclear waste have procedures for dealing with contamination. Before an event, it would be important to communicate to the city and hospital disaster planners the amounts and types of radionuclides present in a local facility. Although national security interests might preclude an exact accounting of amounts of materials, the general nature of the materials should be available to emergency services and healthcare providers who would be dealing with victims of such an event.

Drills covering radiation scenarios such as accidental release, conventional explosions, or terrorist attack should be considered and performed to acquaint all providers of emergency care with the special considerations for radiation disasters. Locations of radiation detectors in hospitals and ambulances should be part of the knowledge base of every provider working in those settings, as should basic decontamination principles.

POSTINCIDENT ACTIONS

Immediately upon notification of an explosion at a nuclear waste storage facility, hospitals and emergency services should begin responding according to their disaster plans. Fire and police set up hot and cold zones and begin with victim decontamination. In this scenario, the contamination is assumed to be external, with contaminated wounds and inhalation of dust or debris the exception. Special plans for radiation safety should be implemented as soon as the nature of the event is determined. The need for scene decontamination and the timing of transport must

be determined in the decontamination zone and should be part of planning for radiation events.

At receiving facilities, nonemergent patients should be screened for radiation contamination before entering. Emergent patients have life-saving care provided immediately and are then decontaminated. The ambulatory casualties who have not gone through decontamination at the site must be decontaminated before entering the treatment facility. This may entail police or security personnel equipped with adequate personal protection directing potentially contaminated patients to the appropriate part of the facility to ensure they do not contaminate the treatment area.

If possible, all emergency services and hospital personnel should wear dosimeter badges. Hospital radiation safety officers should monitor treatment areas, casualties, and staff to prevent secondary victims.

MEDICAL TREATMENT OF CASUALTIES

After decontamination, either at the site of the event or at the treatment facility, patients should be treated for their injuries and medical complaints. However, life-saving care should be provided even before decontamination. Most casualties will have blast and thermal burn injury. Basic trauma care should be provided to these patients. (For detailed care information for patients with radiation injury, see Section Eight.) Patients should be reevaluated by the hospital radiation safety officer to determine whether they are decontaminated before admission to the hospital or discharge home. Patients need to be informed of the adverse effects of radiation poisoning, and a system should be established to follow up with potential victims for signs of radiation sickness and secondary illnesses from radiation exposure.

The Federal Emergency Management Agency toolkit for radiologic incidents defines hospital treatment as follows:

“Radiation damage can be repaired if the dose received is not too high and if the dose is received over a long period of time. Injured victims who are suspected of being contaminated by radiological hazards should be treated at

hospital facilities that have the capacity for this specific type of treatment. Local officials must ensure that such facilities are identified in the Emergency Operations Plan. Note: The U.S. medical community is currently ill-equipped to deal with a large-scale incident involving radiation poisoning. Only one hospital emergency room—in Oak Ridge, TN—is dedicated to treatment of this type of injury.”²

Postexposure prophylaxis with iodine would need to be instituted if the facility contained spent nuclear fuel or other iodine-containing waste.

The World Health Organization guidelines for use of iodine after radiation exposure are presented in Table 178-1.³

CASE PRESENTATION

“Oh my God!” The sound erupts from the waiting room. The triage nurse comes running back and tells the staff there has been an explosion at the nuclear power plant. As you watch the television, horrified, the local news program reports that there has been radiation released. The Nuclear Regulatory Commission and Federal Emergency Management Agency are going to be involved. Four people come running through the ambulatory door of the emergency department claiming they have been “irradiated,” while the patients waiting to be seen gather their belongings and run to the parking lot.

You call the administrator and ask to go to your highest-level disaster plan. The resource nurse hands you the “triage officer” vest and directs you to the ambulance entrance.

UNIQUE CONSIDERATIONS

Internal Contamination

Patients with inhalation or ingestion of radiation sources cannot be decontaminated by traditional washing methods. Contaminated wounds can be debrided.

TABLE 178-1 REFERENCE LEVELS FOR DIFFERENT POPULATION GROUPS FOR CONSIDERATION IN PLANNING STABLE IODINE PROPHYLAXIS*

POPULATION GROUP	EXPOSURE PATHWAYS TO BE CONSIDERED	REFERENCE LEVELS
Neonates, infants, children, adolescents to 18 years and pregnant and lactating women	Inhalation (and ingestion†)	10 mGy‡ avertable dose to the thyroid
Adults younger than 40 years	Inhalation	100 mGy‡ avertable dose to the thyroid
Adults older than 40 years	Inhalation	5 Gy§ projected dose to the thyroid

(From Guidelines for Iodine Prophylaxis following Nuclear Accidents Update 1999.)

*These idealized levels do not take into account the practicalities involved in planning to respond to an accident involving many radionuclides in unknown quantities in real time. For this reason, a generic intervention level of 100 mGy has been specified in the Basic Safety Standards. Nevertheless, this does not preclude the need to consider the practicality of planning to implement iodine prophylaxis for specific age groups.

†Ingestion of milk by infants where alternative supplies cannot be made available.

‡Adherence to these values would ensure that doses for all age groups would be well below the threshold for deterministic effects.

§Intervention for this group is undertaken to ensure prevention of deterministic effects in the thyroid. Five Gy is the recommended limit for deterministic effects given in the Basic Safety Standards.

Decontamination of the pulmonary tree is difficult, but irrigation of the nasal mucosa may remove a large amount of trapped particles. Use of agents to speed passage through the gastrointestinal tract is the treatment modality of choice. All effluent must be collected for a 24-hour period or until no radiation is detectable.

Pregnant Women

Pregnant women would need to be counseled regarding the effect of radiation on their fetus. Consideration would need to be given to amount of exposure and stage of fetal development.

Mental Health Issues

A radiologic incident can be expected to cause widespread public panic and fear related both to the current dangers and to the possibility of long-term health effects. Crisis counseling should be available for incident victims, and a greater demand can be expected on long-term mental health services.

Chronic Health Issues

Exposure to radiation has the potential for stochastic effects, including cancer and genetic effects. The local medical community should expect an upsurge in patients seeking treatment, and anyone exposed to unsafe levels of radiation will require long-term monitoring.

PITFALLS

Several potential pitfalls in response to an explosion at a nuclear waste storage facility exist. These include the following:

- Lack of knowledge about a nuclear waste storage facility in the area
- Lack of training in radiation-decontamination procedures
- Contamination of ambulances and treatment facilities
- Possible contamination of treatment facility, if located near the event
- Location necessitating evacuation of treatment facility
- Loss of staff due to fear for family and safety

Maritime Disasters

Lucille Gans

DESCRIPTION OF EVENT

Although maritime disasters no longer occur with the frequency of past centuries, when tens of thousands of ships sinking to the bottom of the world's oceans left thousands of persons dead, they remain a major source of tragedy and loss for the transportation industry.¹ Maritime disasters include incidents involving cruise ships, yachts, ferries, barges, container and cargo vessels, fishing boats, submarines, offshore oil platforms, and other watercraft.

The loss of seaworthiness of a ship can result from several causes, often occurring in combination. Disasters are most often caused by storms, fires, and explosions, although loss of life generally results from human error. Contributing factors may include excessive reliance on technology, which can result in the loss of basic and advanced sailing techniques, plus underestimation of potential vessel vulnerabilities and risks posed by weather and sea conditions. Technologic advances have meant increases in the size and carrying capacity of ships, with concomitant increased potential for loss of life and property. Human factors also include failure to establish or follow procedures to enhance the safety of ships, their passengers, and crew; inexperience; and "cutting corners" to save time and money. If commercial concerns such as competitiveness, maintaining schedules, and cargo take precedence over passenger and crew safety, disasters can and do result. Survival is enhanced by diligent compliance with appropriate procedures and standards combined with knowledge, experience, and resourcefulness.²

Drowning is the most common cause of death due to maritime disasters, followed by hypothermia,² although traumatic injuries may also occur because of the event that produced the disaster. These injuries include but are not limited to burns, blast injuries from explosions, and both blunt and penetrating trauma.³ In addition, victims who survive the initial sinking of the ship but who are not rescued in a timely manner may ultimately die from dehydration, starvation, or exposure while occupying life rafts or floating in the sea.

Maritime disasters also include events when no human lives are lost but loss of the ship's cargo results in pollution and damage to the ocean waters, marine life,

and shoreline. Such situations have most often involved oil tankers, as in the cases of the *Exxon Valdez* in Alaska and the *Sea Empress* in Australia. Other cargo ships carrying hazardous materials that have been damaged while near shore and habitation include the *Multitank Ascania*, carrying highly explosive vinyl acetate, and the *Bilboa*, carrying ferrosilicon (which can release toxic and explosive gases when exposed to moisture), to list only a few of the hundreds of incidents that have occurred in recent decades.⁴ There are huge costs associated with rescue, salvage, and recovery in such situations. For example, the cost for clean-up after the *Exxon Valdez* spill is estimated at \$2.2 billion (U.S.).

PREINCIDENT ACTIONS

Before leaving port, both cargo and passenger vessels are subject to various laws and maritime agreements. These requirements include the national laws of the country under which the ship is registered. Many ocean-going vessels are registered under "flags of convenience" to take advantage of national marine laws that may be less stringent than those of the country from which the passenger or cargo company most often sails.³

In addition, there are further security requirements imposed by the individual ports that the ship enters. The International Maritime Organization (IMO) is the specialized agency of the United Nations that has the responsibility for the safety of shipping and the prevention of marine pollution by ships.⁵ As well, following the Sept. 11, 2001, terrorist attacks on the World Trade Center in New York City, the IMO developed and adopted port security measures as outlined in the International Ship and Port Facility Security Code, which came into effect in 2004.⁶

All ships should be required to sail with adequate life jackets and lifeboats or rafts aboard for all passengers and crew. National standards for life jackets or personal flotation devices (PFDs) vary among countries. In addition, PFDs designed to allow greater freedom of movement for participation in water sports, such as windsurfing, may provide lesser degrees of buoyancy. PFDs should be adjustable to fit various body shapes and statures and volumes of clothing, including specialized

protective gear. Ideally, the PFD should be self-righting, should maintain the wearer at the water surface, and should keep the airway clear of water, which requires a minimum of 34 lb (150 newtons) of buoyancy. PFDs should be fitted with a crotch strap to prevent the device from riding up over the shoulders. Even with a properly fitted PFD, however, the dependent legs of the wearer act as a sea anchor, turning the face toward the waves. A person with impaired consciousness, a condition that may develop with hypothermia after immersion in cold water, may be unable to coordinate breathing with the irregular pattern of wave splash over face, and death by drowning may occur.²

Lifeboat drills and other safety instruction should be provided once the vessel leaves port. However, there is no guarantee that such information will be provided in multiple languages or that passengers will understand, remember, or comply with directions at the time of an emergency.

Lifeboats, life rafts, and their launch equipment must be maintained to ensure that they are functional and seaworthy. At the bare minimum, each lifeboat should be supplied with a container of survival supplies including water, food rations, raft repair equipment, a sea anchor, and signaling equipment such as flares, lights, and mirrors. The IMO stipulates the equipment that survival craft must carry, based on the number of persons to be carried. Anyone aboard a vessel should consider assembling a grab bag containing additional supplies, clothing, and medications should it become necessary to abandon ship, using as a guide the requirements listed by maritime regulators or sailing race authorities.^{2,7}

Because factors external to the ship such as weather and sea conditions can affect the safe passage of the vessel, technologic advances such as Doppler weather radar and Global Positioning Systems, combined with enhanced global communication systems, have contributed greatly to improved ocean safety records in recent years.⁷

POSTINCIDENT ACTIONS

Once the integrity of a ship is breached, or as soon as some other threat to passenger or crew safety is recognized, it is essential that rescue procedures be initiated. Alarms both onboard and via radio transmission to appropriate sea- and land-based rescue facilities should be raised. The extent of the potential danger to the ship and those onboard should be assessed, with consideration for potential worsening of conditions.

If the problem can be adequately managed with onboard resources, appropriate personnel should be advised and intervention measures initiated. Procedures for fire suppression must be well understood and initiated immediately once a fire is detected.

If the incident is thought to be manageable with the resources available onboard, a “Pan Pan” message should be sent via radio transmission. If the vessel is in immediate danger, a “Mayday” message should be transmitted. In both cases, the radio message should include the vessel name,

nature of the incident, number of persons onboard, and geographic location with latitude and longitude. Maritime history includes many cases in which rescue was delayed by either incomplete information or failure of notification from the stricken vessel, often resulting in loss of life.²

Generally, those onboard will be better off remaining on the ship unless the captain determines that the ship is in danger of sinking. Before leaving the ship, each person should put on a lifejacket or PFD. If available, survival suits should also be worn.

Lifeboats and rafts are smaller and less comfortable than a full-size ship, especially in rough ocean waters. In addition, there is no mechanism for steering or sailing most rafts.

The crew should instruct passengers in how to get into lifeboat or rafts and the procedures for launching them. Once afloat, occupants should attempt to rescue survivors in the water, which may be hampered greatly by hypothermia of both parties. Therefore, bailing and drying procedures must be adopted early on in the survival craft.² Additionally, rationing of food and water should be initiated, even if rescue is anticipated in a short time.⁷ No one should drink seawater, in any quantity, as this markedly reduces the chance of survival.² Measures should be taken to reduce seasickness, including taking antinausea medications, if available, because seasickness will worsen most medical conditions and has further negative effects on hygiene and morale for all persons in a survival craft.⁷

MEDICAL TREATMENT OF CASUALTIES

Rescuers may include those specially equipped and trained for water rescues—for example, the U.S. Coast Guard Search and Rescue program.⁸ Often, however, rescue comes from those closest who may not have the knowledge or gear to mount the most effective rescue or resuscitation.

The most common conditions suffered by those rescued from the water are near drowning and hypothermia. Rescuers should remove wet clothing and dry the skin and hair of victims before providing warm and dry clothing. If survival suits are available, it may be adequate to dress the victims in these for passive rewarming. However, particularly in the setting of multiple victims rescued from cold ocean waters, the rescuing vessel may not have enough gear for all persons rescued. It may be necessary to put two persons into each suit, and in this case, a warmer victim should be paired with a colder one.²

Although hypothermia causes deterioration more commonly and more rapidly, victims rescued from lifeboats and rafts may suffer heat illnesses, including sunburn, heat exhaustion, and heat stroke, the last of which requires urgent medical intervention.²

Survivors who are rescued after a prolonged time adrift at sea may be suffering from dehydration or starvation plus exposure and may require intensive or prolonged resuscitation and medical care.

CASE PRESENTATION

It is shortly after midnight on an international cruise ship carrying 1200 passengers and 700 crew members. It is the third day of a transatlantic voyage, and the ship is 1000 miles from the mainland. Suddenly there is a large explosion, followed by a fire in the engine room. The crew members on duty reduce ship speed and institute emergency fire suppression measures immediately, with limited success.

An initial assessment of damage indicates no significant hull damage, but there has been loss of electric power to areas of the ship. A crew member who had been working in the engine room is missing. Seven other crew members have been injured by the initial explosion or during efforts to fight the fire. Although many passengers had already gone to bed and are unaware of the situation, a large percentage of those still awake are increasingly concerned and some are agitated, which is worsened by prior consumption of alcohol over the course of the evening. Emergency lighting is on throughout much of the ship.

Less than 1 hour later, the fire has spread. The two nearest large ships that could provide assistance are 250 and 300 miles away, but both have responded to the distress call and are proceeding toward the stricken cruise ship. Smoke is spreading through the many corridors of the lower decks of the ship, so the captain and crew decide to raise a general fire alarm and alert the passengers. Many are slow to waken and are confused by the noise and lack of normal lighting. Some panic when they see and smell smoke in the passageways. Most do not take their lifejackets with them upon exiting their cabins, despite the instructions accompanying the fire alarm.

If rescue does not occur speedily, many passengers who have not donned PFDs and who do not board lifeboats may enter the water unprepared, by jumping in panic or by failing to follow the instructions of the crew. Those without PFDs may drown or suffer hypothermia before a rescue vessel arrives, unless they are assisted into lifeboats by others.

UNIQUE CONSIDERATIONS

Maritime rescues are frequently complicated by the very factors that caused the incident. Poor visibility, strong winds, and rough seas may prevent rescuers from reaching or finding damaged ships or floating victims. Once located, high waves and cold temperatures further endanger both rescuers and victims and may damage rescue and medical equipment. Salt water can reduce the effectiveness of equipment immediately or over time. Noise, impaired visibility, and hypothermia can interfere with communications between rescuer and victim, and language barriers may exist. Victims are often hypothermic, dehydrated, and exhausted, which reduce their ability to assist with their own rescue.

Victims who are rescued from immersion in cold water may experience temperature afterdrop as a complication of hypothermia, with this postimmersion collapse often resulting in death. This condition occurs when chilled blood from peripheral tissues circulates to the body core

with rewarming, causing a drop in the core temperature and a drastically worsened clinical practice.^{9,10}

The clinical status of survivors rescued after near-drowning may worsen gradually or abruptly due to the development of respiratory distress syndrome with hypoxia and subsequent respiratory failure. Pulmonary edema, cardiovascular complications, and multisystem organ failure may develop, even with intensive medical care.¹¹ Supportive care and prompt transport to a tertiary care center are essential.

Victims may be covered with fuel oil or may have swallowed or aspirated oil while immersed. They may develop vomiting, aspiration pneumonia or pneumonitis, or conjunctivitis.²

Oil contamination also complicates the healing of skin wounds such as abrasions or punctures, as does seawater containing bacteria or other contaminants. Prolonged exposure to damp conditions or clothing in a lifeboat may allow saltwater boils, pustules, or even ulcers to develop. Immersion foot can occur in survivors aboard lifeboats and rafts when feet remain cool, damp, dependent, and inactive, with the development of blood stagnation and tissue swelling.²

Survivors rescued from the sea may have swallowed significant quantities of salt water and may develop osmotic diarrhea and hypernatremia, which will require volume replacement and careful monitoring of electrolyte levels.²

After rescue from the sea, there may be delays in reaching definitive medical care. Although the rescue vessel may have adequate personnel and equipment to provide first aid or even major resuscitation for victims, weather and sea conditions may delay transport to a site where surgery or intensive care could be provided, such as a mainland tertiary care center. As well, distances to the nearest appropriate healthcare facility may be significant, particularly in the case of mid-ocean rescues.

The same conditions that complicate rescue also make investigation of ship and submarine accidents difficult and hazardous. Evidence may be scattered over the ocean floor, resting several kilometers below the surface in cold, dark water, subject to strong ocean currents.¹² There may be no survivors to describe the events leading up to a tragedy or any actions taken in response, whether or not they were effective, heroic, or foolhardy. There may be no conclusive determination of the cause of a tragic event at sea—rather, only conflicting theories and conjecture—but experts must nevertheless attempt to identify what went wrong so that they may recommend methods to prevent future disasters.¹³

PITFALLS

Several potential pitfalls exist in response to a maritime disaster. These include the following:

- Failure to appreciate dangerous weather and sea conditions, especially when combined with ship weaknesses or damage
- Failure to adapt course or sailing techniques to changing conditions

- Failure to follow rules of sailing, navigation, and sea transport
- Excessive reliance on technology and failure to identify deficiencies or weakness in ship structure and function
- Failure to request assistance or rescue in a timely manner
- Failure to follow safety procedures and lack of familiarity with evacuation and emergency exits and equipment
- Failure to abandon ship or deploy emergency escape equipment, such as lifejackets or PFDs, survival suits, and lifeboats
- Failure to activate the emergency position indicator rescue beacon before abandoning ship
- Failure to ration water and food supplies after abandoning ship

Cruise Ship Infectious Disease Outbreak

Scott G. Weiner

DESCRIPTION OF EVENT

Throughout the ages, infectious diseases traveling by boat have affected the course of history. For instance, the Black Death caused by *Yersinia pestis* was brought by boats coming from the east to Europe. The plague caused the death of at least one-third of the European population during the 1300s. This epidemic led to the practice of refusing the landing of ships with suspected cases of plague for 40 days—the first practice of “quarantine,” from the Italian word *quaranta* for “forty.” Shipborne smallpox also played a role, actually saving England from a French invasion in 1779 after an outbreak spread among the French sailors.¹ The closed environment of the ships and the prolonged duration of voyages led to a high infection rate.

In modern times, airplanes have replaced the boat for long-range passenger transportation, but recently a steadily increasing number of people choose to go on cruises as a form of vacation. Over 9.5 million people went on cruise vacations in 2003, an increase of 10.2% from 2002 and 198% from 1994.^{2,3} The average length of cruise in 2003 was 6.88 days.² And with the standard capacity of the newer cruise ships reaching well over 2000 passengers, hundreds of people may potentially be at risk from an infectious disease outbreak onboard.

The infectious diseases that affect cruise ships can be divided into three categories: gastrointestinal, respiratory, and miscellaneous infections.

Gastrointestinal Illness

Gastrointestinal illness is by far the most common result of cruise ship outbreaks. A study of 31 investigated cruise ship gastroenteritis outbreaks between 1986 and 1993 found that 39% were from bacterial sources (including enterotoxigenic *Escherichia coli*, *Shigella* species, *Salmonella* species, and *Staphylococcus aureus*), 29% were from Norwalk or Norwalk-like virus (collectively called *norovirus*), and 32% were of unknown etiology.⁴ Of the determined sources, 48% were from onboard exposures (particularly food), 10% were obtained during onshore excursions, and 42% of sources were unknown.⁴

A more recent study found a shift in epidemiology, with an increase in the incidence of norovirus.⁵ Twenty-

one outbreaks of acute gastroenteritis were studied, of which nine episodes were caused by norovirus, three were caused by bacteria, and nine were of unknown etiology. The rate of passenger infection ranged from 5% to 19%.⁵ However, in one outbreak in 1998, more than 80% of the 841 passengers were affected, indicating the highly infectious nature of this virus.⁶ Because norovirus is so infectious, the organism passes easily between passengers in the confined space of a cruise ship, and hundreds may be at risk.

Respiratory Illness

Whereas the most common illness afflicting passengers and crew aboard cruise ships is gastroenteritis, respiratory infections comprise about one-third of sick bay visits.³ Outbreaks of Legionnaires' disease and influenza have been reported in the literature.^{7,8} One outbreak of *Legionella pneumophila* infection in 1994, linked to the ship's whirlpool spa, affected 50 passengers on 9 different cruises, including the death of 1 passenger.⁷ Another study documented an outbreak of influenza A and B in 2000, in which 37% of passengers developed an influenza-like illness, 40 passengers were hospitalized, and 2 died.⁸ Though never reported as outbreaks in the literature, other diseases with respiratory transmission, such as diphtheria, tuberculosis, and meningitis, remain outbreak possibilities.¹

Miscellaneous Infections

Other miscellaneous infections, including malaria, yellow fever, and varicella, also involve potential pathogens on a cruise ship.¹ A 1997 outbreak of rubella among crew members, mostly from countries that did not have routine immunization programs, serves as a reminder that unanticipated outbreaks can arise in close quarters.⁹

PREINCIDENT ACTIONS

Prevention is the single most important action that can be taken to avoid an infectious disease outbreak. To achieve this goal, the U.S. Centers for Disease Control and Prevention (CDC), in a cooperative arrangement

with the cruise ship industry, created the Vessel Sanitation Program (VSP) in 1975.¹⁰ The program is designed to prevent the introduction or transmission of infectious diseases in the United States as well as to assist the cruise ship industry in the development and implementation of sanitation programs to protect passengers and crew.¹⁰ The VSP also involves unannounced twice-yearly inspections of all cruises traveling to the United States from international ports and publishes its findings as a sanitation score on a biweekly basis.^{4,10,11}

As part of the VSP arrangement, cruise ships must maintain an incident report of gastrointestinal illness for each cruise. A reportable case of gastroenteritis is defined as three or more episodes of loose stools in 24 hours, or vomiting and any additional symptom suggestive of the illness (excluding nausea, which can be a symptom of seasickness).¹⁰ It is also essential that cruise lines use adequate infection control measures, including proper disinfection, filtering, and storage of water and regular maintenance of spas and ventilation systems to prevent the spread of airborne infections.⁶

Another important step is provision of onboard healthcare facilities that will be capable of treating patients with outbreaks. The American College of Emergency Physicians published guidelines for a ship's medical facilities, and the 16 members of the International Council of Cruise Lines have agreed to meet or exceed these requirements.^{12,13} Although the guidelines do not identify specifics regarding outbreaks, they do require ships to have properly trained physicians and nurses, an infusion pump, gastrointestinal system medications, respiratory system medications, and an emergency preparedness plan.¹² At a minimum, ships should have the capacity to provide oral and intravenous rehydration therapy and have sufficient doses of or ready access via airlift to antibiotics to treat *Legionella* infection and bacterial gastroenteritis.

POSTINCIDENT ACTIONS

Once an outbreak is identified, it is crucial that a predetermined decontamination plan is commenced immediately.⁵ Rapid implementation of control measures at the first sign of a suspected outbreak is fundamental for three important reasons: (1) many people share the same water, food, and environment, and are all at risk for infection; (2) the ship's medical resources can quickly become overwhelmed in an outbreak; and (3) without intervention, the infection can spread to subsequent cruises.¹⁰

After an outbreak, international quarantine regulations dictate that the master of the ship traveling to a U.S. port report to the closest quarantine station. Furthermore, the master of a ship carrying more than 12 passengers is required to report the number of passengers or crew who reported diarrhea during the cruise 24 hours before arrival to the United States. If at least 3.0% of the ship's passengers or crew is ill, the VSP may conduct an investigation.¹⁰

The investigation is composed of three phases: (1) an epidemiologic investigation, in which interviews and questionnaires are performed; (2) a laboratory

investigation, in which the CDC attempts to determine the agent responsible for the outbreak; (3) an environmental health investigation, in which the source of transmission (usually water, food, or air) is analyzed. After the investigation is complete, the information, including recommendations for control and prevention, is sent to the cruise line.¹⁰

Complete guidelines for stool and water collection are available on the CDC Web site.¹⁰ Furthermore, the World Health Organization publishes a *Guide to Ship Sanitation*, which offers further assistance in the prevention of the spread of infection.⁶ Once an outbreak occurs, prompt disinfection of the ship and isolation of ill crew members and, if possible, passengers for 72 hours after clinical recovery are ideal.⁵ Suitable disinfectants such as chlorine, phenol-based compounds, or accelerated hydrogen peroxide products should be used to disinfect the ship.⁵ Furthermore, the staff should remind passengers and the crew to perform frequent, rigorous handwashing with soap and water.

MEDICAL TREATMENT OF CASUALTIES

The first problem facing the medical staff and crew of the ship is the logistics of treating hundreds of casualties onboard and finding an appropriate docking port. The ship's medical staff will be forced to ration care as they balance resources with numbers of afflicted patients. The most seriously affected should receive care first. For instance, those who are very young, very old, or significantly dehydrated should receive intravenous fluid before the others. The crew should locate a suitable port where hundreds of casualties can be most easily cared for. If there is a choice, the ship should not dock at a small port if a larger port near a large city is available. Calling ahead and warning the receiving port is also crucial.

The treatment of the casualties should be tailored to the individual disease process. For patients with viral gastroenteritis, only supportive care is necessary. Norovirus illness lasts 12 to 60 hours and is usually accompanied by sudden onset of nausea, vomiting, and watery diarrhea. Its incubation period is 12 to 48 hours. No specific treatment or vaccine exists.⁵ Although generally self-limited, viral gastroenteritis may cause problems in children, elderly persons, and persons with serious underlying medical conditions. Treatment should include oral rehydration for mild cases and intravenous fluid for more significant dehydration. If the cause is determined to be bacterial, appropriate antibiotics (e.g., ciprofloxacin) should be administered to the affected passengers.

Other treatments will depend on the infectious agent. Legionnaires' disease may present with a range of systems from a mild febrile illness to a severe pneumonia with malaise, cough, and gastrointestinal symptoms.¹⁴ Standard pneumonia antibiotic therapies such as azithromycin or levofloxacin are curative, and these should be stocked on the ship. Regardless of the etiology, air evacuation is indicated for very ill patients.¹⁵

Fortunately, cruise ship infectious disease outbreaks are rare and are usually self-limited and nonfatal. Between 1986 and 1993, the CDC investigated 1.4 outbreaks per 1000 cruises, or just 2.3 outbreaks per 10 million passenger-days, and more recent research demonstrates that the VSP is effective in helping to further reduce this number.^{4,11} However, once it occurs, an infectious disease outbreak on a cruise ship can represent a major medical disaster. An outbreak can quickly overwhelm the limited medical resources available on a ship. Proper preparation and planning can help prevent a catastrophic event.

into a country. Increased vigilance among the ship's crew and medical staff is indicated.

An infectious disease outbreak may represent a huge financial loss to a cruise line because cruises may need to be cancelled and future passengers may be less likely to travel on an affected line. Again, preventive measures are paramount.

PITFALLS

Several potential pitfalls exist in response to an outbreak of infectious disease aboard a cruise ship. These include the following:

- Failure to properly staff and supply the ship's medical clinic
- Failure to recognize or report an infectious disease outbreak
- Failure to quickly isolate and treat affected passengers and crew
- Failure to properly sanitize the ship after an outbreak
- Failure to create a plan for mass treatment in the event of an outbreak, including provisions for airlifting patients out or supplies in

CASE PRESENTATION*

A relatively new cruise ship that is able to carry 2500 passengers and 800 crew members embarked on its usual tour. During a 7-day trip from Miami to various ports in the Caribbean, an increasing number of patients began reporting to the ship's sick bay complaining of diarrhea. By day 3 of the voyage, 30 passengers (1%) and 10 crew members (1%) presented with gastroenteritis. By day 7, a total of 285 passengers (11%) and 25 of the crew members (3%) had reported the illness.

As is required, the CDC was notified and an investigation ensued. A questionnaire was distributed to all passengers, and it was determined that the conditions of 523 passengers (21%) met the definition for acute gastroenteritis. Several stool specimens tested positive for norovirus by polymerase chain reaction. Of the patients with gastroenteritis, 418 patients (80%) had symptoms that spontaneously resolved within 48 hours, 89 patients (17%) had symptoms that resolved within 96 hours, and 4 elderly patients were hospitalized after their return to shore and then were subsequently discharged without complication.

Despite aggressive disinfection, the outbreak continued on the next cruise. The cruise line then removed the ship from service for 1 week for further cleaning and sanitizing, and no subsequent cases were reported.

*Adapted from Outbreaks of gastroenteritis associated with noroviruses on cruise ships—United States, 2002. *MMWR Morb Mortal Wkly Rep*. 2002;51:1112-5.

UNIQUE CONSIDERATIONS

Cruise ships are closed spaces, and the combination of thousands of people contained for several days in this space represents an opportunity for infection to spread rapidly. Only limited resources are available onboard, so a ship's medical bay may become quickly overwhelmed during an outbreak.

Ships often visit ports in countries where infectious disease is more prevalent than it is in the United States, so the potential for bringing an agent onboard is elevated. In addition, the background of the crew is often diverse, and some may be at increased susceptibility to diseases, depending on immunization status.

Although there have been no reported incidents of bioterrorism on cruise ships, this possibility cannot be excluded. A cruise ship might become a means for an infectious disease agent to be purposefully transmitted

Hostage Taking

Dale M. Molé

DESCRIPTION OF EVENT

Incidents of hostage taking and kidnapping are on the rise around the world. Some are politically motivated; others involve simple greed. A few are just the result of being in the wrong place at the wrong time. According to the Hiscox Group, a leading international specialty insurer, the number of reported worldwide kidnappings for ransom increased from 1690 in 1998 to 1789 in 1999. Over 90% of those incidents took place in what have been deemed the top 10 riskiest areas: Colombia, Mexico, the former Soviet Union, Brazil, the Philippines, Nigeria, India, Ecuador, Venezuela, and South Africa.¹ The rise can be blamed on a combination of factors such as lawlessness, political unrest, and poverty. Kidnapping is an appealing crime for many since the perpetrators are rarely caught and it is a much easier way to make money than drug dealing or robbery. The epidemic of kidnapping/hostage taking is much greater than demonstrated by statistics, since many kidnappings are handled privately and remain unreported.

In about 67% of cases, a ransom is paid and usually averages about \$2,000,000 in countries where the “business” is well established. If a ransom is not paid chances of survival for the victim are slim, especially in Latin America. According to insurance industry sources, Americans with kidnapping and ransom insurance are four times more likely to survive a kidnapping than are those who have none.

This is not only a problem overseas, however. Each year, the U.S. Federal Bureau of Investigation is involved in approximately 400 domestic kidnappings, with about one third involving a ransom demand. Branch bank managers and their families appear to be favorite targets.² Some kidnapping/hostage taking occurs incidentally to the commission of another crime, with the victim being a target of opportunity for the perpetrator trying to negotiate his way out of a losing situation.

With the growing threat of international terrorism and the increasing political value of American hostages, it is the official policy of the U.S. Government not to make concessions to individuals or groups holding official or private U.S. citizens hostage. However, the United States will make use of every appropriate resource to ensure the release and safe return of American citizens. The goal is to deny

the hostage takers the benefits of ransoms, prisoner releases, policy changes, or other acts of concession, which would increase the risk that other Americans would be taken hostage. The State Department will contact representatives of the captors in an effort to secure release.

Although very dangerous, hostage rescue is sometimes the only viable option. Local, state, and federal law enforcement agencies have specialized teams to rescue hostages or deal with standoff situations. These teams rely on training, speed, coordination, stealth, and overwhelming force to rescue hostages and take control of the situation.³ The Federal Bureau of Investigation’s Hostage Rescue Team (HRT) was established in 1982 and has been deployed more than 200 times in support of hostage rescue, counter-terrorism, stopping violent crime, and other federal law enforcement activities.

Tactical emergency medical services (TEMS) is emerging as a special interest area within emergency medicine to provide medical services within a civilian law enforcement environment for both law enforcement personnel and suspects. Beyond increasing the chances of successful mission accomplishment, TEMS reduces the morbidity and mortality among innocent persons, suspects, and officers. Medical care in a tactical situation is frequently very different from the care provided by routine civilian EMS.

Law enforcement agencies manage crisis situations with zones of containment. The inner perimeter is a geographically defined circle around an incident and is controlled by the tactical law enforcement element (i.e., special weapons and tactics teams, special response teams, and the like). The outer perimeter is a larger boundary that excludes the public, provides additional safety, and is controlled by patrol or regular uniformed officers.

Similarly, zones of care (i.e., hot, warm, and cold zones) help define appropriate care in a tactical law enforcement environment. The *hot zone* includes those areas where the threat to safety is direct and immediate and the threat for additional injury is high, where it would be extremely hazardous to provide medical care; for example, the area surrounding a sniper’s position in a building with a clear field of fire. Extraction to a safer area to render medical assistance is about the only option. The *cold zone* is where no threat exists and care can be provided in much the same manner as in any routine civilian situation. The *warm zone* is an area where the threat is intermediate

between these two extremes; this is often the most challenging regarding medical decision-making. The benefit of a particular intervention must be considered relative to the risk of additional injury to the patient or the medical tactician. Certain actions considered standard for care in normal situations, such as applying a cervical collar for penetrating neck injuries before moving the patient, make no sense in a tactical environment.

PREINCIDENT ACTIONS

Personal

Taking simple steps and altering certain behaviors can help travelers avoid putting themselves at risk. Anonymity is the best defense for foreign travelers.⁴ When traveling abroad, persons should keep a low profile and not advertise their wealth. Jewels and expensive clothes should be left at home. Travelers should de-Westernize their attire as much as possible, since a middle class income in the United States places a person in the top few percents of incomes worldwide. Travelers should not follow a regular routine, nor should they make restaurant reservations in their own names. Colleagues, friends, and family should be kept informed as to travelers' whereabouts.

When traveling in third-world countries, travelers should not wear military-style clothing. Blue or other neutral colors should be worn, since green or brown clothing is often associated with the military.

Persons taking trips abroad should avoid luggage tags, behavior, and dress identifying them as American. Reading maps in public or carrying a camera around the neck will let others know a person is a tourist and therefore a target of opportunity. If traveling on a bus, the safest areas are the aisle seats near the middle of the bus. When on an airplane, the safest areas are the window seats near the middle of the aircraft.

Personal papers should not be left in the hotel room, and hotel guests should not open the door for strangers. Travelers should make sure they have mentally planned an escape route in case of fire or other disaster. Hotel rooms on the first floor should be avoided, if possible.

When driving through crowded areas, windows should be kept closed. Travelers are advised to make sure their vehicle is in good condition, and they should plan the route before traveling. They should make mental notes of safe havens such as police stations, hospitals, and hotels. In addition, they should steer clear of rural or isolated areas, especially when traveling alone or in a small group.

It is recommended to schedule direct flights when possible and avoid stops in high-risk areas. Travelers should be aware of what they discuss with strangers and what may be overheard. Routines should be varied, especially if one stays in a country for an extended time. Persons should not take the same travel routes, eat at the same restaurants, or jog on the same pathways on a regular schedule. When walking around foreign cities, it is prudent to ignore the attempts of strangers to engage the traveler in conversation. Letting one's familiarity with a country lull one into a false sense of security is a mistake.

In conflict or disaster areas, travelers should beware of roadblocks. The people controlling the roadblock may desire to extort money or other items of worth. If a person is working with a relief agency, he or she should ensure that proper identification is available and that he or she is traveling in a clearly marked vehicle. Vehicles painted in military colors should be avoided.

If a roadblock is encountered, the personnel manning it may be aggressive, undisciplined, untrained, and intoxicated. Travelers should not make any aggressive movements or statements. They should be firm but polite, stating that the authorities have given them permission to travel in the area. If a person is an aid worker, he or she should establish his or her affiliation quickly because it is one of the greatest assets a traveler has.⁵

Medical Support Elements

Integrated medical support for specialized law enforcement/hostage rescue teams is mandatory. Just-in-time training for supporting medical personnel is not an option and places the mission, the hostages, and the rescuers at risk. TEMS training for physicians, paramedics, and emergency medical technicians is available from several organizations. One of the first and most widely recognized is Counter Narcotics and Terrorism Operational Medical Support. Established within the Casualty Care Research Center at the Uniformed Services University of Health Sciences, lessons learned on the battlefield providing care in austere environments are applied to civilian law enforcement situations. The core curriculum of any TEMS course should include didactic and practical exercises in at least the following areas:

- Threat assessment and medical intelligence
- Care under fire
- Hostage survival
- Clinical forensic science
- Weapons and their effects
- Medicine across the barricade
- Toxic hazards (e.g., clandestine drug labs, weapons of mass destruction)
- Medical effects of extended operations
- Special equipment and medical kits

POSTINCIDENT ACTIONS

The two most dangerous times during a hostage situation are at the beginning and at the end, especially if a rescue is attempted. Initially, persons in a hostage situation should make themselves as inconspicuous as possible. They should listen to the terrorist's commands and respond without questioning. "Passive cooperation" should be enacted. It is recommended to avoid sudden movements or threatening behavior and avoid eye contact or any other actions that may single a person out. If ordered to be silent, hostages should not talk or whisper. If possible, they should dispose of identification or documents that would make the hostage takers more

hostile toward them. Persons should eat or drink sparingly during the first few hours and should not consume alcohol.

If taken hostage, persons should help their kidnappers establish contact with their organization as soon as possible. Hostages should try to remain calm and remember that the vast majority of kidnappings end with the hostages released. Death is usually the result of a medical condition, an unsuccessful escape attempt, or perhaps a botched rescue. It is not advisable to act as a spokesperson for the hostages. Persons should rehearse what they will say to the hostage takers if questioned about their documents.

Persons taken hostage should look after their health as much as possible. Because they don't know where, when, or what their next meal will be, hostages should eat all of the food they are offered after the initial few hours, once the hostage situation has stabilized. They should also try to exercise regularly.

Since hostages may be guests of their captors for quite a while, they should try to establish rapport. The better the relationship they establish, the harder it will be for the hostage takers to kill or injure them. Escape should not be attempted unless hostages are absolutely certain of success.⁶

If a hostage is bound by his or her captors, slumping in the chair while they are tying the person up will allow some slack in the ropes. The same can be accomplished by keeping the chest inflated or wrists slightly apart. Hostages should try to catch a gag in their teeth to prevent it from being forced all the way back in the mouth. If a person's hands are tied behind him or her, if possible, the hostage should pass his or her hands under the feet. With the hands in front of the body, the hostage can use the teeth to untie knots.

Wherever hostages are being held, they should look around for safe areas in case of a rescue attempt. It is a good idea to drop to the floor immediately if there is shooting or an explosion. If possible, persons should seek shelter in a ditch, in a depression, or near a solid wall. They should not jump up and try to run.

MEDICAL TREATMENT OF CASUALTIES

The medical care required depends on the length and conditions of captivity, preexisting illnesses, and whether the hostage was released or had to be rescued. Rescue attempts are inherently very dangerous situations and may result in injury to rescuers as well as hostages. The three most common causes of preventable death in a tactical situation are uncontrolled hemorrhage, airway compromise, and untreated tension pneumothorax.

Perhaps most important is the emotional and mental health support required by all hostages, even those not sustaining any physical trauma. The lack of control over one's fate in a highly stressful life and death situation will tax the emotional resources of even the most robust person.

CASE PRESENTATION

On the evening of May 23, 2004, three suspects abducted South African Deputy High Commissioner Nicky Scholtz on one of Kuala Lumpur's busiest streets, near the hotel where he was attending a conference. One man confronted him and forced him into a car where two men were waiting. He was struck with a blunt object and then driven away. The abductors rendezvoused with four men, who became the hostage holders, in another car. This demonstrated operational planning, as well as a level of sophistication not usually seen in a random abduction. Scholtz was taken about 12 miles south of Kuala Lumpur and held hostage for a week. He was bound with wire and beaten while the attackers forced him to write checks and withdraw funds on his credit card, to a total of about \$4200, sufficient to purchase weapons or explosives. He suffered two fractured ribs, a dislocated jaw, and severe bruising of his back, face, arms, and legs.

The kidnappers released Scholtz after his disappearance was reported locally, but they threatened to kill him if he reported the incident. Based on information he provided, seven suspects were later taken into custody. There is no indication the attack was politically motivated, but rather, it is believed that he was simply a target of opportunity.

This incident illustrates the importance of good situational awareness, whether an individual is at home or abroad.

UNIQUE CONSIDERATIONS

Being kidnapped or held hostage is perhaps one of the most likely events to cause posttraumatic stress disorder (PTSD). PTSD is characterized by reexperiencing the traumatic event (e.g., vivid nightmares, recurring visual images, reacting physiologically to stimuli associated with the event), avoidance behavior (i.e., avoiding things associated with the trauma such as activities, places, or people), and hyperarousal symptoms (e.g., insomnia, startle behavior, attention deficits). PTSD is a normal reaction to an abnormal situation and can be prevented or mitigated with timely intervention.

Critical incident stress debriefing (CISD) is an essential component of post-event care. It involves at least one structured meeting with a trained mental health professional between 24 and 72 hours after release or rescue. The first day after the event is necessary for rest—emotionally and physically. After about 3 days, victims will begin to suppress/repress emotions in an attempt to isolate or compartmentalize the traumatic experience, hence the need to act quickly.

The CISD usually takes several hours and includes an explanation of the purpose of the debriefing, a brief personal history of the people involved in the event, a discussion of what each person saw or experienced and their emotional reactions, a query regarding symptoms associated with PTSD, education regarding PTSD as a normal response to horrific events, and referral of those who require further treatment.

PITFALLS

Several potential pitfalls exist in response to a hostage-taking event. These include the following:

- Lack of situational awareness in a high-risk environment
- Underestimating the danger or threat posed by female terrorists⁷
- *The Stockholm syndrome*: First described by Professor Nils Bejerot to explain the phenomenon of hostage victims bonding with their captors, following a 6-day ordeal in which two bank robbers held four hostages in Stockholm, Sweden, in 1973. Symptoms include emotional bonding with captors, seeking approval or favor from the captors, resenting police or other authorities for attempts at rescue, and refusing to seek freedom when the opportunity is available.

- Lack of properly trained and integrated medical support for specialized law enforcement teams
- Failure to perform a CISD in a timely fashion

Civil Unrest and Rioting*

Denis J. FitzGerald

DESCRIPTION OF EVENT

Civil unrest, also termed *civil disturbance*, is a spectrum of activities progressively disruptive to public order and tranquility. Civil unrest can occur whenever a group in the community feels, accurately or not, that some aspect of society is antithetic or apathetic to their views, rights, or needs. Examples of civil disturbance include labor strikes, large demonstrations, and riots. As the most extreme situation, a *riot* is a violent disruption of the public order that threatens public safety. In describing civil unrest, it is valuable to consider first a historical perspective, then to discuss the etiology and evolution of these incidents.

Civil unrest has been a part of the fabric of life in the United States since before the country was founded, dating back to the Boston Massacre in 1770.¹ Governed by a set of laws to define mechanisms for peaceful conflict resolution, American society has nonetheless experienced many instances throughout its history of violent civil unrest. More recent events include the widespread turbulence of the late 1960s, the civil unrest surrounding the Rodney King incident (1992), and the clashes between the police and protesters at World Bank Demonstrations in Washington, DC (2000). Especially when it turns violent, civil unrest can strain or even shatter the delicate equilibrium between the societal need for public order and the individual's constitutional right to freedom of expression.

Civil unrest arises from the interplay of several factors.² These factors include confrontational participants, catalyst causes, group dynamics, group leadership, and emotional electricity. To better understand civil unrest, it is important to discuss briefly the role of each causal factor.

Across the spectrum of various events, participants in civil unrest span all demographic, political, and socioeconomic categories. At baseline, all participants are connected to the group by a variable degree of investment in a specific cause. Some core persons are highly

committed to the issue, while others merely become caught up in the frenzied periphery of the event.

Catalyst causes that trigger civil disturbance include any perceived wrongful policy or event felt worthy of active dissent. These issues include special interest topics, perceived law enforcement injustices, and political grievances. Rioting can occur when the group directs its frustration over a given issue toward persons with opposing views or officers charged with keeping the peace.

As a behavioral dynamic, groups foster an environment in which individual inhibition is lowered due to a collective sense of anonymity, a diffusion of personal responsibility, a strong social urge toward conformity, and a loss of individual decision-making. Additionally, persons in groups also become more susceptible to suggestion, manipulation, and imitation during moments of uncertainty or frustration by strong leaders who are often the first and most assertive agitators. The emotional volatility of a group can also be a powerful unifying force, creating an almost electric connectivity between participants when sparked.

Given the right circumstances, the net effect of these factors is the evolution of *group cohesion*. The group becomes, in essence, its own autonomous organism with a collective identity, purpose, focus, and coordinated response. In general, members of a group are more prone to participate in activities that they would not do if alone. If the tone of the group shifts toward anger or frustration, a "mob mentality" may take over, violence can erupt, and a riot can ensue. Of note, in the context of a counter-transference dynamic, police and others involved with the response to civil unrest must be constantly vigilant in guarding against any negative impact of these factors on their behavior as well.

Two recognized patterns exist for the emergence of civil unrest. First, civil unrest can be a fluid event that escalates along a progressive continuum of disruption. For example, the incident may begin as a planned *demonstration*. A demonstration is a group of people (termed *protestors* or *demonstrators*) specifically called together for a common purpose, such as to protest a political policy. Under ordinary circumstances, demonstrations are peaceful expressions of First Amendment rights and remain law-abiding entities. However, some demonstrations become increasingly disruptive, with individuals

*The content of this chapter exclusively reflects the view of the author and does not represent official policy of the U.S. Department of Defense or the United States Government.

in the group engaging in unlawful activity. If violent tactics are adopted, the situation then degenerates into the anarchy of a riot and the group becomes a *mob*. During a tense confrontation, violence can beget violence, requiring control measures to diffuse the situation.

Second, an additional pattern has been clearly identified in many instances of modern civil unrest.³ A *crowd* is an unrelated group of people assembled together due to similar circumstances, such as for a sporting event or for a court proceeding. A catalyst event, often a verdict in a law enforcement incident, incites a small ultraviolent group in the crowd to riot in immediate response, often fueled by a deep underlying schism along racial, ethnic, or socioeconomic lines within the community. This core group engages in random acts of violence and looting, subsequently engulfing larger segments of the population. These incidents typically overwhelm the initial public safety resources, requiring an influx of outside support to defuse the situation.

PREINCIDENT ACTIONS

Preplanning saves lives when time counts. It is critical to plan for civil unrest events because time is limited for life-saving intervention if violence should erupt. Baseline preparation should focus on the development of infrastructure necessary for mitigation of a worst case scenario, such as widespread rioting. Involving both training and resource coordination, effective medical preplanning for civil unrest involves preparation for the continuum of patient care from the field through initial hospitalization. Important planning aspects include: (1) integration of the field medical response with the tactical response; (2) coordination of regional medical resources at all levels; and (3) development of individual hospital response procedures. Building on this underlying foundation, preparation for specific events (such as announced demonstrations) should involve the completion of a medical threat assessment.

To ensure optimal medical care for all participants on the frontline, it is important that medical support be integrated into the initial tactical response. At the flashpoint of a violent incident, the tactical response involves containment and control of the riot through use of a *mobile field force* (MFF), a special response team for civil disturbance. Successful integration of medical support into the MFF requires the establishment of a working relationship between both parties prior to an actual incident. Planning for organic medical support of such tactical operations should focus on many areas, including the following:

- Logistics—deploying, training, and equipping medical personnel for the field
- Preventive strategies—ensuring that needs are met for hydration and adequate protective equipment during deployment of the MFF
- Acute care delivery—coordinating injury treatment and casualty evacuation from the scene
- Decontamination systems—identifying and eliminating contamination thrown by protestors

- Advanced care access issues—connecting MFF field response to the emergency medical system and hospitals

On a regional level, prior planning must ensure that medical resources will be coordinated on all levels of the healthcare response to function seamlessly within the Incident Command System. First, the regional disaster plan for large incidents of civil unrest should include a medical annex that focuses on the integration of healthcare delivery with other public safety functions under such conditions. Resource planning for patient care should address issues related to emergency medical services (e.g., protection of ambulance crews and field rehabilitation logistics),⁴ hospital transport (e.g., ensuring safe travel routes), local hospital capabilities (e.g., determining trauma level and diversion status), and mutual aid. Second, the development in advance of a reliable communication system to facilitate information sharing between the lead law enforcement agency, the emergency medical system dispatch, and regional healthcare facilities is essential. This system may be effectively adapted from preexisting disaster networks to function as well in the limited scope of civil unrest incidents.

Individual hospitals also need to look at planning for civil unrest incidents, particularly in the emergency department setting. In many respects, this preparation may be incorporated into the existing disaster plan, with such provisions as increased staffing and the establishment of an Emergency Operations Center. Unique aspects of preparation for civil unrest include hospital security concerns in the face of violent agitators outside, management of injured disorderly protestors requiring treatment, contamination issues, the potential for mass-casualty situations, and the control of arrested persons.

For demonstrations that are announced in advance, it is advisable for regional medical planners to develop a *medical threat assessment* (MTA). The MTA is an approach used to prepare for the foreseeable medical issues associated with a particular event by analyzing various health threats, assessing medical vulnerabilities, identifying possible countermeasures, and exploring different resources to optimize healthcare delivery. Relevant information tied to the anticipated circumstances can be gathered in advance through several methods, including hospital site surveys, route surveys, open-source material, and information known about the past behavior of the protest group. Specific MTA components may include an analysis of environmental conditions, hospital capabilities, and substances likely to be thrown by demonstrators.

POSTINCIDENT ACTIONS

In the wake of violence associated with widespread civil unrest, the medical community should strive to promote recovery efforts both within its ranks and within the region. In the short term, attention should be paid to the emotional impact of the civil disturbance on healthcare workers, and any persons suffering residual critical

incident stress effects should be supported. Hospital personnel should continue to provide needed care for victims and their families, as well as to release appropriate information to the community as indicated. In the long term, it is valuable for medical professionals to meet with civic representatives to debrief medical aspects of the incident. The main focus should be an effort to enhance the medical response to similar situations in the future. By discussing both what worked and what did not, lessons learned can be applied to improve patient care delivery in the event of a future civil disturbance.

MEDICAL TREATMENT OF CASUALTIES

Several important factors should be considered with regard to the medical treatment of casualties from civil unrest. For a large-scale incident, the care should be delivered under conditions defined in the disaster plan of the hospital or agency. Important and unique aspects of medical treatment during civil disturbance are the potential for large numbers of patients, the nature of the injuries seen in riots, and the use of less lethal weapons.

The number of casualties from an incident varies widely with the scope of the disturbance. Depending on available resources, it is possible that medical providers may need to implement mass-casualty triage protocols in given situations. The need for this approach may also depend on the timing of the injuries over the course of the incident and the distribution of patients among different hospitals.

As exemplified in the civil disturbance surrounding the Rodney King incident,⁵ three main patterns of injury have been identified in civil unrest. The first type of injury involves assaults suffered by active participants in rioting or other criminal behavior such as looting. With a mixture of blunt and penetrating trauma, these persons may present with gunshot wounds, stab wounds, or injuries incurred in beatings. A second category of injury that has been noted in civil disturbance involves automobile accidents. Suffering primarily blunt trauma, these patients include struck pedestrians and victims of motor vehicle collisions that result from disruption of traffic patterns, erratic driving, or broken traffic signals. The last group of patients present with an acute decompensation of a chronic medical condition because they were unable to obtain needed care. Included in this group are patients receiving dialysis and persons with diabetes.

Less lethal weapons are routinely used in the context of modern civil unrest. Less lethal weapons are devices designed to incapacitate persons or to disperse crowds without causing serious harm. As reflected in the term *less lethal*, the potential does exist, however, for serious harm or even death with these devices. There are two general categories of less lethal agents used in the law enforcement response to civil disturbance. Chemical agents, such as tear gas or pepper spray, cause noxious upper respiratory irritation when deployed. Treatment should focus on removing ongoing contamination, maintaining access to fresh air, and applying cool water.

The injury pattern for projectile munitions, such as “bean bag” rounds, ranges from minor lacerations to significant internal injury.⁶ It is advisable for healthcare providers to be familiar with these less lethal devices and their effects.

UNIQUE CONSIDERATIONS

Medical personnel should remember three unique considerations during a response to civil disturbance. These considerations include awareness of the threat environment, the medical-legal context, and the role of field testing. These three considerations are applicable across the spectrum of medical care settings.

The most important consideration for healthcare providers during civil unrest is to recognize that care is being delivered in a *threat environment*. A threat environment is a situation in which a person is at risk for harm or injury during the performance of a given task. In civil unrest, there are several personal safety concerns for the provider such as violent demonstrators, dangerous crowd tactics, contamination from thrown substances, denial of essential supplies, and the presence of improvised weapons. The provider must provide simultaneous care to different categories of patients placed in confrontation by the event—arrested demonstrators, injured bystanders, and wounded law enforcement officers. In addition to using appropriate protective equipment, medical providers must continually maintain situational awareness and practice scene safety in the threat environment posed by civil unrest.

Providers should also appreciate the medical-legal environment created by civil unrest and the consequent implications for healthcare delivery. In the care of patients, providers must be careful (to the extent possible) not to destroy evidence such as collected weapons, bullets, or clothing. In the event that court testimony is later required, the medical practitioner should also have a basic understanding of forensics as it applies to recognition of injury patterns.

During violent demonstrations, protestors may throw a variety of substances at responding police officers. One significant concern with both medical and legal implications is the potential exposure to contaminated blood in this setting. A field blood sampling protocol to assess

CASE PRESENTATION

On a hot summer day, after a well-publicized trial, a jury acquits several police officers of any wrongdoing in a shooting incident earlier that year. Shortly after the verdict is announced, an angry crowd begins gathering downtown amidst cries for justice. The crowd swells in number as it heads for City Hall to protest the verdict. Incited to violence, some members of the crowd then begin breaking windows of nearby buildings, setting fires to trash cans, and pulling drivers out of their cars.

thrown red liquids can help clarify this issue. This protocol can be developed using screening field assays in conjunction with professional laboratory confirmation.

PITFALLS

Several potential pitfalls exist in the medical response to an episode of civil unrest. These include the following:

- Failure to understand the dynamics and impact of civil unrest within modern society
- Failure to plan for medical contingencies, communication, and coordination along the continuum of health-care delivery before an event occurs
- Failure to understand the nature of medical casualties in civil unrest, including the injury pattern associated with less lethal weapons
- Failure to promote recovery in the wake of an incident through both short-term and long-term measures
- Failure to consider personal safety while providing care in the threat environment of civil disturbance
- Failure to recognize the unique medico-legal implications of civil unrest

Massive Power System Failures

M. Kathleen Stewart and Charles Stewart

DESCRIPTION OF EVENT

Electric power outages can be caused by lightning, high winds, ice storms, hurricanes, and floods, as well as either accidents or deliberate sabotage or attack of the power system.¹⁻⁵ In some cases, these power failures have been massive and prolonged, creating their own addition to an ongoing disaster such as a flood. In other cases, they have been the sole contributor to the disaster.

This chapter will discuss the potential causes of massive power failure, how it may affect disaster operations, and some selected actions that a physician involved in the disaster might encounter. It should be stressed that this chapter is not exhaustive and is intended only to illustrate how the technology base of the world, and emergency medical services (EMS) in particular, are vulnerable to a variety of attacks.

A modern electric power system consists of six main components:

1. The power station
2. A set of transformers to raise the generated power to the high voltages used on the transmission lines
3. The transmission lines
4. The substations at which the power is stepped down to the voltage on the distribution lines
5. The distribution lines
6. The transformers that lower the distribution voltage to the level used by the consumer's equipment

Electricity generation stations throughout the United States are interconnected via power grids. This allows electricity generated in one state to be sent to users in another state. It also allows distant power generation stations to provide electricity for cities and towns whose power generators may have failed or been destroyed by some accident or sabotage.

In the United States, the electric system is divided into three grid systems: the northeastern grid, the western grid, and the Texas grid. Two major power subgrids, the Ontario-New York-New England pool and the Pennsylvania-New Jersey-Maryland pool (the PJM interconnection), together make up the northeast power grid. Power from these stations is moved around the country on almost a half million miles of bulk transmission lines that carry high-voltage charges of electricity.

In a typical system, the generators at the power station deliver a voltage of 1000 to 26,000 volts (V). From the high-voltage transmission lines of the power grid, electric power is transmitted to regional substations. Transformers step this voltage up to values ranging from 120,000 to 750,000 V for the long-distance primary transmission line because higher voltages can be transmitted more efficiently over long distances. At the regional substation, the voltage can be transformed down to levels of 69,000 to 138,000 V. Another set of transformers at neighborhood substations step the voltage down again to a distribution level such as 2400 or 4160 V or 15, 27, or 33 kilovolts (kV). Finally, the voltage is transformed once again at the distribution transformer near the point of use to a voltage that can be used in homes, hospitals, and offices (220 to 1200 volts).

The towers that carry the high-voltage lines present the easiest pathway for a terrorist to destroy the power system. Only modest amounts of conventional explosives detonated at two to three transmission towers are sufficient to interrupt a high-voltage transmission line. Repair and replacement may take days to weeks.

Simple explosives can easily be used to sabotage any above-ground high-voltage power distribution system. A below-ground system is somewhat more difficult to access and has some additional security afforded by this limited access. Although this tactic will destroy the distribution system, it will not destroy the equipment that it powers. In this regard, the consequences will be similar to those of a naturally occurring event.

Another device—graphite bombs—works by exploding a cloud of thousands of electrically conducting carbon-fiber wires over electric installations and power-distribution systems. This short-circuits the electric systems.

A graphite bomb (sometimes called a *G-bomb*) was used in the 1991 Gulf War to successfully disable 85% of Iraq's power supply. The North Atlantic Treaty Organisation (NATO) used a later version in May 1999, to successfully disable 70% of Serbia's power supply.⁶ These bombs will destroy the distribution system, but not the equipment that it powers.

Finally, electromagnetic pulse (EMP) devices can be used to cause massive power failures. When “detonated,” an EMP weapon (also known as an *E-bomb*) generates a powerful pulse of energy capable of short-circuiting

a wide range of electronic equipment, including computers (even those contained in ignition circuits in cars and trucks and those that operate traffic lights), radios, and public utility power supplies. These weapons can disable practically any nonshielded modern electronic devices within the effective range of the weapon. (Some military-grade radios are designed to resist EMPs, but most civilian equipment is not adequately shielded for this type of attack.) The damage from burnout or overload of the electronic circuits would extend far beyond the area directly affected by the blast and radiation of the EMP.

It is unknown whether the nation's air traffic control system has been "hardened" against EMPs.⁶ The extent of the risk to Federal Aviation Administration systems from EMPs is probably (and appropriately) classified. Civilian airliners may be lost. They will not have communication, navigation aids, or landing lights, and in some cases they may not even be able to control the aircraft after electronic fly-by-wire circuits are destroyed by a massive EMP.

Commercial computer equipment is particularly sensitive to EMPs,⁴ as are UHF and VHF radio receivers, televisions, and cell phones.⁵ The consequences of disabling such equipment are mind boggling for the now technology-dependent healthcare community. However, although devastating to electronic equipment, EMPs, at least in theory, do not hurt humans.⁷

Three basic types of EMP weapons exist: nuclear weapons, flux compression generators, and high-power microwave generators. Although an in-depth discussion of each is beyond the scope of this chapter, suffice it to say each weapon would create differing levels of havoc. Those who have only basic engineering and technical skills can harness EMP technology. EMP weapons can be built with materials available to governments and terrorists alike. Fully developed, ready-to-deploy weapons may be available to clandestine markets at any time. Since the United States has actually deployed such a weapon (in Desert Storm, an EMP designed to mimic the flash of electricity from a nuclear bomb was used),⁸ it is quite possible that the design is available to terrorist nations today. EMP devices are highly portable and can even be operated from a distance. Detonating the EMP in the air or near the top floors of a skyscraper maximizes the effects of the weapon.

PREINCIDENT ACTIONS

Even before the terrorist attacks of September 2001, disaster planning in U.S. hospitals was designed primarily for external disasters involving large-scale trauma or mass casualties; for example, airline crashes, radiation accidents, or outbreaks of infectious diseases. Although it is certainly necessary to plan for such events, catastrophic power failures are actually more likely hospital scenarios. By the 1960s, engineers and architects began sealing off buildings from the outdoors, constructing mechanical environments solely controlled by electric power. When this power supply fails, the modern hospital may become totally uninhabitable.

Preparation for an Unscheduled Power Outage

The disaster planner must not only consider the usual devices such as lights and power to critical areas, but also must take steps to ensure against unintended actions when power is restored.⁹ Fiscal restraints often prevent hospitals from spending adequately on emergency power protection. Hospital accountants do not consider absolutely fail-safe 24-hour power for hospitals to be cost-effective. Ironically, when hospitals do provide power protection, it is often used to protect their data systems, not their critical care systems.

Devices expected to operate when the power fails need to be inspected, maintained, and tested as part of an equipment preventive maintenance program. Plans and checklists to maintain critical services need to be prepared, implemented, and tested. Many hospitals test their emergency power supply systems at night or early in the morning before the bulk of the hospital's daily activities begin. This test time is often chosen because it is one of low clinical activity, and will therefore cause less disruption, but normal or peak clinical loads will not be reflected in this emergency power supply system test loading. Many hospitals do not test their emergency power supply systems when their operating rooms are in use. Also, the mechanical, building, radiology, and other clinical processes all vary during a typical hospital day.

Protective Measures Against an EMP Device

It is difficult to protect against an EMP weapon without purchasing military-grade communications equipment. Vehicles require computers to satisfy U.S. Environmental Protection Agency requirements, and these computers are vulnerable. Some anti-EMP measures that EMS providers can take include the following:

1. Build a Faraday cage. A Faraday cage can be made from fine metal mesh that is connected to a ground and completely encloses the items to be protected. If any power cables, data cables, or antennae go into the cage, it may be rendered worthless. Keep all equipment in the cage disconnected from batteries and other power supplies.
2. Maintain a supply of spare radio, monitor, and engine ignition spare parts. Keep the spare parts in the Faraday cage.
3. Use one system at a time during a threat period. Disconnect other systems from power and antennae and keep them in the Faraday cage.
4. If your vehicle ignition fails, disconnect the negative battery terminal, wait 2 minutes, and attempt to restart the vehicle. Some computerized ignition systems on late-model cars might be reset in this way.

Continuity of Critical Services

Backup power generators and uninterruptible power supplies should be selected and installed by qualified electric service contractors and then coordinated with

the electric utility company. It is particularly important to avoid improper switching from one power supply to another. This can lead to power feedback into the regular power system, resulting in damage to equipment and the generator itself.

As plentiful and redundant as backup power sounds, diesel generators alone cannot provide fail-safe backup power to protect hospital patients. The lag between utility shutdown and generator power startup may destroy computerized diagnostic and life-support equipment. Even a 3-second disruption can be perilous to this sensitive electronic equipment. For this same reason, budgets permitting, electric engineers and contractors like to specify uninterruptible power supplies to protect vital equipment from even brief disruptions.

POSTINCIDENT ACTIONS

When the power is restored, the following equipment and checklists will be useful:

- List manually operated switches that may need to be placed in the *off* position.
- List valves that need to be checked for proper position.
- List utilities such as steam, radio, telephone, computers, and pager communications that need to be verified for operability after the power is restored.
- List automatic starting equipment that should be shut down for safety and to minimize load demand when the power is restored.

MEDICAL TREATMENT OF CASUALTIES

Power outages may cause differing types of injuries. In more rural areas, victims may be trapped for prolonged periods of time without adequate food, water, and medications. In colder climates, this may also result in casualties due to exposure. The risk and type of injury to the general population will be determined by the area in which the power outage strikes.

Risks to Worker Safety and Health

Workers operate machines and power tools and are engaged in chemical processes. These workers could be at risk of injury, exposure to dangerous chemicals, or death from a sudden loss of power without immediate restoration of power for vital systems.

People may sustain injuries when trapped in elevators, subways, and mass transit systems. Many of these injuries are sustained during attempts to get out of the local environment to a “safer” area.

Risks to Hospital Patients

Ventilator-dependent patients will need supplemental breathing equipment such as a bag-valve-mask operated by qualified personnel. Some ventilators have built-in,

short-term uninterruptible power supplies and may supply oxygen to patients for a few moments after the power fails. Operating room equipment may fail. Some equipment, such as a heart-lung bypass machine, is mission critical and should be protected by an uninterruptible power supply. Other equipment, such as lights, can be operated by battery power after a short interval of power outage without damage. Laboratory equipment, particularly computerized equipment, may not adequately survive a power loss of only a few seconds. This equipment must be protected by uninterruptible power supply to ensure that data being tested are not lost or degraded.

CASE PRESENTATION: NORTHEASTERN UNITED STATES BLACKOUT, AUGUST 14, 2003¹⁰

On Aug. 14, 2003, a blackout in the northeastern United States occurred at 4:11 PM. Within 9 seconds, the grid had collapsed with a surge of nearly 300 megawatts moving east on the grid and then reflecting back westward. The power outage affected 24,086 km² of area, and about 50 million people were without power. One hundred power plants, including 22 nuclear power plants, were shut down. (It takes about 36 hours to restart a nuclear power plant after shutdown.)

Because the pumping stations failed, 1,500,000 people in Cleveland were without water. These people were relieved by 7600 gallons of water trucked in by the National Guard. Since the airports and air traffic control systems were without power, an estimated 300 flights were cancelled in North America on August 14. New York City had six serious fires, 800 elevator rescues, more than 80,000 calls to 9-1-1, and over 40,000 police called to duty. Toronto had more than 100 elevator rescues and 1484 fire calls.

If the power outage had been deliberately caused by terrorist actions with an EMP bomb, the affected areas might have had no EMS, police, or fire rescue capability (due to transportation failures). Unprotected equipment might have been destroyed.

UNIQUE CONSIDERATIONS

Catastrophic power failure caused by EMP devices may require replacement of all computerized circuitry within the equipment. This means that ambulances may not be operable until the computer ignition control circuitry has been replaced. It may also mean that every computerized piece of equipment from cardiac monitors to laboratory devices within the hospital may need to be replaced.

PITFALLS

Several potential pitfalls exist in the response to a massive power system failure. These include the following:

- Backup generator failure due to battery failure, insufficient fuel supplies, overheating, or fuel pump failure.

Many generators are *standby rated*, meaning that they can reliably perform for only 2 out of 24 hours.

- Failure to check that backup generators will run for prolonged periods at anticipated full load. This should be checked at least twice a year for at least 12 hours.

Hospital Power Outage

Marc C. Restuccia

DESCRIPTION OF EVENT

The loss of power can be catastrophic for any medical institution, its patients, and its staff. The smooth operation of the facility, the safe treatment and diagnosis of patients, and the comfort of all persons in the facility require the continued availability of heat, cooling, and electric power. Loss of any or all of these can lead to an institutional disaster.

In colder climates, loss of heat forces staff to function in uncomfortable and difficult working conditions. For patients, loss of heating can mean they are at risk of hypothermia. Loss of cooling in hotter climates or months will fatigue the medical professionals laboring to diagnose and treat patients. For patients, the loss of cooling could make them susceptible to hyperthermia, dehydration, and worsening of their underlying condition(s). Finally, loss of electric power will severely affect any medical facility. Gone will be the ability to power the many instruments and equipment used to diagnose and treat patients. Computers used to track patients, their past history, and their tests and to order interventions will be offline if an interruption in their supply of electric energy is experienced. Electrically powered ventilators will not function, potentially leading to hypoxia and death for patients in the event of a loss of electric power. Almost all ability to perform laboratory tests and radiographic examinations will not be present in the event of an electric failure. Intravenous pumps, defibrillators, and other life support equipment will suddenly go “dead,” with consequences for the patients who are dependent on them. Likewise, the ability for medical care providers to adequately see their environment, access patient information, perform diagnostic and therapeutic interventions, and function in general will be severely or perhaps totally degraded. Operating rooms will be in the dark, possibly in the middle of procedures. A more mundane, but still important, aspect is the institution’s ability to store and prepare food for patients and staff, which will also be significantly degraded. The stability and potency of many medications and vaccines will be compromised if the facilities necessary to maintain them at their optimal storage temperatures are lost, meaning, at worst, that these medications will not be effective or, at best, they

will be “wasted,” costing the facility money to replace them. Finally, the restoration of power can potentially entail risk for staff and patients. Such power outages can be predicted to be the result of terrorist activities or, much more likely, natural disasters.

PREINCIDENT ACTIONS

Hospitals should all have general disaster plans in place. Among the scenarios envisioned *must* be the loss of electric power, heat, or cooling. Such contingencies must include whether the facility affected is unique, meaning all other local medical facilities are unaffected, or whether the entire local/regional area is affected. In both cases, a plan should be in place for the care, transport, and triage of patients requiring emergent care. Input from and acceptance and knowledge of such a plan and its contingencies must be sought from local and regional emergency medical services (EMS) agencies as well as geographically contiguous medical facilities. In the event of a loss of power, it may be necessary to move patients from the affected facility, move triage patients away from the affected institution, and coordinate local, regional, and perhaps even national resource availability.

Loss of Heating Capacity

Although not a common problem to encounter, hospitals in colder climates must have emergency plans in place for the protection of staff and patients in the event of the loss of ability to heat the institution. In the event that such an occurrence was experienced in a remote hospital with no contiguous medical facilities, the difficulties in transferring patients would be magnified.

If such a scenario were due to a natural or manmade occurrence, involved multiple contiguous healthcare facilities, and had an attendant increase in the number of affected patients, the complexity would increase. Not only would a far greater number of in-hospital patients be affected, but those in the local population requiring routine, ongoing, and especially emergent medical care would also be affected. Such an event would require regional, state, and most likely federal responses to mitigate the disaster.

Preincident actions necessary to prepare for a loss of heating should consist of the following:

- Forming a well-planned and drilled disaster strategy
- Regularly testing the hospital's heating system and identifying alternative mechanisms for heating the facility
- Identifying means to heat patient care areas in the event of failure of all primary heating capabilities
- Adopting and drilling of the hospital Incident Command System (ICS). This must include identifying who should report to the Emergency Operations Center (EOC) and developing a chain of command with clear functions, reporting lines, and expectations for each individual, including both those in the EOC and those throughout the facility
- Identifying and equipping an EOC (communications being the weak link in most plans)
- Identifying potential alternative sites/facilities for the care of the currently hospitalized patients and for the public seeking healthcare during the emergency
- Identifying staff to staff these alternative facilities (if needed)
- Developing Memoranda of Understanding with other institutions covering such contingencies. These should include means of transferring patients to unaffected facilities. Such plans should include local, regional, statewide, and other facilities
- Involving local EMS personnel in planning for the transfer of large numbers of patients
- Determining what group of patients may be continued to be cared for, if any, at the affected facility
- Determining how to best notify the general public about the nature of the emergency, how it will affect them, what the capabilities are of the affected facility, and when a return to normal operations can be expected

Loss of Cooling Capability

Loss of the ability to effectively air-condition hospitals would lead to similar considerations; however, the problems encountered should be less pronounced than the concerns surrounding a loss of the ability to heat the facility. Planning for such an emergency would be similar.

Preincident plans for the loss of hospital cooling should consist of the following actions:

- Forming a well-planned and drilled disaster plan
- Regularly testing the hospital's cooling system and identifying alternative mechanisms for cooling the institution
- Identifying alternative means to cool patient care areas in the event of failure of all primary cooling ability
- Adopting and drilling hospital ICS, as outlined above
- Identifying and equipping a hospital EOC
- Identifying alternative facilities for the care of currently hospitalized patients and for the public seeking healthcare during the emergency
- Identifying persons to staff these facilities if needed
- Developing Memoranda of Understanding with other facilities covering such contingencies, including transfer of patients to those institutions

- Involving local EMS in planning for the transfer of large numbers of patients
- Determining what group of patients, if any, can be continued to be cared for at the affected facility
- Determining how to notify the general public about the nature of the emergency, how it will affect them, what the capabilities are of the affected facility, and when a return to normal operations can be expected

Loss of Electric Power

A loss of electric power, having the potential to be extraordinarily disruptive, is an unfortunately common occurrence.¹ In a modern healthcare facility, the number of critical patient care and ancillary devices, equipment, and services powered by electricity is enormous.² Interruption of continued, reliable electric power, even of a very brief duration, can be catastrophic. Modern computers, monitoring systems, laboratory instruments, and many more computer driven devices do *not* function well with even a short duration power loss. This vital dependence on electric power creates an inviting target for terrorist activities.

Each healthcare facility must preplan for this event and have a robust disaster plan in place. Multiple redundancies in the delivery of uninterrupted electric power must be ready and able to function *immediately* in the event of a loss of electric power. Identification of those systems and equipment that cannot function for even a short time without power must be accomplished in advance and these must be continuously tested and ready. Identification of potential events (e.g., an extraordinary heat wave, a tornado, a hurricane, or a manmade event) must be planned for in advance and preparations made for implementing the disaster plan if such an event is anticipated or actually occurs. For loss of electric power to any medical facility, being ready for such an incident in advance of its occurrence, if at all possible, is infinitely preferable to trying to react to such a condition *after* it has happened.³

Preincident plans for the loss of electric power should include the following actions:

- Forming a robust, well-thought-out, and drilled disaster plan
- Identifying the primary source of electric power. This should include potential scenarios for the loss of this electric input
- Identifying alternative sources of electric power. This would include uninterruptible power system(s) for equipment not able to tolerate the delay for emergency generators (usually 3 or more seconds¹) to begin operation. In addition, emergency generators, usually diesel motors, in adequate number and/or capacity are available for use
- Continued interfacing with electric utilities and equipment suppliers of electricity-generating equipment to ensure prompt response to a loss of power
- Testing the primary electric source and all emergency systems on an ongoing basis

- Making ongoing training of hospital personnel in the use of all of the emergency backup electric systems a top priority
- Ensuring that adequate fuel for any emergency electric generating systems be on hand or immediately available
- Identifying alternative methods of delivering care to patients and allowing staff to function in the event of the failure of all electric generation capability
- Adopting and drilling hospital ICS and identifying the command structure that would ultimately order the evacuation of the hospital patients to another facility
- Identifying and equipping a hospital EOC, making allowance for the loss of all electric power
- Identifying alternative facilities for care of currently hospitalized patients and for the general public who may be seeking routine and emergency care in the event of a loss of all electric power
- Identifying personnel to staff such facilities, if needed
- Developing Memoranda of Understanding with other facilities covering such contingencies, including transfer of patients to those institutions
- Involving local EMS personnel in planning for the transfer of large numbers of patients
- Determining what group of patients, if any, can continue to be cared for at the affected facility
- Identifying means of informing the general public about the nature of the emergency, its impact on the hospital, what services will and will not be available, and the expected duration of the emergency
- Identifying which medications and vaccines are temperature dependent (most are) and making alternative plans for those thought to be most critical for the immediate care of in-patients in the hospital
- Identifying alternative means of feeding patients and staff

POSTINCIDENT ACTIONS

Once a loss of power of any type is experienced, the medical facility must activate its disaster plan, staff its EOC, and begin to follow the plan's steps. Notification of local, state, and federal public health and public safety agencies would be necessary, depending on the type of emergency, its scope, its expected duration, and its source of origin. The response made by any of these agencies would be contingent on the factors listed above. The disaster plan, and its implementation, should be flexible enough to adapt to any new information about the disaster, as it is obtained. The medical facility should take great pains to document the resources needed to meet the healthcare needs of its patients and to address the crisis. Initial attempts to bring the facility to a predisaster state of operation should be attempted rapidly, but if unsuccessful, the order to evacuate patients should be made through the ICS. Potential state and federal reimbursement of the costs incurred will be absolutely dependent on such documentation.

MEDICAL TREATMENT OF CASUALTIES

Cooling Loss

The loss of cooling power for a medical institution would not usually be expected to lead to an influx of new patients. The exception to this rule would be if the loss of cooling were due to an accident, manmade or natural, affecting a local or regional area. Examples of such would include explosions, fires, earthquakes, hurricanes, or tornadoes. In such a case, it would be expected that the local resources would be overwhelmed and outside resources would be needed. It would take time to get these resources into place, and contingency plans should be made to care for the patients in the hospital, care for new patients from the community, as well as prepare for transferring patients to other unaffected facilities in the meantime.

The hospital's disaster plan would guide treatment of patients in a hospital experiencing a loss of cooling. Patients at the highest risk of heat injury—very young children, elderly persons, and those with concomitant medical conditions (such as cardiac disease)—would need to be rapidly identified and arrangements made to either warm their environment or transfer them to unaffected hospitals. The decision whether continue to care for other patients in the hospital would need to be a joint one involving the medical staff leadership, medical staff, and hospital leadership. Consideration of evacuating the hospital must be guided by the best interests of each patient, the availability of beds in alternative facilities, and the ability of EMS personnel to effect such transfers. Just as each medical facility is unique, each such disaster is unique, requiring preplanning, strong leadership, good communication, and commitment from the hospital and its staff.

Heating Loss

A loss of the ability to heat a hospital will engender most of the same difficulties and issues as in loss of cooling. A key difference is that, in most cases, loss of the ability to heat the hospital in a colder climate will lead to the need to evacuate all of the patients in the hospital and to divert all new patients.

Electric Loss

In the event of a loss of electric power to a hospital, the first priority is those patients who are dependent on electrically driven life support systems. Such patients are patients breathing via ventilators, patients using intra-aortic balloon pumps, patients using electrically driven intra-venous infusion pumps with critically important medications (e.g., vasopressor agents), and patients in the operating room. In many cases, if all electric power is lost, battery backup will be available for most of these devices. For patients on ventilators, life-saving alternative means of ventilating include the Oxylator (Lifesaving Systems, Inc, Roswell, Ga), which is an oxygen-powered, nonelectric ventilation device, or hand-powered bag-valve-mask ventilation. Contingency plans for alternative, often

St. Joseph's, a community hospital in Minnesota with 200 beds, is located in a city of 200,000 people. The city is served by two other similarly sized institutions: City Hospital, with 250 beds, and Memorial Hospital, which has 275 beds. On a particularly cold January day, the heating unit at St. Joseph's, an old plant that is scheduled for upgrade as soon as capital funds can be raised, suffers a pre-dawn fire. All ability to heat the institution is lost. Within the hour, the temperature begins to fall. The hospital is 80% occupied with 162 patients in the emergency department (ED), on the floors, and in the single intensive care unit.

A disaster is declared, and an EOC is opened. The chief executive officer; chief financial officer; chief medical officer; heads of the ED, the intensive care unit, and the Chief Nursing Officer; nursing supervisor; director of facilities; director of social services; director of safety; chief of police; and director of public relations all convene in the EOC. It is quickly determined that the heating plant is severely damaged and will take days to weeks—perhaps months—to get back online. Alternative sources of heating the patient care areas are being sought. Immediately the chief executive officer issues the following orders:

- A hospital ICS is established
- The ED is closed to incoming ambulance traffic (i.e., diversion) via notification of local and regional EMS and regional EMS authority
- The ED makes provision(s) for walk-in patients
- The facility is secured from unauthorized entrance
- All elective admissions and surgeries are cancelled and the affected patients notified

- A public announcement of the state of the hospital is prepared for broadcast on local television and radio stations. News outlets are notified
- The other area hospitals are notified of the ongoing problems at St. Joseph's. Assistance is requested in dealing with the ongoing emergency
- Local municipal authorities are notified about the nature of the emergency and request their assistance
- The director of facilities, ED director, ICU director, the director of the community nursing organization, and the nursing supervisor are directed to develop an action plan

The action plan will consist of:

- Securing alternative means of heating patient care areas; for example, space heaters, radiant heaters, and warming blankets
- Identifying those patients who require transfer to fully functional facilities such as nearby hospitals, rehabilitation facilities, and nursing homes
- Obtaining acceptance from physicians and facility administrators for those patients
- Determining appropriate means of transferring those patients
- Determining which patients can be safely discharged home, and making arrangements for this
- Determining what additional staff will be needed

After 12 harrowing hours, all of the critically ill patients have been transferred to other facilities. All other patients have been discharged or have been sent to appropriate care institutions. At this point, the EOC is demobilized and the process of determining the amount of damage, the cost of repair, and the length of time for restoration of normal services is begun.

portable, sources of electric power for other devices should be in place. Preplanning, strong leadership, good communication, contingency plans, and hospital staff commitment are essential.⁴

UNIQUE CONSIDERATIONS

A modern medical facility is uniquely dependent on the continued availability of heating, cooling, and most especially electric power. Loss of any of these is most certainly a cause for the implementation of the institution's disaster plan. Prior planning, contingency identification, practice, and commitment of the facility and staff are crucial to the positive outcome of such an emergency.

PITFALLS

Several potential pitfalls exist in the response to a hospital power outage. These include the following:

- Failure of the disaster plan to adequately address the loss of heat, cooling, or electricity
- Failure to address alternative sources of cooling, heating, and most especially electric power

- Lack of Memoranda of Understanding with other healthcare facilities to support the stricken institution in such emergencies
- Failure to adequately inform and train medical and support staff in their expected roles in the event of the loss of power
- Lack of training of staff before the occurrence of a disaster
- Failure to include the prehospital (EMS) system in pre-disaster planning
- Failure to continuously test the system's response to a failure of any of the above; this would include failure to test backup systems
- Failure to evacuate the hospital soon after attempts to remedy the problem have failed

Intentional Contamination of Water Supplies

Patricia L. Meinhardt

DESCRIPTION OF EVENT

The terrorist events of Sept. 11, 2001, have forced the public health and medical community, federal security and regulatory agencies, and state and local water utilities to consider the possibility of intentional contamination of U.S. water supplies as part of an organized effort to disrupt and damage important elements of the nation's infrastructure.¹⁻⁴ Water supplies and water distribution systems represent potential targets for terrorist activity in the United States based on the critical need for water in every sector of its industrialized society.² Even short-term disruption of water service can significantly affect a community, and intentional contamination of a municipal water system as part of a terrorist attack could lead to serious medical, public health, and economic consequences. The magnitude of water service disruption for a community has been vividly demonstrated by the destruction of water supply systems in the Gulf Region as a result of Hurricane Katrina in 2005. As this massive hurricane illustrated, contamination of water with biologic, chemical, or radiologic agents has generally resulted from natural disasters, industrial pollution, or unintentional man-made accidents in the United States. However, the deliberate contamination of the wells, reservoirs, and other water sources for civilian populations has been used as a method of attack by opposing military forces throughout the history of war. Many armies have resorted to using this method of warfare, including the Romans, who contaminated the drinking water of their enemies with diseased cadavers and animal carcasses.⁴ With enhanced technology and modern scientific advances, the mechanisms of dispersal of biologic, chemical, and radiologic warfare agents have expanded considerably and currently include water as a delivery mechanism. Whether advanced scientific techniques or ancient warfare methods are used by terrorists, overt and covert contamination of water supplies remains a potential public health threat for the U.S. population.

The plausibility of intentional contamination of water supplies as part of a terrorist attack has been reinforced by recent congressional testimony, a consensus statement by a governmental review panel, and a joint Centers for Disease Control and Prevention (CDC) and Environmental

Protection Agency (EPA) water advisory health alert.^{5,6} As part of its 2002 congressional report, the National Research Council of the National Academy of Sciences concluded that water supply system contamination and disruption should be considered a possible terrorist threat in the United States.⁵ On Feb. 7, 2003, the national terrorism threat level was increased to "high risk" based on information received and analyzed by the federal intelligence community. Subsequent to this heightened alert, the CDC and EPA issued *Water Advisory in Response to the High Threat Level*, which describes the need for enhanced vigilance by the public health, medical, and water utility communities regarding the risk of a terrorist attack on the nation's water infrastructure.⁶ Apprehension regarding a terrorist assault on drinking water systems has also been reinforced by arrests of suspects in 2002 and 2003 who were charged with threatening to contaminate municipal water supplies in the United States.^{3,4}

Spectrum of Disease Resulting from Intentional Water Contamination

The biologic, chemical, and radiologic agents that have been designated as potential terrorist weapons may be dispersed through multiple exposure pathways, including water.^{2,4,7-9} Recognizing and managing a waterborne disease outbreak and the health effects of exposure to water contaminants are diagnostic challenges under normal circumstances, but the challenge will be even more significant during an act of water terrorism.¹⁰ Intentional contamination of water supplies with biologic, chemical, or radiologic agents may produce a broad spectrum of disease and involve virtually every organ system, including, but not limited to, the gastrointestinal, respiratory, dermatologic, hematopoietic, immunologic, and nervous systems. In addition, waterborne agents may enter the body through various portals, including the following: (1) ingestion and aspiration of contaminated water, (2) dermal absorption of contaminated water during bathing activities, (3) inoculation of skin lesions from direct contact with contaminated water, (4) consumption of food directly contaminated by water during food preparation, and (5) consumption of contaminated food indirectly contaminated by water through uptake in the food chain or through agricultural practices.⁴

A key factor in the accurate diagnosis and appropriate management of disease resulting from intentional contamination of water supplies is inclusion of water by the healthcare provider as one possible exposure pathway for the dissemination of biologic, chemical, and radiologic agents at the time of initial case presentation. The categories of compounds that may cause a diverse spectrum of water-related disease during an act of water terrorism include many of the agents traditionally associated with other modes of delivery. Biologic, chemical, and radiologic agents that have been designated as possible terrorist agents of public health concern that include the potential for waterborne route of exposure and weaponized agent delivery are presented in Table 185-1.

PREINCIDENT ACTIONS

Although medical practitioners may not be able to prevent the first cases of illness or injury resulting from an act of intentional water contamination, they are positioned to play a critical role in minimizing the impact of such an event by practicing medicine with an increased index of suspicion that such an attack may occur in their community. To prevent a missed diagnosis of a case of terrorism-related waterborne disease, it is vital that medical practitioners understand how water could act as a potential exposure pathway or mode of dispersal for biologic, chemical, and radiologic agents *before* an incident occurs.⁴

TABLE 185-1 SELECTED BIOLOGIC, CHEMICAL, AND RADIOLOGIC AGENTS THAT INCLUDE WATER AS A POTENTIAL MODE OF DISPERSAL FOR TERRORISM*

BIOLOGIC AGENTS		
<p>Bacterial Pathogens</p> <p>Anthrax <i>Bacillus anthracis</i></p> <p>Brucellosis <i>Brucella melitensis</i>, <i>B. suis</i>, <i>B. abortus</i>, <i>B. canis</i> (undulant or Malta fever)</p> <p>Cholera <i>Vibrio cholerae</i></p> <p>Clostridium perfringens</p> <p>Glanders <i>Burkholderia mallei</i> (formerly <i>Pseudomonas mallei</i>)</p> <p>Melioidosis <i>Burkholderia pseudomallei</i> (formerly <i>Pseudomonas pseudomallei</i>)</p>	<p>Plague <i>Yersinia pestis</i></p> <p>Salmonella <i>Salmonella typhimurium</i> and <i>S. typhi</i> (acute gastroenteritis and typhoid fever)</p> <p>Shigellosis <i>Shigella dysenteriae</i> and other <i>Shigella</i> sp.</p> <p>Tularemia <i>Francisella tularensis</i></p> <p>Viral Pathogens</p> <p>Hepatitis A virus (HAV)</p> <p>Smallpox <i>Variola major</i></p> <p>Viral encephalitides (e.g., Venezuelan equine encephalomyelitis [VEE])</p>	<p>Viral hemorrhagic fevers (e.g., Ebola, Marburg, Lassa fever, Rift Valley fever, Yellow fever, Hantavirus, and Dengue fever)</p> <p>Parasitic Pathogens</p> <p>Cryptosporidiosis <i>Cryptosporidium parvum</i> and other <i>Cryptosporidium</i> sp.</p> <p>Rickettsial and Rickettsial-Like Pathogens</p> <p>Psittacosis <i>Chlamydia psittaci</i></p> <p>Q fever <i>Coxiella burnetii</i></p> <p>Typhus <i>Rickettsia prowazekii</i></p>
BIOLOGIC TOXINS		
<p>Bacterial Biotoxins</p> <p>Clostridium botulinum toxins (collectively BTX)</p> <p>Clostridium perfringens toxins</p> <p>Staphylococcus enterotoxin B (SEB) (e.g., protein toxin from <i>Staphylococcus aureus</i>)</p> <p>Fungal-Derived Biotoxins (Mycotoxins)</p> <p>Aflatoxin metabolite of <i>Aspergillus flavus</i></p>	<p>T-2 mycotoxin extract from <i>Fusarium</i> spp.</p> <p>Anatoxin A product of cyanobacteria, <i>Anabaena flos-aquae</i></p> <p>Microcystins products of cyanobacteria, <i>Microcystis</i> spp.</p> <p>Plant- and Algae-Derived Biotoxins</p> <p>Ricin extract from castor bean</p>	<p>Marine Biotoxins</p> <p>Saxitoxin (Paralytic shellfish poisoning or PSP) product of dinoflagellate, <i>Gonyaulax</i></p> <p>Tetrodotoxin neurotoxin from pufferfish sp.</p>
CHEMICAL AGENTS		
<p>Nerve Agents (“Gases”)</p> <p>G agents (Volatile) GA (Tabun), GB (Sarin), GD (Soman)</p> <p>V agents (Nonvolatile) VX</p>	<p>Vesicant and Skin Blistering Agents</p> <p>Lewisite L, L-1, L-2, L-3</p> <p>Nitrogen mustards HN-1, HN-2, HN-3</p>	<p>Industrial and Agricultural Agents</p> <p>Pesticides, persistent and non persistent</p> <p>Dioxins, furans, polychlorinated biphenyls (PCBs)</p>

TABLE 185-1 SELECTED BIOLOGIC, CHEMICAL, AND RADIOLOGIC AGENTS THAT INCLUDE WATER AS A POTENTIAL MODE OF DISPERSAL FOR TERRORISM*—CONT'D

Blood Agents (Asphyxiant or Systemic Agents)	Incapacitating Agents (Psychotropic or Behavior-Altering Compounds)	Dioxins, furans, polychlorinated bphenyls (PCBs)
Cyanide Compounds Hydrogen cyanide (AC) Cyanogen chloride (CK)	CNS Depressants (e.g., BZ [3-quinoclidinyl benzilate] and similar compounds)	Explosive nitro compounds and oxidizers (e.g. ammonium nitrate combined w/fuel oil)
Arsine Compounds (Arsenicals) Ethylidichloroarsine (ED) Phenyldichloroarsine (PD)	CNS Stimulants (e.g., LSD [D-lysergic acid and diethylamide])	Flammable industrial gases and liquids (e.g., gasoline and propane)
		Poison industrial gases, liquids, and solids (e.g., cyanides and nitriles)
		Corrosive industrial acids and bases (e.g., nitric acid and sulfuric acid)

RADIOLOGIC AGENTS

Radiation Terrorism Threat Scenarios	Potential Exposure Pathways and Agent Source
Nuclear Blast Detonation of suitcase-sized nuclear bomb	External Exposure External radiation exposure from nuclides in the plume after detonation External radiation and contamination from surface-deposited contamination and activation products Personal contamination of skin and clothing
Nuclear Reaction Sabotage of nuclear power plant or “melt-down”	Internal Contamination Internal contamination from plume inhalation due to nuclides in plume after detonation Internal contamination due to inhalation of re-suspended contamination Internal contamination due to inhalation or ingestion from personal contamination Internal exposure due to ingestion of contaminated food and water Internal contamination through skin or wound absorption or deposition from contact with contaminated material, including water
Radiation dispersal device RDD or “dirty bomb” release

Preincident preparedness by the medical community will be critical to reduce the following: (a) the public health impact of a water terrorism incident, (b) the secondary disruption to potable water availability and distribution, and (c) the psychological impact of the public’s lack of confidence in water safety and quality after an incident of intentional contamination of water.^{2,4} If preincident actions include terrorism preparedness and disaster readiness, educated medical and public health professionals may make the difference between a controlled response to a water terrorism event versus a public health crisis.^{4,11}

It is important to note that a major effort has been undertaken to improve and enhance the ability to detect and characterize deliberate contamination of water systems in the United States as part of a collaborative effort by local water utilities and several federal public health agencies.^{3,4,12} As a result, U.S. water systems are more physically secure than ever before, with multiple layers of enhanced protection. However, there are several potential points of contamination that could be targeted for acts of water terrorism. Therefore, it is critically important for the medical community to have a basic understanding of these water system vulnerabilities in order to be able to complete an accurate exposure

history when evaluating a suspected case of water-related disease. Various scientific consensus groups, public health agencies, and water utility specialists have outlined a series of potential points of contamination of the U.S. water supply and distribution system.^{4,5} This information is summarized in Table 185-2 and acts as a valuable resource for healthcare providers and public health professionals when evaluating an unusual symptoms complex or an atypical illness pattern that may represent a case of waterborne terrorism.

POSTINCIDENT ACTIONS

Although environmental monitoring of water supplies is improving rapidly, the most likely *initial indication* that a water terrorism incident has occurred may be an increased number of patients presenting to their healthcare provider or emergency department with unusual or unexplained illness or injury, a change in local disease trends and illness patterns, or a community-wide waterborne disease outbreak. Therefore, healthcare providers and public health practitioners may be the first to discover that a waterborne release of biologic, chemical, or radiologic agents has

TABLE 185-2 POSSIBLE POINTS OF INTENTIONAL CONTAMINATION OF U.S. WATER

Healthcare providers should keep these sources of potential water contamination and unusual modes of delivery of biologic, chemical, and radiologic agents in mind when evaluating a suspected case of terrorism-related disease*:

- **Upstream of a community water supply system or collection point:** Water supply systems are composed of small streams and bodies of water, rivers, service reservoirs, aquifers, wells, and dams that may act as points of deliberate contamination of water.
- **Community water supply intake access point or water treatment plant:** Many water supply systems are designed to receive water from source water reserves at a central intake point, with this source water being subsequently filtered and sanitized at the community water treatment facility for eventual distribution as potable water. Both a water intake point and a community water treatment plant may be targeted for terrorist activity and deliberate water contamination.
- **Selected points in the post-treatment water distribution system:** Treated water is distributed to water consumers or end-users through transmission pipelines to homes and businesses. Selected portions of a water distribution system or water main are another potential point of water contamination that may be targeted by terrorists and could affect a subdivision, specific neighborhood, school, medical center, or nursing home.
- **Private home or office building water supply connection, individual building water supply, water tanks, cisterns, or storage tanks:** Treated water that is stored very close to the water consumer or end-user as well as individual house or building connections may serve as points of contamination of water by terrorists.
- **Water used in food processing, bottled water production, or commercial water:** Water used for food processing or preparation as well as bottled water production also represent points of potential water contamination by terrorists.
- **Deliberate contamination of recreational waters and receiving waters:** Both treated and untreated recreational waters may serve as a point of potential contamination of water, including swimming pools, water parks, and natural bodies of water (small lakes and ponds). Receiving waters, such as rivers, estuaries, and lakes, may be secondarily contaminated with wastewater from sanitary and storm sewer systems that may have been environmentally contaminated by a biologic, chemical, or radiologic agent used in a terrorist assault.

*Modified and reprinted with permission from *Physician Preparedness for Acts of Water Terrorism: An On-line Readiness Guide*. Accessible at: <http://www.waterhealthconnection.org/bt>.

occurred in a targeted population and must understand their critical role as “front-line responders” in detecting water-related disease resulting from terrorist activity.⁴

Certain clinical manifestations and disease syndromes may be characteristic of a terrorist attack in which biologic, chemical, or radiologic agents are used via a waterborne route. A heightened level of alertness and awareness by the medical community of these patterns of illness and clusters of disease may enhance the initial discovery of a waterborne terrorist attack and are critical to any postincident action plan. Early and accurate clinical detection of a suspicious case of terrorism-related disease will be especially important for timely follow-up epidemiologic investigations to be initiated and appropriate remediation and prevention efforts to be instituted by the public health and water utility communities.⁴ During the postincident period, healthcare practitioners will need to “think like an epidemiologist” when evaluating any suspect case or unusual pattern of disease in their clinical practice.¹³ A medical practitioner’s diagnostic acumen for recognizing waterborne disease resulting from intentional contamination of water can be augmented significantly by embracing this epidemiologic approach. Several epidemiologic patterns and sentinel clues have been published and provide a valuable resource for both the medical and public health community facing the challenges of diagnosing terrorism-related disease that may result from multiple exposure pathways, including water, and have universal application in a clinical and public health setting (Box 185-1).

Postincident actions also require that healthcare providers become familiar with the appropriate mechanisms for communicating with law enforcement agencies, public utilities, the media, and the concerned public. If a healthcare provider suspects that an act of water terrorism is responsible for a patient’s symptoms complex or an unusual illness pattern in his or her practice, *immediate*

action to contact the appropriate public health authority is essential, even before laboratory confirmation or final diagnosis. This contact is the critical first step necessary for the public health authority to (1) initiate a prompt investigation; (2) provide guidance to healthcare providers and the affected community; (3) establish communication and cooperation with other local, state, and federal agencies as warranted; and (4) contact local water utilities for prompt remediation and protective measures. Attention to this postincident procedure by healthcare providers is mandatory to initiate the appropriate response to a potentially high-risk public health event that may indicate intentional contamination of drinking water supplies.

MEDICAL TREATMENT OF CASUALTIES

The nature of the medical sequelae resulting from exposure to intentional contamination of water supplies depends on a multitude of factors including the following: (1) agent characteristics, including toxicity and virulence; (2) individual host susceptibility and level of immunity; and (3) movement and dilution of the agent in the environment.^{14,15} Individual host susceptibility and differences in biologic, chemical, and radiologic agent virulence and toxicity may result in a wide variation in the severity of disease resulting from a waterborne terrorist event.¹⁶ Water-related disease resulting from intentional contamination may present as benign symptoms or self-limited illness in a healthy patient population, whereas the same waterborne exposure in a vulnerable patient population may result in serious morbidity and mortality. In addition, as is apparent from the 50 agents that may be dispersed in water (see Table 185-1), the medical management and treatment protocols for water terrorism-related disease vary significantly depending on the agent used.⁴

BOX 185-1 EPIDEMIOLOGIC INDICATORS AND SENTINEL CLUES INDICATING POSSIBLE TERRORISM-RELATED EXPOSURE AND DISEASE

Several epidemiologic patterns have been identified as possible sentinel clues of a terrorist attack. However, none of these indicators alone is pathognomonic for terrorism-related disease. These indicators and sentinel clues are presented here as an educational tool for use by healthcare providers and public health practitioners as possible disease trends that may warrant further investigation*:

- Point source illness and injury patterns with record numbers of severely ill or dying patients presenting within a short period of time
- Very high attack rates, with 60% to 90% of potentially exposed patients displaying symptoms or disease from possible biologic, chemical, or radiologic agent exposure
- Severe and frequent disease manifestations in previously healthy patients
- Increased and early presentation of immunocompromised patients and vulnerable population patients with debilitating disease since the dose of inoculum or toxic exposure required to cause disease may be less than for the general healthy population
- "Impossible epidemiology" with naturally occurring diseases diagnosed in geographic regions where the disease has not been encountered previously
- Higher-than-normal number of patients presenting with gastrointestinal, respiratory, neurologic, and fever diagnoses
- Record number of fatal cases with few recognizable signs and symptoms, indicating lethal doses of biologic, chemical, or radiologic agents near a point of dissemination or dispersal source
- Localized areas of disease epidemics that may occur in a specific neighborhood or sector, possibly indicating contamination of a selected point in a post-treatment water distribution system
- Multiple infections at a single location (school, hospital, nursing home) with an unusual or rare biologic pathogen
- Lack of response or clinical improvement of presenting patients to traditional treatment modalities
- Near-simultaneous outbreaks of similar or different epidemics at the same or different locations, indicating an organized pattern of intentional biologic or chemical agent release
- Endemic disease presenting in a community during an unusual time of year or found in a community where the normal vector of transmission is absent
- Unusual temporal or geographic clustering of cases with patients attending a common public event, gathering, or recreational venue
- Increased patient presentation with acute neurologic illness or cranial nerve impairment with progressive generalized weakness
- Unusual or uncommon route of exposure of a disease such as illness resulting from a waterborne agent not normally found in the water environment

*Modified and reprinted with permission from *Physician Preparedness for Acts of Water Terrorism: An On-line Readiness Guide*. Accessible at: <http://www.waterhealthconnection.org/bt>.

An online clinical management guide has been developed for healthcare practitioners and public health specialists faced with addressing the evaluation and management of water-related disease resulting from terrorist activity.^{4,10} This free resource, *Physician Preparedness*

for Acts of Water Terrorism: An On-line Readiness Guide, which is accessible at www.waterhealthconnection.org/bt, is highlighted in Figure 185-1 and provides "24/7" access to medical management guidelines addressing water-related disease resulting from intentional contamination of water supplies from biologic, chemical, and radiologic agents.

UNIQUE CONSIDERATIONS

1. Even though environmental monitoring of water supplies continues to improve, the most likely initial indication that an intentional water contamination event has occurred in a population may be a change in disease trends and illness patterns. Therefore, healthcare providers may be the first to recognize that an act of water terrorism has occurred in their community.
2. Use of water as a mode of dispersion for terrorist agents may confound diagnosis, delay treatment, and impede protective public health measures if clinical evaluations and epidemiologic investigations do not include the possibility of a waterborne route of exposure or mode of dispersal.
3. Prompt identification of waterborne disease resulting from water terrorism may be difficult since the signs and symptoms of waterborne disease and the health effects of water contamination are often nonspecific and mimic more common medical conditions and disorders unrelated to water contamination.
4. Co-infections with waterborne pathogens, coupled with multiple chemical agent exposure during an act of water terrorism, may result in exposed patients presenting with both acute and delayed symptoms from mixed agent exposure, complicating accurate and timely diagnosis.
5. Waterborne exposure to biologic, chemical, or radiologic agents may result from both direct and indirect environmental contamination, including contamination through wastewater from sanitary and storm sewer systems receiving run-off from an aerosolized terrorist attack or through decontamination wastewater generated during patient decontamination procedures.

PITFALLS

- Failure to include water as a possible exposure pathway or mode of transmission during initial case presentation of a suspected terrorist incident
- Failure to recognize that more than 50 potential terrorist agents of public health concern may be distributed through water as a mode of dispersal
- Failure to notify appropriate public health authorities immediately of a suspected case of waterborne disease, preventing timely remediation efforts and protective public health measures
- Failure to consider the special needs of susceptible populations most at risk for morbidity and mortality from intentional water contamination

- Failure to identify alternative sources of drinking water as part of disaster preparedness plans in order to ensure that affected communities have adequate drinking water for days to weeks after a water contamination event
- Failure to provide effective risk communication regarding water safety to concerned patients and the public

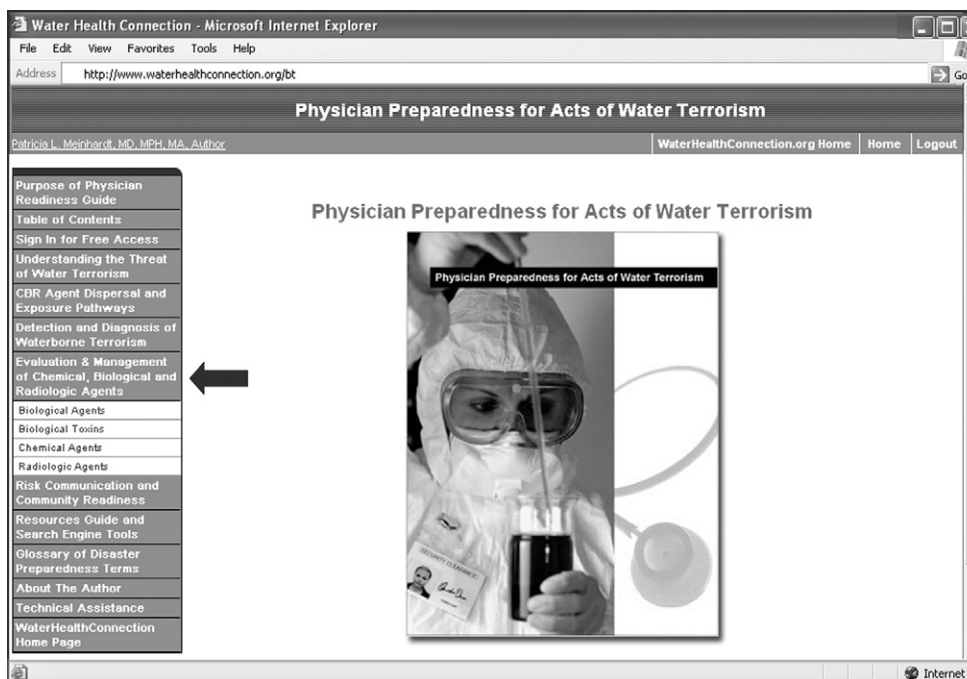

FIGURE 185–1. *Physician Preparedness for Acts of Water Terrorism: An On-line Readiness Guide* is a free online medical resource accessible at: <http://www.waterhealthconnection.org/bt>.

CASE PRESENTATION

A sensitive communication advisory from the Department of Homeland Security is issued stating that recent intelligence indicates members of Al Qaeda have discussed plans to attack drinking water supplies. Two potential attack scenarios have been uncovered: (1) disruption of the water delivery system through a physical attack on the water infrastructure and (2) introduction of chemical and/or biologic agents into the water distribution system and post-treatment facilities. Several days later, a large medical center's emergency department (ED) experiences a very active night in which a series of patients complaining of generalized weakness, fatigue, dry mouth, and dysphagia are evaluated. One elderly patient also complained of blurred vision, partial paralysis, and slurred speech. There is no apparent age or sex distribution in the presenting ED cases, but the number of presenting patients with similar symptoms continues to escalate throughout the day. Laboratory confirmation is not yet available, but by early the next morning, the presumptive diagnosis for the unknown epidemic in the community is botulism. The sudden appearance of multiple patients with acute onset of characteristic symptomatology for botulinum toxicity with no common ingestion of high-risk food suggests a possible terrorist event, and the local public health authorities are contacted. Although the cases of botulinum toxicity appear to be mild at this point, the medical center terrorism preparedness team and the health department are concerned that these initial cases herald a mass exposure event.

Through excellent history-taking techniques, a water-borne source for the community botulism outbreak is

uncovered. It is apparent that “finished water,” or drinking water that has already been treated, has been intentionally contaminated with botulinum toxin in one of the community water districts. The intentional contamination of post-treatment drinking water with botulinum toxin has generated real fear and distress in the community. Local healthcare providers are bombarded with questions from their patients, including: “Is my water safe?” To make matters worse, the national news media have arrived and are positioned right outside the medical center entrance.

The intentional contamination of the community drinking water has led to the closure of a targeted water treatment facility until further notice. This closure has led to denial of potable water for several water-dependent sectors in the community. Local businesses, schools, and nursing homes in the affected water district are very concerned about how long they will be expected to be without municipal water supplies. Several days later, the contaminated water treatment facility is still “off line” and local community governing officials are under pressure to address the disruption of potable water and the resulting financial and public health consequences as well as the ongoing public risk communication crisis. The public health and medical community is faced with developing contingency plans for ongoing disruption of the water delivery system, determining when it will be “safe” to bring the contaminated water treatment facility back “on-line,” and then convincing the local residents that their municipal water is safe again.

Food Supply Contamination

Marc C. Restuccia

DESCRIPTION OF EVENT

Despite the many improvements made in overseeing the nation's food supply, foodborne illness remains a serious cause of morbidity and mortality throughout the world, including the United States. Many factors contribute to an ideal chain for amplification of foodborne pathogens, including the following: growth of modern mass production farms; the scale of modern water supplies; importation of food from other countries, which may lack the strict food handling and shipping guidelines present in the United States; adoption of immense food and processing plants; and distances, sometimes quite lengthy, that food is transported to consumers. The scale of the problem is not known with great accuracy.¹ It is estimated that millions of people are affected worldwide. The majority suffer only temporary discomfort. However, for the young, the very old, patients with concomitant systemic illness, and, increasingly, for the immunocompromised (cancer patients, AIDS patients, patients who have had organ transplants), foodborne illness can be fatal. In the United States, approximately 76 million people suffer foodborne illnesses every year, and approximately 5000 deaths are attributable to this annually.²

Foodborne illnesses are virtually always the result of human actions (or omissions). They can be categorized as those seen routinely in daily life or as intentional attacks on the food chain for a given population. Each will be described separately.

Typical Food Poisoning

Improper handling, leading to fecal contamination of food, is the usual cause of most foodborne illnesses. Typical agents causing the illness include bacteria, viruses, parasites, and toxins. Recently, a newly described class of agents, prions, has been implicated in causing human illness, namely transmissible spongiform encephalopathies. Infected beef cattle have been discovered in several countries. Documented cases of human illness have been described in the United Kingdom. These discoveries have devastated the cattle industries in both Britain and America and have led to the banning of British and American food imports.

In addition, many people around the world have considered changing their dietary habits, with a significant decrease in beef consumption.

One cause of food supply contamination may be seen when the food supply chain is disrupted by a natural event. Scenarios such as an earthquake, tornado, hurricane, or flood contaminating foods during production, processing, transportation, or preparation would have severe consequences on the affected population. Fortunately, in such an event, unaffected areas of the state, region, country, or world could supply untainted food to the stricken area or region.

The diagnosis of foodborne illness in the typical scenario is difficult. Unless multiple persons present with symptoms and a clearly identifiable source is determined, an individual healthcare provider may have difficulty in identifying a foodborne epidemic. The incubation period can range from a few hours, in the case of bacterial toxins, to days, as with many bacterial, viral, parasitic, and protozoan agents, to years with prion-induced illness. Multiple other causes of gastrointestinal dysfunction may mimic foodborne illness, making the diagnosis exceedingly difficult.

In the case of typical foodborne illnesses, if multiple persons are affected and have a common point in their history, such as attending a particular wedding, eating at a specific restaurant, or buying a specific food item at a particular food market, the diagnosis may quickly become evident. If patients present at multiple emergency departments, physicians' offices, and urgent care facilities, the appropriate questions may not be asked or accurately answered, and the diagnosis may not be made in a timely manner. The typical signs and symptoms of foodborne illness—nausea, vomiting, diarrhea, abdominal pain, fever, and dehydration—may be seen with many non-foodborne illnesses and require an astute clinician to make the connection.

Intentional Attack on the Food Supply

In the current climate of worldwide terrorist activities, the potential for an individual or group to deliberately contaminate a population's food supply cannot be discounted. Due to this concern, congress enacted the

Public Health Security and Bioterrorism Preparedness and Response Act of 2002. The Food and Drug Administration (FDA) was charged with developing guidelines to ensure the safety of food produced in the United States and that which is imported from outside U.S. borders. These regulations, currently still being formulated, may be viewed on the FDA's Web site. In addition, when the Department of Homeland Security was created, it was recognized that U.S. agriculture and food industries had to be included in the list of critical parts of society's infrastructure needing protection.³ The expanding aggregation of growers, suppliers, and long lines of transportation, often stretching across international boundaries, made this chain of supply uniquely susceptible to intentional contamination. Although never actually experienced by a society, warring nations historically have sought biologic weapons to sabotage an opposing nation's food supply.⁴

A terrorist seeking to sabotage a nation's food supply, especially in a highly industrialized nation like the United States, has many potential targets for food contamination. Crops, livestock, fertilizer, cattle feed, products in the food processing and distribution chain, storage facilities, transport modes, and food and agricultural research laboratories all provide potential sites for such an act of terror. As the General Accounting Office (GOA) noted in its 2003 report, individuals or groups seeking to cause economic disruption may well target livestock and crops.⁵ Conversely, if such groups seek to inflict human illness, they might contaminate finished food products at the processing stage, the distribution or transportation stage, or potentially at the site of consumption. An example of the latter was a cult in the 1980s which, seeking to sway a local election, contaminated a local restaurant's salad bar with *Salmonella*.⁵ This act would, the cult envisioned, sicken enough of the local populace so as to render them unable to vote, allowing the cult to gain a majority in the election.

The GAO's report³ noted that there are significant gaps in federal controls for protecting agriculture and the food supply. These gaps include inadequate education of border inspectors on foot-and-mouth disease, inadequate numbers of inspectors to handle the magnitude of international passengers, and inadequate scanning technology or inconsistency in its use at cargo and bulk mail facilities.³

The potential costs of a bioterrorist attack on the food supply, especially if it involved livestock, would be much greater than simply the cost of the livestock and disposal of the animals.⁴ As was seen in Great Britain with the outbreak of foot-and-mouth disease (a nonterrorist incident), the loss of confidence in British food suppliers and the loss of tourism income multiplied the loss to the U.K.'s economy significantly. In the case of a terrorist-sponsored food contamination attack, assuming that the terrorists were seeking to maximize the impact, the economic losses and disruption could be magnified many times.

Lastly, the mere threat or suggestion of a biologic attack on the food supply would be sufficient to seriously disrupt the economy and the lives of the population targeted. Lack of confidence in the safety of the food available would have unimaginable consequences for the area targeted.

In the event of a contamination of the food supply, the speed at which it would be recognized would vary depending on the agent(s) used. For long-incubating agents, such as bovine spongiform encephalopathies (mad cow disease), the first indication would be positive test results of the disease in sample livestock. It would not, however, appear in the human population at risk for years. With other agents targeted at the human population and introduced at later stages of the food production chain, such as the *Salmonella* attack previously described, it would take only hours to a few days for the population at risk to show signs and symptoms of food poisoning. Such signs and symptoms would mirror those of a typical foodborne illness event, only potentially magnified many times. It is entirely conceivable that not only would healthcare facilities and providers be overwhelmed with the numbers and severity of patients, but it is also extremely likely that the healthcare providers also would be stricken. A calculated terrorist act might very well *first* target the healthcare infrastructure to maximize the disruption and loss of life and productivity of the stricken populace.

PREINCIDENT ACTIONS

Planning for the possible contamination of any part of the food supply chain, whether due to deliberate acts of terrorism or simply to human carelessness, must be done in advance of the event. Developing a plan for such a situation must include the following: rapid identification of the altered food supply, limiting its health and economic impact, treatment of affected persons, and identification of alternative sources of noncontaminated food. Adequate numbers of unaffected public safety and healthcare workers need to be available to identify the outbreak, limit its expansion, maintain public safety, and treat victims. Local, state, and federal officials need to identify beforehand those links in the food supply chain that are particularly vulnerable to contamination and implement policies and plans for prevention.

Education of the entire population would be beneficial. Farmers, distributors, retailers, and consumers need to be informed about the potential for foodborne illnesses, recognizing signs and symptoms, identifying when the food supply chain is compromised, and acting decisively if such a situation arises. Legislators at local, state, and federal levels need to understand the vulnerability of the food supply and be proactive in initiating legislation, including funding. This legislation would be to protect the food supply, treat the victims, and limit the economic devastation of any disruption in the supply.

Syndromic surveillance is a fairly new method of rapidly tracking and identifying disease trends. It allows cities, regions, states, and even wider communities to share, via computer, the background health of a population. An example would be a surveillance system that receives data on symptoms and diagnoses of patients admitted to the area emergency departments on a daily basis. This system, in theory, would quickly identify unusual disease clusters and alert boards of health, triggering a preplanned

response. This powerful tool has implications beyond that of food supply contamination and could well be invaluable in any disease outbreak or bioterrorist attack.

Every hospital, locality, state, and nation should have predeveloped disaster plans to cover the eventuality of a food supply disruption. These should include access and distribution of needed medications and methods for communicating with local boards of health, public safety agencies, the medical community, and especially the public. Identification of alternative food supplies should be part of the plan. Although state and federal assistance can be expected, such responses will take some time and each of the aforementioned entities should have a detailed plan for dealing with the first few hours of the disaster, possibly even the first 3 days.

Greater state and federal oversight of the food supply, as previously mentioned, is critical to prevent and limit the impact of a widespread foodborne illness. Improved inspection of all food products, during both production and shipping (potentially over international borders), is desirable. Rapid containment of such an outbreak will limit its progression, minimize its economic impact, and restore the public's confidence in the food supply.

POSTINCIDENT ACTIONS

After an outbreak of foodborne poisoning, a high degree of suspicion is necessary, especially on the part of medical professionals, to determine whether a cluster of illnesses is something out of the ordinary. Open lines of communication and the use of tools, such as syndromic surveillance, will be essential for early identification of the problem, limitation of a burgeoning outbreak, and prompt and appropriate treatment of victims. Consideration of the impact on critical societal elements, such as police, fire, and healthcare, must be made along with restoration of more normal functioning of the area affected. Early notification and clear lines of communication will be vital in controlling the situation.

MEDICAL TREATMENT OF CASUALTIES

For many people suffering from foodborne illness, the treatment is primarily supportive. With some diseases, the addition of appropriate antibiotics can be lifesaving or at least shorten the duration of the illness.

UNIQUE CONSIDERATIONS

The major difficulty in determining whether a food supply contamination has occurred will be the way patients present. Early on, many medical practitioners generally will see a few cases each of what appears to be viral gastroenteritis. Only if the healthcare community, food supply industry, and governmental agencies are communicating and ready to act will such an event be identified and addressed before serious health and economic consequences occur.

PITFALLS

- Failure to have a disaster plan in place that specifically details the steps to take in the event of a food supply contamination
- Failure to communicate among the healthcare community and boards of health regarding new trends in disease appearance
- Failure to protect the healthcare community and public safety agencies from being ravaged by an outbreak
- Failure to identify alternative means of feeding the population if the primary food supply is contaminated or unavailable
- Failure of legislators, at all levels, to be proactive in preventing and limiting the effects of an outbreak

CASE PRESENTATION

Bedford Falls is a fairly isolated town located on the coast of New England. Recently a group of people advocating an anarchistic form of government have begun moving into town and buying property. The locals are increasingly uneasy with the influx of newcomers. As their ranks swell, the newcomers begin asserting political power, with their members winning seats on governing boards and committees. Alarmed, the locals schedule a referendum that would effectively remove the newcomers from these positions of authority. A bitter, often acrimonious debate between the groups ignites. One week before the vote on the referendum, many of the longtime residents present to the local emergency department (ED) and physicians' offices complaining of vomiting, diarrhea, and abdominal pain. The director at the local ED, remembering a *Salmonella* outbreak in the past decade under similar circumstances, becomes suspicious. When multiple stool cultures from those affected return as being positive for *Salmonella*, the ED director contacts the local authorities and board of health. The police chief immediately arrests the newly elected selectman, the representative of the school board, and other members of the anarchist group, charging them with deliberate food poisoning intended to influence the upcoming vote. The head of the board of health contacts the state and the Centers for Disease Control and Prevention for assistance. By the time help arrives, 25 local residents have fallen ill, virtually all of them longtime residents opposing the new group. Prompt attention to medical care for those who are ill is instituted, and a full investigation is commenced. Investigators quickly determine that all those who have fallen ill ate at the same restaurant, catering mainly to locals and infrequently visited by members of the anarchist group. All of the ill patients had consumed the same batch of egg salad. Examination of the restaurant's food processing areas reveals multiple positive cultures for *Salmonella* species indistinguishable from those infecting the victims. Further investigation reveals, however, that the egg salad in question was inadvertently left outside the refrigerator for 24 hours before being mixed with fresh egg salad served to the restaurant's patrons. Fortunately, all the victims recover after 5 to 7 days without serious sequelae. The police chief releases the suspects and alerts the town's attorney that she may expect multiple legal cases from the incident. The referendum vote proceeds as scheduled.

Mass Gatherings

Katharyn E. Kennedy

DESCRIPTION OF EVENT

Mass gatherings may be defined as events with a large number of individuals gathered together in a specific place for a specific purpose.¹ Thousands of such events take place worldwide each year. In the United States, 5.5 million attend the National Association for Stock Car Auto Racing (NASCAR) events. As many as 65 million attend National Basketball Association (NBA), National Football League (NFL), and/or National Collegiate Athletic Association (NCAA) events. Other such gatherings include leisure events (fairs, sporting events, and concerts), religious festivals, parades, demonstrations, and public disorder. Medical care of some sort has been provided for such gatherings for the last 30 years in both the United States and Europe. Event organizers everywhere need to take responsibility for the safety and well-being of the participants at an event.

Various numbers have been used to define a mass gathering—groups greater than 1000 have been used,² although many researchers use numbers greater than 25,000.³ Considerable variation exists in the type of medical care provided to both participants and spectators at these gatherings. General standards have been proposed for the provision of primary care, emergency and disaster care, and evacuation. Both the American College of Emergency Physicians (ACEP)⁴ and the National Association of Emergency Medical Service Physicians (NAEMSP)⁵ have addressed the previous lack of guidelines and standardized care. A survey in 1998⁶ showed that only six U.S. states provided regulatory guidance for the provision of care at mass gatherings, although many are starting to address this omission.

A number of disasters have occurred at gatherings throughout the world, in particular at soccer events (Table 187-1). Terrorist threats have also become an unfortunate reality, as shown by the bombing at Centennial Park during the 1996 Olympics in Atlanta, Ga.

PREINCIDENT ACTIONS

Mass Gatherings Overall

At organized mass gatherings, predictable medical problems and an unpredictable wide variation in medical care

exist worldwide. Preplanning and prediction of resource requirements, based on careful needs assessment of anticipated medical care usage and public health risks, may lead to a standardized optimal provision of medical care (Box 187-1).⁷

Provision of medical care is the responsibility of the event planners. Public health officials need to be involved early in the planning process, especially for large events, such as the Olympics, world fairs, and pilgrimages. The local health department should be involved in the overseeing of the preparation, storage, and serving of food and sanitation requirements. Once identified, those providing medical care at mass gatherings need to liaise with local emergency medical services (EMS), fire, and law enforcement officials. Ground and building plans, close estimates of possible attendance, and identification of any specific hazards should be shared among these providers. Estimates of attendance may be gleaned from advanced ticket sales or from attendance at previous similar events. However, previous history is notoriously unreliable, as demonstrated at the papal mass in Denver (1993) where 250,000 were predicted but 500,000 turned up. Ticket sales on the day of play may have contributed to crowds rushing into soccer stadiums just before kick-off in both England in 1989 and Africa in 2001, with disastrous consequences (see Box 187-1).

The type of medical care to be provided at the event needs to be considered beforehand (Table 187-2).⁸⁻¹² Primary medical care, such as first aid, emergency care, and preparation for a possible disaster, should be addressed. Staffing levels and type of staffing also need to be anticipated. Recommended ratios include 1 to 2 physicians per 50,000 attendees, 2 paramedics or 1 paramedic and 1 emergency medical technician per 10,000 attendees, and 1 basic first-aid provider per 1000 participants at the event.¹³ On-site physicians have been shown to reduce ambulance transfers to local hospitals by as much as 89%,¹⁴ significantly lessening the impact of an event on local EMS services and hospitals. Physician presence should be strongly encouraged at events where significant trauma may occur, where there is a long distance to definitive care, or to enhance an anticipated disaster response. Multiple variables interact to make planning for a mass gathering event challenging. An understanding of these may allow for a more efficient

TABLE 187-1 MAJOR SOCCER DISASTERS

	DATE	DISASTER
1985	May 11	Bradford, England: 56 burned to death, 200 injured due to a fire at Bradford soccer stadium.
	May 26	Mexico City, Mexico: 10 trampled to death and 29 injured forcing their way into a match.
	May 29	Brussels, Belgium: British soccer fans attack rival Italian supporters at Heysel Stadium. A concrete retaining wall collapses, resulting in 39 deaths and more than 400 injured.
1988	March 12	Katmandu, Nepal: 80 fans seeking shelter during a violent hailstorm are trampled to death.
1989	April 15	Sheffield, England: 96 died at Hillsborough Stadium. Many are crushed to death when a barrier collapses on an overcrowded area.
1992	May 5	Bastia, Corsica: 17 killed when grandstand collapses.
1996	October 16	Guatemala City: 84 killed and 147 injured by stampeding fans at Mateo Flores National Stadium.
2001	April 11	Johannesburg, S. Africa: 43 die, 250 injured at Ellis Park Stadium due to crush as crowds push into an already overcrowded stadium.
	May 9	Accra, Ghana: More than 120 killed in a stampede at a soccer match.

BOX 187-1 REQUIREMENTS FOR MEDICAL CARE AT MASS GATHERINGS

- Identification of those providing care
- Physician medical oversight
- Identification of level of care needed, personnel to provide care, and appropriate equipment needs
- Public health issues
- Treatment facilities and access to care
- Transportation of injured
- Emergency medical aspects
- Communication
- Command and control
- Documentation

Adapted from data from NAEMSP.

and effective planning process. However, the unexpected can be expected.

Environmental factors play a role in anticipating medical usage at events. Heat-related illnesses are a factor in outdoor concerts, papal visits, and political demonstrations. Thirty-one percent of physician encounters recorded at the 1996 California AIDS ride were for heat-related problems.¹⁵ The Denver papal visit resulted in an unanticipated 21,000 patient encounters at a mainly youthful gathering, due in part to the 14-mile walk and high temperatures.³ Preplanning in the form of educational packages that addressed measures to prevent heat-related illnesses given to those who purchased advance tickets for the Atlanta Olympics in 1996 might have led to a decrease in the number of patient encounters for this problem despite the high heat and humidity.¹⁶ Cold weather events generally lead to lower medical usage rates by participants and spectators.¹⁷

Alcohol and illicit drug usage may increase the number of patient encounters. Historically, the consumption rate of alcohol and drugs may be higher at music festivals, rock concerts, and raves. Open-air music events in the

United Kingdom have resulted in a primary diagnosis of alcohol intoxication in 4% of patient encounters.¹⁸ Banning the consumption of alcohol at Wembley Stadium led to a 50% reduction in alcohol-related problems.

Anticipating medical usage rates may allow for more appropriate staffing levels. However, a wide variation in usage rates has been reported. One study has shown that the overall medical usage rate decreases with overall crowd size. Patient encounters at events with more than 1 million participants average 10 per 10,000 patient encounters. Events with lower numbers average 41 per 10,000 spectators.¹ The medical usage rate can vary even within an event itself. At the Los Angeles Olympics, soccer events had usage rates of 68 per 1000 and rowing and canoeing 6.8 per 1000. Other variables to consider include ages of attendees; event duration and time of occurrence; mobile versus stationary event; event type; presence of fireworks, torches, or bonfires; outdoor versus indoor event; and the physical plant and location. Attendance at “on-off” events can be very difficult to estimate, and advance ticket sales can help considerably.

Anticipated crowd demographics may be useful in the preplanning stage. Older groups may be expected at papal visits, classical music concerts, and large sporting events.¹⁹ Younger age groups frequently attend rock concerts and auto-racing events.²⁰ The needs of children also must be considered. Most children present with minor injuries, but medical teams need to be prepared to deal with serious medical emergencies and trauma. Overall medical usage at a children’s fair was 19.2/10,000, and one-half of those who presented were younger than 14 years old. Protocols need to be in place for the provision of care to minors who present without an accompanying adult.¹¹ Crowd “mood” is an unpredictable variable. Certain types of music, known team rivalry, and religious furor may lead to disruptive behavior and an increase in medical usage rates. Crowded events may lead to a “too-close-for-comfort” feel among event-goers. Environmental conditions,

TABLE 187-2 ANTICIPATING MEDICAL NEEDS AT MASS GATHERINGS

TYPE OF EVENT	INJURIES TO BE EXPECTED
Political events:	Minor and major trauma
Religious events:	Minor injuries, heat-related problems, cardiac problems
Sports/musical events:	Drug/alcohol use, minor trauma
Sporting events:	Minor trauma, heat-related problems, and cardiac issues
Auto racing:	Severe trauma, heat- and alcohol-related problems

such as inclement weather, squalid conditions, poor sanitation, and lack of access to drinking water, may lead to ugly crowd dynamics.

Despite the many variables to be considered, it has been shown that event type and temperatures are the variables that best predict medical usage rates.^{1,9,21}

After the anticipated usage rates and staffing levels have been addressed, the positioning, number, and type of aid stations should be considered. Fixed events at stadiums may have areas specially designed and designated for medical care. For other events, aid station locations should be no more than a 5-minute walk for attendees. Stations should be clearly visible, and the locations should be known to participants and other event personnel. These areas need to be adequately and appropriately staffed before the anticipated start of the event and remain so until the event is completed. Consideration needs to be given to providing medical care in the crowd for occurrences such as cardiac arrests or lower extremity fractures, including how to transport these patients back to aid stations. Thought needs to be given regarding provision of ambulances for hospital transport and access and egress for these vehicles. The organizers of medical care need to know the capabilities of local hospitals and should liaise with hospital personnel before the event. Attention to the location, staffing, and communication needs of a medical command center should be addressed. Communication needs should be considered for event medical providers; other event planners; and local EMS, police, and fire personnel. Back-up communication in the form of handheld devices or cell phones should be decided on, and medical personnel must be able to connect with local dispatch centers.

An incident command structure for medical personnel may be used. The event medical officer oversees all aspects of medical care provided at the site. The event triage officer conducts and directs medical assessment of casualties at designated treatment areas or while roving through the crowds and transporting patients to a central area. The event treatment officer oversees treatment to the sick and injured. The event transport officer directs transport to other facilities, and the logistics officer provides the necessary support for EMS at the event. Consideration may be given to the need for hazardous materials teams, decontamination, wilderness medicine, or use of amateur radio groups.

All patient encounters should be documented. Use of NCR (noncarbon record) paper will facilitate a copy accompanying a patient who needs transport to a medical facility. Records are needed for medical and legal reasons and also may be useful for research purposes.

Concerts/Sports Gatherings

The medical usage rate may vary by type of music, with rhythm/blues having rates of 1.3/10,000 and gospel/Christian 12.6/10,000. The overall median usage for concerts is 2.1/10,000.¹⁹ Rock concerts typically have rates 2.5 times that of other concerts. The anticipated audience participation in “moshing,” crowd surfing, and stage diving may lead to a dramatic increase in medical incidents.²² Other problems encountered include minor trauma and ethanol or illicit drug intoxication.²³

Surgical problems may be caused by falls; assaults; being crushed against barriers; and assorted “missiles” causing head injuries. Severe trauma may occur in up to 1.4% of attendees at rock concerts. Medical issues include headache, syncope, asthma, and hypoglycemia. Cardiac arrest is uncommon, with a rate of 0.01 to 0.04/10,000. Asthma may be very common at rodeos.²⁴

The ultimate sporting event is probably the Olympics. Planning for the medical care of both spectators and participants begins as soon as the host city has been announced. Apart from routine medical care, there exists a potential for transmission of infectious diseases, risk of injury from crowd crushes, and now the very real risk of terrorist activity or political protests. Extensive planning at local, state, and federal levels is vital to ensure the health and safety of all concerned.²⁵⁻²⁷ At the 1996 Atlanta games, specialized incident assessment teams were set up to analyze terrorist risks and to address issues such as stockpiling antibiotics and antidotes. Medical providers of all levels received training in awareness of chemical, biologic, and radiologic weapons.²⁸ Local hospitals were updated to include mass decontamination units. Local EMS providers were given uniform operational plans and procedures, enhanced communications were agreed on, protocols were developed for the management of heat-related illnesses, and guidelines for response to mass casualties were issued. Public health initiatives to address heat-related illnesses included a media campaign; packets sent to ticket purchasers; shelters; and provision of water, wide-brimmed hats, sunscreen, and water misters at the most crowded sites. These, plus the cooler-than-normal temperatures, may have led to a decrease in the expected number of hyperthermia victims.

Marathons

More than 300 marathons are staged each year, along with countless half marathons, triathlons, and 5K or 10K events. Preincident considerations include course layout, number of runners, climate, and medical team experience. Earlier start times and the addition of half marathons have led to a decreased risk of injury.^{29,30} Encouraging runners to seek help early has also reduced

serious medical problems.³¹ Educating runners before the event on issues such as dehydration, low blood sugar, exhaustion, blisters, the importance of good preparation and training, and the use of energy drinks may lessen the need for medical intervention. Runners with a history of asthma are encouraged to carry their inhalers and not to run if they feel ill. Accessible, visible first-aid stations along the route, use of mobile paramedic teams, and a medical control center should provide adequate medical coverage. Radio communication is essential between medical providers, and a treatment tent at the finish line should include paramedic/triage teams, massage therapists, and podiatrists. The use of computer tracking chips may be used to identify how many runners use medical treatment and help in the planning of the provision of care and supplies in the future.

Pilgrimages

Millions of people perform pilgrimages every year. The Muslim pilgrimage, the Haji, to the Holy Land of Makkah (Mecca) in Saudi Arabia may have up to 2.5 million participants from 140 countries for a period of 5 to 7 days. The pilgrimage involves a 24-mile round trip from Makkah through the plains of Arafat. Many of the pilgrims are elderly, come from poor countries, live in tents in extreme conditions, and perform physically exhausting religious rituals. In India, millions of pilgrims visit Lord Ayyappa at Sabarimala each year. This occurs over a 41-day period and involves a 90-minute trek uphill to the temple. Many other pilgrimages on a smaller scale take place throughout the world.

Several of the problems encountered may be anticipated. Many of the participants are not in good health and may have chronic medical problems. Heat exhaustion is common during the hot cycle of the Haji. Cases of heat stroke doubled from 1980 to 1981. This may be overcome by the education of pilgrims before and during the event. Infectious disease outbreaks are also common. These include meningococcal meningitis; gastroenteritis; hepatitis A, B, and C; and various zoonotic diseases. The implementation of vaccination policies, infection control policies, and public health initiatives are proving successful in addressing these problems.³² Pilgrims need proof of appropriate vaccinations to obtain a visa for travel to Saudi Arabia. Face mask use is encouraged to reduce the spread of respiratory infections. Head shaving by men, at completion of the pilgrimage, has been associated with the transmission of bloodborne diseases as illegal barbers reuse razors several times. The ritualistic slaughter of thousands of sheep during the ending ceremony may lead to outbreaks of Rift Valley fever. This has led to the banning of importation of sheep from countries where this fever is endemic. There is strict surveillance and supervision of accredited slaughterhouses.

Free medical care is provided at the holy site in Makkah. In 1997 and 1998 a "treat and release" program was commenced, leading to a 73% reduction in ambulance transports.³³ In India at Sabarimala, a medical center is provided at the site. Typically 8000 pilgrims receive medical care over the 41-day period.

POSTINCIDENT ACTIONS

In the wake of various disasters at mass gatherings, it is vital to learn from previous mistakes. The European Convention on Spectator Violence and Misbehavior met in 1985 to address issues rising largely from the Heysel Stadium disaster. It identified the need for police and sports authorities to cooperate in ensuring segregation of rival supporters, controlling access to stadiums, and banning the consumption of alcohol. After the 1989 Hillsborough disaster in England, the Gibson Report recommended medical care at stadiums for the first time. All-seats stadiums were to be phased in, leading to safer stadiums with greater attendance.

The Boston Marathon has instituted a postevent clinic that is open for 3 days after the event to meet the delayed medical needs of runners.

MEDICAL TREATMENT OF CASUALTIES

In general, most participants require minor medical interventions that may be addressed by first responders or paramedics.⁸ Paramedics may use triage protocols to identify casualties who should be transported to a hospital after initial stabilization rather than waiting for treatment by an on-site physician.³⁴

At rock concerts, 1.4% of attendees may experience *severe* trauma. Minor trauma results from falls, assaults, being crushed against barriers, and head injuries from assorted "missiles." Anticipated medical problems include headaches, syncope, hyperventilation, asthma, epilepsy, and hypoglycemia. At the Atlanta Olympics, most of the injuries compromised sprains or strains (13%) and contusion abrasions (7%). Bronchitis was common (9%), and heat cramps/dehydration accounted for 7% of those seeking medical care.²⁶ In addition, three cardiac arrests were reported; the provision of defibrillators at mass gatherings is an important consideration.³⁵

Hyponatremia is increasingly prevalent among marathon runners. It is defined as a serum sodium level of less than 136 mmol/L and is commonly caused by overhydration. Mild cases may be treated by fluid restriction and consumption of salty foods until urination resumes. In moderate cases the patient's sodium level may need to be checked hourly and, in critical cases, intravenous access will be required and diuretics and 3% saline may be administered. Complications such as seizures, pulmonary edema, and coma should be treated appropriately. Runners should be encouraged to replace only 16 ounces of fluid along with salt for every pound of weight lost. Exercise-associated collapse may occur at the finish due to venous pooling. This may be treated by laying the patient supine with the legs elevated and rehydrating with oral electrolyte/carbohydrate solution. Dehydration should be assessed clinically and treated with oral fluids. Heat-related illnesses are addressed in the usual fashion. Hypoglycemia is treated with oral or intravenous glucose replacement.

Many pilgrims are in poor health before the event and may need more than minor first aid. Many suffer from heat-related illnesses or infectious diseases. Provision of free medical care and on-site medical facilities with capabilities of providing even an intensive care unit level of care may meet these needs.

Disasters do occur at mass gatherings, and appropriate medical care needs to be available. Frequently, the cause of death is traumatic asphyxia,³⁶ for which rapid interventions may make a difference.

UNIQUE CONSIDERATIONS

Every mass gathering should be considered a unique event. Careful and exhaustive preplanning may reap many benefits. It is important for those providing medical care at the event not to do so in a vacuum. Local EMS providers may well be needed and certainly will be required if a mass casualty event occurs. Mass gatherings occurring in urban settings will have different characteristics and requirements from those in more rural or remote settings. Even though it may be difficult to predict all the medical needs of the crowd, prior studies have started to use a more scientific approach to addressing these needs. Event type, duration, expected attendance, and weather conditions need to be taken into careful consideration in the planning process.

PITFALLS

- Lack of legislation regulating minimum standards for provision of medical care at mass gatherings
- Lack of a coordinated, integrated preplanning process
- Lack of funding to provide needed public health initiatives and medical resources
- Failure to identify a medical director for the event
- Failure to learn from previous experiences
- Underestimating expected attendance
- Failure to consider all variables, such as crowd size, demographics, event duration, and environmental factors

CASE PRESENTATION

Always eager for a challenge, many months previously you accepted the position of medical director to oversee medical care at a large open-air concert to be held in your city to celebrate its 250th anniversary. Fifty thousand spectators are anticipated based on advance sales. You have spent many hours in meetings with all the key players arranging appropriate medical care for this event. On the morning of the event, the temperature has already risen 10 degrees above average and the humidity is climbing. An hour into the event, it becomes apparent that many people have forged tickets, and the crowd is now estimated at 75,000. Shortly before the much anticipated heavy metal band is due to play, you receive a call on your radio that the crowd is getting unruly in the mosh pit, and your paramedics are concerned that people will be crushed....

- Failure to consider and prepare for a terrorist or mass casualty event
- Inability to allow capacity crowd ingress to a stadium in a 1-hour period
- Failure to consider ambulance access and egress at an event
- Lack of training of security personnel, leading to failure to recognize and control potentially dangerous situations

Ecological Terrorism*

George A. Alexander

DESCRIPTION OF EVENT

Ecological terrorism or *ecoterrorism* may be defined as the use of force directed at the environment or ecosystem to terrorize, frighten, coerce, or intimidate governments or societies.¹ The scenario of a terrorist or rogue nation group using nuclear, radiologic, biologic, or chemical agents or weapons as a means of ecoterrorism is plausible. Radiologic agents can be obtained readily through legal and illegal means. Chemical and biologic agents are easy and cheap to develop and use. In addition to the devastating human effects of such agents, they can have destructive environmental consequences. For these reasons, global terrorists are more likely to resort to ecological terrorism.

Ecological terrorism may occur as a result of sabotage or attack on commercial nuclear power reactors, spent fuel storage depots, or nuclear fuel reprocessing facilities. There are 107 nuclear power plants in the United States and more than 429 nuclear power plants worldwide.²

The 1986 Chernobyl nuclear power plant accident in the former Soviet Union serves as a harsh reminder of potential scenarios in which terrorists could engage in ecological terrorism by trying to release radioactive nuclear materials into the environment. As a result of the Chernobyl accident, 28 people died acutely from radiation exposure, 134 patients suffered from acute radiation syndrome, hundreds of thousands of people were evacuated, and almost as many people were involved in the cleanup efforts.³ The extensive atmospheric fallout caused considerable concern far from the accident site. Within 10 days after the accident, elevated levels of radioactivity were reported from Israel, Kuwait, Turkey, Japan, China, the United States, and Canada.⁴ In addition, radioactive fallout contaminated large forested areas in Europe.⁵

A large radiologic dispersal device (RDD) also has the potential to contaminate the environment or ecosystems. The environmental hazards from dispersal of highly radioactive fuel in a large RDD would be similar to

that which occurred at Chernobyl, but on a smaller scale.⁶ Radioactive gases, liquids, and particulates would cause considerable environmental contamination. The areas of risk from radioactive contamination can extend many miles away from the explosion site.

Biologic pathogens may be used to perpetrate ecological terrorism. For example, *Bacillus anthracis*, the organism that causes anthrax, is very stable because of its ability to sporulate. This characteristic makes it attractive for terrorists to use anthrax spores to contaminate the environment. Dormant spores are known to have survived in some archaeological sites for perhaps hundreds of years.⁷ An aerosol release of anthrax spores in parks, playgrounds, or sports fields using a portable crop duster sprayer would contaminate these areas and may infect unsuspecting people who come in contact with the spores. A public acknowledgment of such a release by a terrorist group would cause widespread distress, panic, and fear.

During the Gulf War of 1990, the Iraqis deliberately released oil from Kuwaiti oil fields with the intention of polluting and contaminating Saudi Arabian waters and coastlines. These acts were tantamount to ecological terrorism.¹ Approximately 400 miles of Persian Gulf shoreline were contaminated with oil.⁸ The environmental consequences of these oil spills will adversely affect these shorelines and coastal waters for years to come. Similar acts of oil dispersal on land resulted in much larger oil-polluted areas in Kuwait.

The burning of Kuwaiti oil fields by the Iraqis was another form of ecological terrorism. More than 700 oil wells in Kuwait burned for about 10 months.⁹ These fires consumed up to 6 million barrels of oil per day and engulfed the entire region with massive clouds of smoke.¹⁰ These acts of ecological terrorism resulted in a level of environmental pollution exceeding that of any other previous manmade disaster.¹¹ The long-term environmental impact of this ecological catastrophe is unknown.¹²

The estimated deaths of more than 10,000 people and morbidity of approximately 200,000 persons from the accidental release of methyl isocyanate in Bhopal, India, in 1984¹³ serve as a bleak reminder of potential scenarios in which terrorists could engage in ecological terrorism by attempting to release toxic industrial chemicals into the environment.¹ Unlimited possibilities of threats

*The views expressed in this chapter are those of the author and do not necessarily represent the official policy or position of the National Cancer Institute, the National Institutes of Health, or the Department of Health and Human Services.

exist from chemical ecoterrorism. An estimated 70,000 chemicals are used commonly worldwide, and an additional 200 to 1000 new synthetic chemicals are marketed by the chemical industry each year.⁹

PREINCIDENT ACTIONS

The first challenge for medical and public health providers in preparing for ecological terrorism is to make an assessment of potential environmental targets and ecological threats from nuclear, radiologic, biologic, and chemical agents. Medical response plans for a variety of likely targets should be developed. These should contain descriptions of the types of possible ecological terrorism, including the identification of anticipated hazards and the response actions that can be taken to minimize them. The medical resources needed for each threat situation and a plan for augmenting those resources should be specified. Consultation should be sought with specialists who have experience in the management of terrorist threats. Management response plans should be scenario-based according to the particular type or category of agent. Planning should be coordinated with local and state hazardous material response teams and medical and environmental laboratories.

POSTINCIDENT ACTIONS

Awareness of ecological terrorism is the second challenge and should focus on recognizing that an act of terrorism has occurred. Early detection of an ecological hazard should be the goal to prevent or reduce adverse human and environmental health risks. Any assessment of potential hazards or risks from chemical or radiologic exposures should consider not only the innate toxicity of the substance, but also the nature of the exposure. Once aware of the threat, executing a credible medical response to any attack is the third challenge. An ecological risk assessment should be performed to estimate the probability that untenable ecological health effects may occur in populations as a result of exposure to a specified hazard. The basic elements of an ecological risk assessment should include defining the problem, obtaining the necessary information/data, assessing the hazard potential, assessing the exposure potential, integrating the hazard and exposure assessment (risk characterization), and summarizing and presenting the results.¹⁴

MEDICAL TREATMENT OF CASUALTIES

Management of specific human injuries associated with various forms of ecological terrorism is beyond the scope of this chapter and is readily available elsewhere in this book. An intentional release of nuclear, radiologic, biologic, or chemical agents or weapons into the environment has the potential to cause a major public health disaster. Such incidents pose special features that require specific considerations by emergency respon-

ders. A latent period may occur between release of the agent and the development of symptoms associated with illness. Symptoms of acute disease may be seen within minutes or hours, whereas chronic exposure can be insidious and continue undetected until large numbers of people develop catastrophic illness. Several months may pass without people knowing they have been exposed and are at risk. The long-term effects of these exposures may be the most important consideration, particularly if there are no acute effects.¹⁵

The clinico-pathologic effects of the terrorist weapons previously mentioned are well known. Certain syndromes with specific symptomatology may arise as the focus of a known or suspected incident. Acute radiation syndrome is associated with nuclear or radiologic incidents. Specific biologic syndromes are associated with a variety of infectious disease agents. Chemical syndromes also exist for numerous toxic chemical agents.

UNIQUE CONSIDERATIONS

As already indicated, the medical, public health, and environmental consequences of ecological terrorism require specialized considerations. Emergency responders and healthcare providers should apply similar medical and public health management principles regardless of the ecological threat. Exposure to pollutants from ecological terrorism may or may not result in acute illness requiring the treatment of large numbers of people. In fact, after exposure to any terrorist ecological hazard, people may present with nonspecific symptoms such as headache, fatigue, skin rashes, fever, eye and respiratory irritation, gastrointestinal problems, tiredness, and poor concentration.

Depending on the agent involved, evacuation from the scene of a terrorist toxic release contaminating the environment may need to be made immediately after the release. Unfortunately, the information needed to fully evaluate the risk and on which to base an evacuation decision may not be available. In this situation, a health risk assessment should be considered to help decide whether evacuation is necessary immediately after the terrorist release or to predict long-term health consequences. The health risk assessment includes hazard identification, dose-response assessment, exposure assessment, and risk characterization.¹

PITFALLS

Obstacles to the provision of optimal medical and public health management include the following:

- Lack of adequate preparedness, emergency response, and recovery planning for possible ecological terrorist attacks before they occur
- Lack of coordination with local and state medical, public health, and environmental response agencies
- Lack of consultation with health professionals who have expertise to manage specific types of ecological terrorism

- Lack of recognition that reporting of nonspecific symptoms among an affected population may be associated with various forms of ecological terrorism
- Lack of involvement of behavioral and social health professionals to address the psychosocial consequences of ecological terrorism

CASE PRESENTATION

While walking past a television in your emergency department, you see a news alert that a series of explosions occurred about 20 minutes ago at a nuclear power plant located 5 miles south of your 120-bed community hospital. An aerial view from a news helicopter shows a fire involving the containment structure with a gigantic plume that is reported to be moving horizontally in a northeast direction toward a populated city 10 miles away. More than 500 workers were on-site at the time of the explosion. Hundreds of additional personnel have been called in for rescue, plant control, and firefighting operations. An anonymous caller has just contacted the local newspaper and is reported to have said that the power plant explosion was no accident. The plant was sabotaged to pollute the air, land, and waters of America. The governor of your great agricultural state declares a state of emergency and appeals to the public to remain calm. One hour later, three patients with serious trauma injuries, including thermal burns, are brought to the hospital by ambulance. After another 30 minutes, five rescue workers arrive complaining of nausea and vomiting.

Computer and Electronic Terrorism and EMS

M. Kathleen Stewart and Charles Stewart

DESCRIPTION OF EVENT

Every machine connected to the Internet is potentially a printing press, a broadcasting station, and a place of assembly. With the advent of the Internet, a terrorist group can disseminate its information undiluted by the media and untouched by government censors.¹ It should come as no surprise, then, that these same terrorists have used the Internet to spread instructions, propaganda, and plans for both devices such as improvised explosives and attacks. This use of computers for terrorism is both real and a true threat to societies.²

Unfortunately, actual terrorist use of computers, networks, information architectures, and the Internet has been largely ignored by the media in favor of a headline-grabbing “cyber attack” or “cyberterrorism.” The reality of our weaknesses and vulnerabilities is both more chilling and far less reassuring.

Three major venues of attack that would affect emergency medical services (EMS) are a “viral” attack, a denial of service attack, and a “social engineering” attack to retrieve secure or restricted data for nefarious purposes.

Viruses/Worms

Malignant computer programs are often called *viruses* because they share some of the traits of biologic viruses. The computer virus requires a functioning “host machine” to replicate, works only with the proper “host,” and passes from computer to computer like a biologic virus passes from person to person.

There are other similarities. A biologic virus is a fragment of deoxyribonucleic acid (DNA) inside a protective jacket. A computer virus must piggyback on top of another program, document, or e-mail to get into the computer, and it often must disguise itself from antiviral software with a surrounding innocuous package, like its biologic counterpart.

People create computer viruses. A person has to write the code for the virus and test it to make sure that it functions as intended and spreads as designed.

A computer that has an active copy of a virus is considered *infected*. The way that the virus is activated

depends on the design (coding) of the virus. Some viruses become active if the user simply opens an infected document. Others require specific actions on the part of the user.

Traditional computer viruses were first noted in the 1980s. During that decade, computers were not only found in large centralized areas, but also small businesses and homes because of the availability of small computers—the advent of the personal computer, or PC. The first viruses were “Trojan horse” viruses. A *Trojan horse* is a malignant computer program that claims to do one thing (often a game or a utility) but actually does something else instead, such as erase your disk. A Trojan horse program has no way to replicate automatically.

Another early virus was the *boot sector virus*. The boot sector is a small program that initializes the computer and the process of loading the operating system, thus “booting” it into the memory. By putting code in the boot sector, the virus guarantees that it will be loaded into memory immediately and will be able to run whenever the computer is on.

Modern viruses are much more insidious in their invasions. Attachments that come as word files (.doc), spreadsheets (.xls), and images (.gif and .jpg) can contain viral attachments. Even opening a contaminated Web site may download a viral program. A file with an extension such as .exe, .com, or .vbs is executable and can do any damage the designer wants. Many viruses disguise themselves by doubling the suffix of the program name, such as stuff.gif.vbs.

Once the virus is active on the computer, it can copy itself to files, disks, and programs as they are used by the computer, whether automatically or by the computer user. The big difference between a computer virus and other programs is that the computer virus is specifically designed to make a copy of itself. When the viral programs are executed, the virus examines the hard drives to see whether there is a susceptible program on the disk. If found, the virus adds the viral code to the program or replaces the program or file with its own code. The virus has now reproduced itself so that two or more programs are infected. Every time the user runs any infected program, the virus has the chance to reproduce

by attaching to other programs, and the cycle continues. This replication often occurs without the knowledge of the computer user (sometimes the programs infected are system programs that the user doesn't control).

A virus often contains a "payload," or an additional program that the virus will carry out in addition to replicating itself. Payloads vary from trivially annoying to destructive. Some nondestructive and nontrivial payloads include logging programs that record every keystroke typed in, programs that automatically send e-mail to every address in the computer, and programs that open portals for strangers to examine and use your computer. If the payload is well designed, the user may not even be aware that the computer is infected. Public machines, nonsecure business or official machines, and some secure systems can be used as remote intelligence gathering devices. Locating the offending program is often difficult because many of the keylogging programs are titled or disguised as necessary system files or folders.

A *worm* is simply a virus that has the ability to copy itself from machine to machine. A copy of the worm looks around and infects other machines with the same security defect through any available computer network. Using the networks and the Internet, worms can infect other machines incredibly quickly.

Modern computer viruses can be found in programs available on floppy disks, CDs, and DVDs; can be hidden in multiple kinds of e-mail attachments; and can be found in material that is downloaded from the Internet.^{3,4}

Examples of Recent Destructive Viruses/Worms

Code Red (now with multiple variants) first appeared in July 2001 and ultimately infected more than 300,000 computers in the United States.⁵ The worm exploited a security opening in Microsoft's IIS Web servers. No one knows where this worm originated or by whom it was written. The worm was time sensitive, based on dates. From days 1 to 19 of the month, the worm would propagate. From days 20 to 27, it would launch a denial of service attack against a particular site. From the 27th through the end of the month, the worm would "sleep" in the computer.⁶ Some variants have opened covert access ports (back doors) in operating systems that allow other intrusions.

The concept of the covert access port (back door) is important. These covert ports of entry allow a malicious programmer remote access and even control of programs running on the affected computer. The access may be gained by contaminating programs with a virus, as part of the "remote help" services in some operating systems or by being built into a program by the designer or a programmer (either disgruntled or operating under instructions).

Even though Microsoft provided a patch for Code Red, many system administrators did not obtain or apply the patch to their systems. These unprotected computers remain vulnerable to this virus.

The newer intrusions using similar exploits may have a more malignant purpose:

For example, the *Nimda* worm appeared 1 week after the Sept. 11, 2001, terrorist attacks on the United States

and targeted the financial sector.⁷ A more "intelligent" worm, *Nimda* could replicate itself in several ways: by infecting e-mail programs, by copying itself onto the computer servers, or by affecting users who downloaded infected pages from the infected Web servers. The *Nimda* affected millions of computers and brought the Internet to a crawl. The *Nimda* worm replicated itself much faster than the Code Red worm did and caused billions of dollars in damage.⁸

The *Slammer* worm, or *Sapphire* worm as it is also known, surfaced Jan. 25, 2003, on Super Bowl weekend.⁹ The *Slammer* exploited a vulnerability in the servers delivering Web pages to users. It was the fastest cyber attack in history. The number of *Slammer* infections doubled every 8.5 seconds, and the *Slammer* did more than 90% of its damage in the first 10 minutes of its release. *Slammer* incapacitated parts of the Internet in Korea and Japan; disrupted phone service in Finland; and markedly slowed airline reservation systems, credit card networks, and ATM machines in the United States.⁸

Slammer could have been much more destructive had it been properly programmed. When the next "new, improved *Slammer*" is released, it could do much more damage. It could even affect phone and other trunking communication systems (including some radio links) for a city or larger region of the country. Although control systems are unlikely to be directly damaged by an Internet virus like *Slammer*, the denial of service to control points for water distribution systems, railroad switch points, power grids, chemical plants, and telephone systems may cause widespread nondestructive failures. Since the "mapping" (remote identification) of the covert access points previously described, terrorists may well have targeted specific weak spots for harassment.

Any of the modern viruses/worms could be redesigned to destroy, or at least severely cripple, the 911 emergency response system in the United States. They could also cripple or destroy electrical power, transportation, and telecommunications systems, as well as disrupt water supplies and perhaps our defense systems.

Social Engineering Attacks

"Social engineering" is the exploitation of the "weakest link" in the security chain of an organization—the human.¹⁰ The aim is to trick people into revealing passwords or other information that compromises a target system's security. The infamous Kevin Mitnick, for example, conducted most of his corporate intrusions by using the telephone, relying on the gullibility and friendly helpfulness of real people to gain access to corporate networks.¹¹ Hackers may call an organization and pretend to be users who have lost their password or show up at a site and simply wait for someone to hold a door open for them.^{12,13}

Techniques to mitigate a social-engineering attack include the following:

- Activate caller ID at work. Match the name given by the caller with the number and extension.
- Set your organization's outbound caller ID to display only the front desk's phone number, not individual phone extensions.

- Implement an organizational call-back policy. If someone calls asking for information about the organization, say you'll call them back, then look up and dial the number or go through their company's switchboard operator.
- Be mindful of information posted in out-of-the-office messages.
- Never allow another person to piggyback his or her physical access into a secured room or facility on your security ID card—even if the person apparently has his or her own card.
- Confront strangers. Ask whether you can take them to someone's office or help escort them outside. If they balk, contact security.
- Get to know your information technology (IT) support staff.
- Never write down your network password on a sticky note or tape it to the bottom of your keyboard. "Crackers" (experts at finding and cracking passwords) know where to look.
- Beware of e-mail that asks for verification of your password. This is often a practice called "phishing" that solicits passwords for illicit use.
- Periodically perform a Google search on your organization and scrutinize whether sensitive information is available outside your organization's firewall.
- Institute a security alert system. Have anyone who receives a suspicious phone call report it to a simple e-mail address, something like securityalert@company.com. If someone calls saying he or she from IT and asks for your network password, say "no," hang up, and contact IT and security.

Denial of Service Attack

A denial of service (DoS) attack is not a virus but a method hackers use to prevent or deny legitimate users access to a computer or servers. The loss of service may be as simple as the inability of a particular network service to use e-mail or the loss of all network connectivity and services for every computer attached to the Internet in any way.

The most common DoS attack is simply to send more traffic to a network address than the programmers who planned its data buffers anticipated someone might send. The attacker may be aware that the target system has a weakness that can be exploited, or the attacker may simply try the attack in case it might work. For example, a terrorist creates a computer program that automatically calls 911. The 911 operator answers the telephone but discovers it is a prank call. If the program repeats this task continuously, it prevents legitimate customers from using 911 because the telephone line is busy. This is a denial of service.

Many DoS attack tools are also capable of executing a distributed DoS (DDoS) attack. For example, imagine the terrorist now plants his or her program onto many computers on the Internet and has them all call 911 at once. This would have a bigger impact because there would be more computers calling the 911 operators. It would also be more difficult to locate the attacker, since the program is not running from the attacker's com-

puter; the attacker is only controlling the computer that secretly had the program installed. This is a DDoS attack. A DoS attack can also destroy programming and files in a computer system.

In the worst case, an Internet-connected site can be forced to cease operation. If this is a critical control system, the organization will lose the use of the control functions that are connected to the Internet.

How Can Antivirus Software Help Against a DoS Attack?

Using a virus, the DoS attack tools can be secretly installed onto a large number of innocent computer systems. Systems that unknowingly have DoS attack tools installed are called *Zombie* agents, or *Drones*. These "Zombie" systems can be centrally managed by a hacker to initiate DoS attacks at targeted computers. Zombies are not the victims of the DoS attack, but they are used to perform the actual attack.

Antivirus software detects viruses that can inject the DoS agents, but it does not detect the DoS attacks. By extracting a pattern or a signature from known *Zombie* agents, antivirus products can detect malevolent software on the compromised system. Antivirus software may also detect when a hacker is secretly installing *Zombie* agents.¹⁴

It is difficult to trace the origin of the request packets in a DoS attack, especially if it is a DDoS attack. It is impossible to prevent all DoS attacks, but there are precautions server administrators can take to decrease the risk of being compromised by a DoS attack. These precautions are beyond the scope of this chapter. By keeping the antivirus software up-to-date and using good computing practices previously listed, the IT service can keep the system from becoming a *Zombie* and aiding a DoS attack.

PREINCIDENT ACTIONS

A significant protection is to install a commercial virus protection program on all computers and to update this virus protection frequently, almost "religiously." Set up a schedule to perform operating system updates and run a virus scan. If a virus is found, eliminate it.

Each virus is tailored for a specific operating system and/or program. If the computer is using a variation of Windows (e.g., Windows 98, 2000, or XP), then a virus tailored for Unix will *not* affect this computer. Likewise, if the computer uses Linux, a Windows virus will *not* affect the computer. Some viruses are built to exploit known weaknesses in popular programs. If Microsoft Outlook, for example, is the target of such a virus, then computer users who do *not* use Outlook as their e-mail program will not be troubled by the virus.

- Have the virus protection set to scan each document before it is opened.
- Don't open any file or attachment unless you were expecting that file from someone you know and trust. The file will execute as soon as it is open, and if it contains a harmful or destructive virus/worm, you have

just infected your system and anyone else you may e-mail.

- Don't use macros in application programs unless they come from a known source. Macros are common ways to introduce viruses into systems.
- Ensure that the system administrator has a solid backup plan that can rapidly restore the operating system and essential programs in an emergency. Make sure that he or she keeps these backup copies readily available and updated to reflect new operating system and program updates.
- Essential operating systems, such as dispatch centers, should have an expert evaluate their computers for the presence of covert back doors that allow other intrusions.
- Ensure that all available updates for the operating system have been applied and that security services within the operating system have been properly activated.

POSTINCIDENT ACTIONS

- Essential operating systems should require that known uninfected working copies of all necessary software be immediately available should a disruption occur. Trained personnel able to "revive" the computer system should be on-duty, in-house 24 hours a day every day for just this type of problem.
- Perhaps the most important action is to report any suspicious e-mail or unusual computer activity to the person in charge, the system administrator, or other designated person. Establish an on-call point-of-contact with your Internet service providers and appropriate law enforcement officials should you discover a launching of a cyber attack by either someone in your organization or an external operator. Attacks on the Web site of the city of Mountain View, Calif., were discovered by astute and observant local operators (described later in this chapter).

MEDICAL TREATMENT OF CASUALTIES

Direct medical casualties from a "cyber" attack would not be expected. The only direct casualties that would result would be those deprived of services due to an inability to dispatch emergency vehicles or to communicate with those vehicles. Medical care would consist of treatment of the underlying illness that originally prompted the call for help. In addition, some institutions use an Internet-based patient care and tracking system. In the event of an attack, these systems may be rendered inoperable or, worse, made to give inaccurate data. All medical facilities that rely on computer and Internet-based systems should have adequate backups in place.

UNIQUE CONSIDERATIONS

Our Internet-enabled (net-centric) society is easy prey for two reasons. First, the growing technologic sophistication

of terrorists includes not only weapons of mass destruction and casualties, but a growing use of computers. Secondly, our own economic and technologic systems have an increasing vulnerability to carefully timed attacks as we increase our dependence on computers to include those that are critical to safety.¹⁵

The entire critical infrastructure of the United States, including electrical power, telecommunications, health-care, transportation, water, and the Internet, is vulnerable to a cyber attack. Many control systems, communication systems, and dispatch systems are now connected to the Internet and thus potentially open to intrusion. This does not include the possible effects that a cyber attack could cause to the finance sector or national defense.

PITFALLS

- Do not use weak passwords, such as "admin," "administrator," or "password."
- Do not leave passwords on sticky notes or taped to computers or desks.
- Do not give out passwords in e-mail or on the phone—ever.
- Ensure that virus protection is updated frequently (set virus protection software to automatic updates for the most rapid protection).
- Do not use wireless networking for secure communications.

CASE PRESENTATION

During the summer of 2001, the IT coordinator for the Web site of the city of Mountain View, Calif., noticed a suspicious pattern of computer intrusions. During a subsequent Federal Bureau of Investigation probe, investigators found that several other U.S. city/municipal government computer sites had had the same intruders. These computer intrusions apparently originated from the Middle East and Southern Asia. The invaders were looking up information about the cities' utilities, government offices, and their *emergency systems*.⁶ This computer intrusion took on new importance when several computers were seized from Al-Qaeda operatives after the Sept. 11 attacks. Officials discovered a broad pattern of surveillance of U.S. infrastructure on these computers.⁸

VIP Care

Lynne B. Burnett

DESCRIPTION OF EVENT

Everyone is created equal. That famous sentiment expressed by Thomas Jefferson, a belief central to the American social and political systems, seemingly calls into question the need for a chapter concerning the care of VIPs—very important persons. Especially in the setting of a disaster, is it proper to deal with VIPs differently than other patients? A response in the affirmative or negative may be equally correct, the validity of each contingent on the specific situation being addressed.

Within the medical context, a *VIP* has been variously defined as any patient who can exert unusual influence on the treating staff,¹ and more broadly, as “anyone whose presence in the hospital, by virtue of fame, position, or claim on the public interest, may substantially disrupt the normal course of patient care.”² Included would be those with public, financial, or political influence, as well as individuals with unusual professional influence,¹ ranging from the president of the United States or another major political figure to the king of the Gypsies, a famous actor, a well-known sports figure, a chair of the hospital board,² and many others. Although it is true that any of the aforementioned persons could potentially disrupt the normal course of patient care in the everyday activities of a hospital, the degree to which they would have such an effect in a disaster would, in large part, be a function of the importance of their role within society.

PREINCIDENT ACTIONS

Healthcare organizations must have a disaster plan for incidents of a magnitude that can be expected to overwhelm the standard operating procedures of the emergency department and hospital. Such a document should include a written plan for treatment of VIP patients and should address, at minimum, the following²:

- Which hospital personnel are to be notified of a VIP’s impending arrival? In what sequence?
- What is the plan for security during the hospitalization of the VIP?
- Who decides whether a command center needs to be established? What will be the makeup of its staff? What is the function of the center?

- How will the press receive necessary information?
- What type of care will other patients receive?

If the VIP is a primary person protected by the U.S. Secret Service, and time so permits, an advance team will assess hospital capabilities, choosing one or more to receive the VIP, while also selecting travel routes that are safest and most secure.³ Advanced planning also entails working with local emergency medical services (EMS) systems, hospitals, and trauma centers on various “what if” scenarios to ensure preparation for the visit⁴; for example, if the president or vice president is to be more than 20 minutes from a trauma unit, capability for helicopter evacuation is a priority.

Decisions are made as to what doors, corridors, and elevators can and should be sealed and which areas can and should be evacuated, if such becomes necessary. If possible, one elevator is selected for movement of the VIP and, following an electronic sweep, continuously guarded. Clinical condition permitting, it is best to have the VIP patient stay in a room (or suite of rooms) in the safest area of the hospital, where equipment may be brought.⁵

The hospital should be prepared to provide the VIP’s security detail a complete personnel roster with the Social Security number and date of birth of all employees.⁵

POSTINCIDENT ACTIONS

Consistent with the planned response, the emergency department (ED) and hospital must be quickly secured, appropriate to the anticipated level of need or threat as well as the demands imposed by the disaster itself. In an assassination attempt, the VIP’s security detail has no way of knowing the extent of the plot and who may be involved.² In such a circumstance, it may be necessary to grant them control over the hospital environment. In the unlikely event that the hospital must be closed for security reasons, notification of EMS dispatch is essential.

Presentation of a VIP often engenders crowd control problems, not only from the media or well-wishers, but also chiefs of service, other medical staff members, administrators, nurses, and other hospital personnel who want to see the VIP or observe what is going on.² The problem of too many hands, rather than not enough,

makes control of access essential and problematic.² Hospital security officers must often play a role in keeping unnecessary hospital personnel out of the VIP's area, as well as ensuring the VIP's safety. Restricting access may best be accomplished by placing a senior emergency medicine physician in a strategic location, in case security is unable to identify who should be allowed access to the emergency department or is hesitant to bar senior physicians or administrators. If the VIP patient is hospitalized, a list of those allowed access to the VIP should be generated and updated daily, with some means that will limit access only to those so authorized (e.g., frequently changed coded pins).⁵

Care of a VIP entails a need to coordinate and organize, lest chaotic care and diffusion of responsibility result.⁶ Clinical and administrative responsibilities should be separated.² In the ED, the patient's condition will be the determinative factor as to whether a senior emergency medicine physician assumes clinical control, delegating administrative control to a more junior physician or charge nurse, or vice versa.

Another consideration the hospital must address is the immense media interest generated by a disaster, which is then magnified by involvement of a VIP. The media policy should ensure that the release of information is well controlled and that the VIP patient's privacy is appropriately protected.² The goal should be the orderly flow of accurate, timely information and the provision of a forum in which reporters' questions may be asked and answered. Consideration should be given to establishment of a press area at a site separate from the hospital. A single physician, who is knowledgeable, should be designated to serve as spokesperson. All other hospital staff should be instructed not to talk with the media and should be cautioned about hallway or elevator conversations.

MEDICAL TREATMENT OF CASUALTIES

One of the first considerations in disaster medical care is triage, with establishment of priority for care. When a VIP is among many patients, determination of who will be treated first has medical, practical, and moral facets. Triage was developed to meet the needs of the military in time of war; thus, priority for care went to soldiers with minor conditions over those more seriously ill or injured. Such an approach has been extended from soldiers to, for example, medical personnel with minor injuries, so that they could care for other patients in earthquakes.⁷

It is considered ethically justifiable for a person to receive priority for treatment based on social utility only if his or her contribution is indispensable to attaining a major social goal.⁷ Thus, someone who achieved VIP status because of fame as an actor would be triaged as would anyone else, based on the disaster triage⁸ factors of medical condition and the availability of personnel and equipment to meet the actor's specific needs, within the context of caring for the needs of everyone else. In contradistinction would be the VIP who is a government official and whose leadership is needed to respond to the

crisis or whose death would significantly affect the resolve of the community, state, or nation. Such a VIP fulfills the criterion of a "mission-essential" role and thus would be triaged, per the military approach, as highest priority irrespective of the severity of the physiologic insult.

A VIP syndrome has been described in which treating staff alter their usual operating procedures because a patient's power and influence cause them to lose their objectivity and thereby the ability to make the cool, rational, detached decisions necessary for good medical care. VIP syndrome may prompt decisions to do fewer tests, diagnostic procedures, or therapeutic maneuvers to save the patient from pain⁹ or embarrassment. Spouses of physicians, for example, are less likely to have a pelvic examination than are other patients.¹⁰ The result may be a missed diagnosis.⁹ On the other hand, if too aggressive of an approach is used, the patient may unnecessarily undergo painful and potentially dangerous procedures. Treat the VIP first as a patient and secondarily as a VIP,² evaluating him or her in a standard manner, including any embarrassing invasive procedures. "There is nothing biologically different from a pope or president, and there is no need to alter one's thinking in caring for them."⁹

To facilitate an orderly and uneventful transfer of care, it is essential that there be coordination between emergency physicians and specialists who will care for the patient in the hospital,⁷ bringing up yet another "syndrome" that has been identified in the care of a VIP patient. The "chief syndrome" occurs when senior physicians who do not routinely work in the ED respond because the patient is a VIP and intervene in an uncoordinated manner, upsetting the fashion in which the emergency team normally works together.² It is essential that healthcare providers function in familiar roles. The attending physician must take command and explain that the care given will be identical to that of all other patients with a similar condition because, "Usual medical care is correct care."⁹ Consults should be obtained as appropriate, but at all times it should be clear which physician is responsible for the patient's clinical care,² whether it be an emergency medicine attending physician, trauma surgeon, or other specialist.

UNIQUE CONSIDERATIONS

The VIP may be traveling with a physician.² If the VIP is a primary protectee of the U.S. Secret Service, it is the responsibility of the Secret Service to protect and, if necessary, rescue the principal. Meanwhile, the White House Medical Unit (WHMU), in conjunction with first responders who may be on-scene, have the responsibility to evaluate, resuscitate, and evacuate the patient to a suitable site for definitive care.¹¹ The WHMU, all of whose members are military personnel, is a team consisting of a physician and emergency or critical care nurse who accompany primary protectees at all times for provision of initial medical care.³ Physicians who have completed Advanced Cardiac Life Support (ACLS) and Advanced Trauma Life Support (ATLS)⁵ represent the specialties of family medicine, internal medicine, or emergency medicine. All WHMU personnel, whether officer or enlisted

status, have completed chemical, biological, radiological, nuclear, and explosive (CBRNE) training, and some of the physicians have completed tactical medicine courses to support SWAT teams.

In a life-threatening situation, the attending physician in the hospital bears the responsibility for patient care decisions,² but diplomacy, collegiality, and good judgment are always required concerning participation by the VIP's physician in patient care. For example, the physician in the ED may be an internist who is called on to provide initial care to an injured VIP who is accompanied by a board-certified emergency physician. Conversely, the ED physician who may be board-certified in emergency medicine may be responsible for providing emergent obstetric (OB) care to a VIP in the company of a family physician with considerable OB experience.

If the VIP is the president of the United States, among the myriad factors needing to be addressed may be the issue of whether the president is capable of making the decisions necessary to fulfill the responsibilities of office. Carried in the "Football," the briefcase in the custody of a military aide who is always near the president, are the codes necessary to launch a nuclear war. Also contained therein is an "emergency action plan" for devolution of presidential powers to the vice president, including the requisite paperwork for its emergency execution.¹¹

The 25th amendment to the U.S. Constitution sets forth the mechanism whereby the vice president may assume presidential powers and duties as acting presi-

dent. In such a situation, the White House physician plays a critical role in the constitutional process of deciding whether the president is, on the basis of medical judgment, fit to govern.⁵ Even though the White House physician has an obligation to preserve the confidentiality of the president's condition, that may, and in fact must, be broken "if the health of the president interferes with his or her ability to do the job."¹¹ "Impairment is a medical judgment, disability is a political decision"¹¹; thus the findings and opinion of the White House physician are reported to a classified group of White House and Cabinet officials⁵ who make the final decision, if the president is unable to do so or if there is a question about the president's decision.

PITFALL

- Not providing medical treatment to the VIP like any other patient—too much, too little.

CASE PRESENTATION

It will be a first for your town. Even though the governor has visited on a few occasions, the president of the United States has never done so—nor has the vice president for that matter—and now all three of them will be at a campaign function together at the high school gymnasium.

Your hospital has 84 beds and even though it well serves many of the medical needs of the local residents, the Secret Service made it clear that any situation necessitating critical medical care for its protectees will result in aeromedical evacuation to the trauma center some 30 minutes away. The snowstorm rapidly approaching from the southeast has prompted a change in plans, however, and your hospital is informed that it is now the primary receiving hospital. The Secret Service agent assigned to the ED provides you with the following situation report: the president and governor are on a campaign bus en route to join the vice president, who has just come from the northern part of the state via another campaign bus, and the first lady, who has just flown in from Washington. Since the snowstorm has slowed the president's bus motorcade, the vice president and first lady are starting the rally in the company of the mayor.

The big question on the mind of most folks that day is the effect the weather will have on the number of people attending the event. That is not the question on the mind of the young fellow in the red hat who finds a place in the front, close to the stage. As the vice president begins to speak, someone in a red hat is seen leaping onto the stage, yelling that he has a bomb and that he is going to kill every-

one. As the Secret Service tackle him, the first lady falls off the stage, striking her head. She begins seizing, vomits, and aspirates significantly. Although not hurt, the vice president falls into a chair, his fist clenched over his sternum in the classic "neck tie sign." The crowd, which is large despite the weather, begins to run from the building in panic on seeing the altercation on stage and hearing the screaming threats of the man in the red hat. Several people are trampled by the hundreds of onlookers attempting to escape the reach of the nonexistent bomb.

The Secret Service informs you that the vice president and first lady are en route to your hospital. Your EMS system relays this information to the base station, plus the fact that the mayor and 27 other citizens of your fair community are to be transported to your facility. While the Secret Service is awaiting the arrival of the vice president and first lady and confirming the rooms that can be used by the president during his wife's hospitalization, they are contacted by their command post and are told the president's bus, driving fast in the snowstorm to get to the hospital at the direction of the president, has gone off an embankment and rolled over several times. The president, governor, and approximately 15 occupants of the bus (driver, Secret Service personnel, White House physician, governor's security officers, presidential staff, campaign aides) are injured and will be transported to your hospital. Fixing his gaze as he walks toward you at a fast clip, someone who carries himself with an air of authority says, "You're the doctor in charge...?"

New York City Poison Control Center
New York, New York

CONSTANCE G. NICHOLS, MD
Assistant Professor of Emergency Medicine
Department of Emergency Medicine
University of Massachusetts Medical School
Worcester, Massachusetts

PATRICIA A. NOLAN, MD, MPH
Director of Health
Rhode Island Department of Health
Clinical Assistant Professor of Community Health
Brown University
Providence, Rhode Island

DANIEL F. NOLTKAMPER, MD, FACEP
Commander, Medical Corps, U.S. Navy
Emergency Physician, Naval Hospital Camp
Lejeune
Jacksonville, North Carolina

DZIWE W. NTABA, MD, MPH
Resident in Emergency Medicine
Department of Emergency Medicine

JAMES PFAFF, MD, FACEP, FAAEM
Staff Physician, Brooke Army Medical Center
SAUSHEC EM Residency Program
Fort Sam Houston, Texas

WILLIAM PORCARO, MD
Harvard Affiliated Emergency Medicine Residency
Program
Beth Israel Deaconess Medical Center
Boston, Massachusetts

LAWRENCE PROANO, MD, FACEP
Attending Physician
Brown University Program in Emergency Medicine
Rhode Island Hospital
Providence, Rhode Island

NAJMA RAHMAN-KAHN, MD
Attending, Lutheran Hospital
Brooklyn, New York

VITTORIO J. RAHO, MD
Resident, Harvard Affiliated Emergency Medicine
Residency Program
Beth Israel Deaconess Medical Center
Boston, Massachusetts

PRASANTHI RAMANUJAM, MBBS
Department of Emergency Medicine
Boston Medical Center
Boston University School of Medicine
Boston, Massachusetts

WENDE R. REENSTRA, MD, PHD
Department of Emergency Medicine
Beth Israel Deaconess Medical Center
Boston, Massachusetts

ANDREW REISNER, MD
Instructor, Harvard Medical School
Massachusetts General Hospital
Emergency Medicine
Boston, Massachusetts

MARK C. RESTUCCIA, MD, FACEP, FAAEM
Assistant Professor of Emergency Medicine
University of Massachusetts Medical School
UMass Memorial Health Care
Worcester, Massachusetts

JAMES MICHAEL RILEY, REMT-P
Senior Security Analyst
Office of Security and Investigations
US Citizenship and Immigration Services
Washington, DC

ALBERT J. ROMANOSKY, MD, PhD
Medical Director
Office of Public Health Preparedness and Response
Maryland Department of Health and Mental Hygiene
Baltimore, Maryland

PETER ROSEN, MD
Senior Lecturer, Department of Medicine
Harvard University School of Medicine,
Attending Physician
Department of Emergency Medicine
Beth Israel/Deaconess Medical Center
Boston, Massachusetts

MARC S. ROSENTHAL, PHD, DO
Assistant Professor of Emergency Medicine
Attending Physician
Research Director/Assistant Residency Director
Wayne State University
Sinai-Grace Hospital Emergency Medicine Residency
Program
Department of Emergency Medicine Sinai-Grace
Hospital
Detroit, Michigan

JONATHAN M. RUBIN, MD
Associate Professor of Emergency Medicine
Medical College of Wisconsin
Associate Director of Medical Services
Milwaukee County EMS
Milwaukee, Wisconsin

LEON D. SANCHEZ, MD, MPH
Attending, Emergency Medicine
Clinical Instructor
Emergency Medicine
Harvard Medical School
Beth Israel Deaconess Medical Center
Boston, Massachusetts

FOREWORD

Throughout recorded history, disasters have caused immeasurable amounts of pain and suffering to affected populations. By far, the most common disasters have been natural ones with cataclysmic storms and seismic and volcanic events reeking havoc on the unsuspecting. Recently, however, the news of disaster has also included pre-meditated attacks by the various terror factions around the world. Prior to Sept. 11, 2001, it is not unreasonable to presume that most of us in the United States didn't think long nor hard about terror attacks. We of course were aware of the bad things that were occurring around the world, shook our heads with bafflement at the Sarin attacks in Tokyo, and managed to underestimate and ignore the bombings and terror attacks in our own country, since so few of us were involved. It always seems like an act far out on the bell-shaped curve of sanity.

We couldn't figure out how James Jones could convince a group of people to submit to suicide and murder; we were appalled at the cyanide attacks in the grocery stores; and we came closer to understanding a potential for terror after the bombing in Oklahoma City.

There were of course small numbers of people who were well aware of the potential; tried to prepare themselves and their country, and did attempt to increase education, preparation and awareness for that special kind of disaster.

Although I was personally almost totally ignorant about bioterror, I was asked to chair a committee on Bioterror for the Institute of Medicine. I still don't know why I was invited, but it was a challenging and highly educational experience. I learned at the very least to think about terror in terms of possible responses and needs for education as opposed to putting it aside as a very improbable event that I would never encounter as a citizen, never mind as a physician.¹ What became increasingly obvious after Sept. 11 was the inability to predict the consequences of the attack, and a need to be able to respond with great flexibility and creativity.

In this regard, acts of terrorism, other than the psychological wounding fact that it is deliberate, manmade, and therefore quite unnecessary, is no different than a large unplanned disaster.

We have seen many such incidents around the world and learned a certain amount at how to prepare and how to respond, but we are always struck by the fact that we can't exactly know when or where the next "tragedy" will occur, or just how much damage it will inflict.

Many of the ingredients for both accidental and terrorist events are present in our daily lives, and it doesn't

require much to unleash them. Fortune sometimes plays in our favor, as the time when I was at the University of Chicago. We received a phone call that there had been some kind of industrial accident on the South Side of the city, and that a large cloud of chlorine gas had been released. We had no idea how many victims there would be, or where the victims would be, and we were somewhat frustrated in trying to notify all possible Emergency Departments to enable their response—this despite several years of intensive planning and practice that had followed a train crash of a commuter train on the Illinois Central Railroad.

Fortunately, the prevailing winds that day blew the cloud out over Lake Michigan, and there was not a single victim. It was estimated at the time, however, that if the wind had not been present, or had changed direction from typical, there would have been over 1 million victims.

Similarly, when I was in Denver, there was a cloud of nitric acid released from a train derailment. Again, fortunately, this occurred very early on a Sunday morning. Only 24 hours later, it would have spewed into the traffic rush of early morning workers. This again prevented a horrible disaster, and we had only three victims who were seriously exposed, and about 20 others with very minor exposure.

Thus it doesn't really matter if the disaster is natural or manmade in terms of unpredictability or horrible consequences. It is clear that the best preparation is going to be that of an already developed, practiced, and efficient disaster program. That, of course, doesn't mean that we have such a program in place, nor does it mean that there are not rare diseases, chemicals, or unprecedented event scenarios that we will have to learn about and prepare for.

The following book is a serious attempt to do just that. When I read it, my initial reaction was that perhaps we needed to eliminate some of the terrorism chapters because they were going to suggest methods of attack. I realized then that this is one of the unique characteristics of terror attacks. It is so unthinkable that we begin to think illogically about how to prepare and how to respond.

A later thought, more cynical, was that we are spending too much time and money to prepare for events that will not recur, even if they ever occur in the first place. Finally, some sanity resumed and I realized that the only way to prepare for rare, uncommon, and unrepeatable events is to think about them, to attempt to generalize the problems they cause, and to try to develop a system that can respond to the known but can improvise and also respond to the unknown and not previously experienced as well.

This book is a very good start in doing just that. It may frighten you, as it did me, and perhaps horrify you, especially when you are stimulated into thinking about how

¹IOM report on Bioterror.

many problems you are personally, as well as your system, not publicly prepared to respond and react to, not only from ignorance, but because an efficient system just isn't there.

Whether or not you have a personal role in disaster management in your community, your hospital, or your state, it will be educational and stimulating to be involved in the thinking about, and planning for, how to respond to the unthinkable. Within these pages I believe you will find the descriptions, facts, and creative solutions to many problems you are aware of, as well as many problems you may not have thought about.

All the planning in the world will not prevent tragedy from occurring, whether it is by natural causes or man-made. There is no question, however, that the right system will alleviate the tragedy; will salvage lives and psyches, and will help us to feel less despondent about the world we have forced upon us.

I think you will find this book a good read. Not only is it well written by a series of authors who are very accomplished and experienced in disaster management,

but I believe you will find it one of the most thought-provoking books that you have read. I certainly did, and while I still am horrified at the variety and depths of tragedy that we may still have to endure, it left me feeling much less helpless, and finally much less angry about the whole situation.

To plan is to take control; it may be imperfect, but it is significantly better than being a passive victim. Just think how many lives were saved because an alert Emergency Physician was able to think about and diagnose an anthrax victim. Would he have thought about this without Sept. 11, I suspect not, but if only one life is saved by improved education and awareness, this book will have been worth the tremendous amount of work and diligence that went into its preparation.
